The reaction of phosphorus(V) chloride with mercurous thiocyanate yielded free dithiocyanogen, $(SCN)_2$, which rapidly polymerized. This suggests that phosphorus (V) *iso*thiocyanate is rather less stable than the corresponding iodide.[1]

## SECTION XX

# THE REDUCED OXYACIDS OF PHOSPHORUS AND THEIR SALTS

BY H. A. J. CHAMP

In recent years several new oxyacids of phosphorus have been described in which one or more phosphorus atoms in the anion have an oxidation number of less than five.[23] This section will describe all the lower oxyacids of phosphorus apart from the three best known, hypophosphorous, phosphorous and hypophosphoric acids, which are discussed elsewhere.

The nomenclature of these reduced acids is rather confused at present, but the generally accepted names will be used in this section together with the shorthand nomenclature proposed by Blaser.[1] In this system the acid is designated by the phosphorus 'skeleton' of the anion, with a superscript figure which is the oxidation number of that particular phosphorus atom. Thus pyrophosphoric acid is represented by $P^5\text{–O–}P^5$ and hypophosphoric acid by $P^4\text{–}P^4$.

Although only three oxyacids of phosphorus containing only one phosphorus atom in the anion can exist, fourteen based on two phosphorus atoms could be postulated, and of these six are known: hypodiphosphorous, diphosphorous, hypophosphoric, pyrophosphorous, pyrophosphoric and isohypophosphoric acids. It is self-evident that with more phosphorus atoms in the anion the number of possible structures (including ring structures) would become legion and there is no obvious reason why many of these should not exist. In fact five acids based on three phosphorus atoms are already known.

The stabilities to hydrolysis and oxidation of these lower acids of phosphorus are briefly compared in Table I and the following general features may be noted. Firstly, acids containing phosphorus–phosphorus bonds only are more stable to hydrolysis than those containing oxygen-bridged phosphorus atoms, particularly under alkaline conditions. However, this stability decreases with increasing chain length.

Secondly, apart from the $(P^3)_6$ ring acid, only acids containing phosphorus–hydrogen links are oxidized by iodine. Finally the phosphorus–phosphorus bond is stabilized to bromine oxidation if either of the phosphorus atoms concerned is linked to a third phosphorus atom through an oxygen bridge.

The properties of the acids and their salts will now be described in order of increasing molecular weight.

## HYPODIPHOSPHOROUS ACID, $P^2\text{–}P^2$ ACID, $H_4P_2O_4$

It has been claimed[2] that the anion of this acid is formed when diphosphorus tetraiodide is hydrolyzed in the presence of sodium bicarbonate. It is said to resist hydrolysis only in the region of pH 7·0 and to be oxidized by iodine in acid, neutral or alkaline solution. The product is diphosphorous or hypophosphoric acid, depending on the pH of the solution. The anion is also oxidized by atmospheric oxygen, and shows a tendency to disproportionate to phosphine and phosphorous or phosphoric acid.

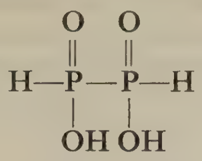
The barium salt is reported to be only sparingly soluble in 2 N. acetic acid (barium hypophosphite being soluble under these conditions), but no analytical details are given.

Table I.—The Stability towards Hydrolysis and Oxidation of Reduced Acids of Phosphorus

| Acid | Structural formula | Rate of hydrolysis in dilute | | Rate of oxidation at 25°C. | |
|---|---|---|---|---|---|
| | | acid | alkali | 0·1 N. $I_2/NaHCO_3$ | 0·1 N. $Br_2/NaHCO_3$ |
| Hypophosphorous<br>$P^1$ |  $\mathrm{H{-}\underset{OH}{\overset{O}{P}}{-}H}$ | Decomposes on heating | | Very slow, but fast in acid | Slow |
| Phosphorous<br>$P^3$ |  $\mathrm{H{-}\underset{OH}{\overset{O}{P}}{-}OH}$ | — | | 100% in 10 min. | 100% in 60 min. |
| Hypodiphosphorous<br>$P^2–P^2$ |  $\mathrm{H{-}\underset{OH}{\overset{O}{P}}{-}\underset{OH}{\overset{O}{P}}{-}H}$ | Very fast | Fast | Very fast | Fast |
| Diphosphorous<br>$P^2–P^4$ |  $\mathrm{H{-}\underset{OH}{\overset{O}{P}}{-}\underset{OH}{\overset{O}{P}}{-}OH}$ | Very fast | No change over 1 hr. in boiling N NaOH | Very fast | 100% in 15 min. |
| Pyrophosphorous<br>$P^3–O–P^3$ |  $\mathrm{H{-}\underset{OH}{\overset{O}{P}}{-}O{-}\underset{OH}{\overset{O}{P}}{-}H}$ | Very fast | Very fast | Stable | Very slow |
| Isohypophosphoric<br>$P^3–O–P^5$ |  $\mathrm{H{-}\underset{OH}{\overset{O}{P}}{-}O{-}\underset{OH}{\overset{O}{P}}{-}OH}$ | Half-life = 50 min. in 0·2 N. HCl at 0°C. | Half-life = 440 min. in 1·0 N. NaOH at 25°C. | Stable | Very slow |
| Hypophosphoric<br>$P^4–P^4$ |  $\mathrm{HO{-}\underset{OH}{\overset{O}{P}}{-}\underset{OH}{\overset{O}{P}}{-}OH}$ | 100% in 1 hr. in 4 N. HCl at 100° | Stable | Stable | 100% in 15 min. |

| | | | | | |
|---|---|---|---|---|---|
| $P^4$–$P^4$–O–$P^3$ |  $HO-P(O)(OH)-P(O)(OH)-O-P(O)(OH)-H$ | Fast | Fast | Fast | Fast |
| $P^4$–$P^4$–O–$P^5$ |  $HO-P(O)(OH)-P(O)(OH)-O-P(O)(OH)-OH$ | Half-life = 95 min. in 0 8 N. $HNO_3$ | 5–10% hydrolysis on boiling for 1 hr. in 2–5 N. NaOH | Stable | Very slow |
| $P^4$–$P^3$–$P^4$ |  $HO-P(O)(OH)-P(O)(OH)-P(O)(OH)-OH$ | Slow | Very slow | Stable | Fast |
| $P^4$–$P^3$–$P^3$–$P^4$ |  $HO-P(O)(OH)-P(O)(OH)-P(O)(OH)-P(O)(OH)-OH$ | Fast | Slow | Stable | Fast |
| $(P^4$–$P^4$–$O)_2$ |  | Fast | Half-life = 138 min. in 0·28N. NaOH at 20°C. | Stable | Stable |
| $P^4$–$P^4$–O–$P^4$–$P^4$ |  $HO-P(O)(OH)-P(O)(OH)-O-P(O)(OH)-P(O)(OH)-OH$ | Fast | 100% in 2 hr. in 60% NaOH at 150°C. | Stable | Stable |
| $(P^3)_6$ ring acid |  | Fast | Fast | Fast | Fast |

The structure proposed from the chemical evidence is:



$$H-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-H$$

The relation of this form to the tautomeric $P_2(OH)_4$, postulated[3] as the first hydrolysis product of diphosphorus tetraiodide, would then be similar to that existing between the $HPO(OH)_2$ and $P(OH)_3$ forms of phosphorous acid.

The isolation of salts of hypodiphosphorous acid, with the exception of the barium salt mentioned above, does not appear to have been described.

## DIPHOSPHOROUS ACID, $P^2$–$P^4$ ACID, $H_4P_2O_5$

The presence of a previously unknown acid among the hydrolysis products of phosphorus trichloride was first suggested in 1935.[4] Further work confirmed the existence of an anion containing two directly bonded phosphorus atoms, though the free acid has not been described.

The trisodium salt is usually prepared by hydrolysis of phosphorus tribromide in neutral or weakly alkaline solution.[5,6,7]

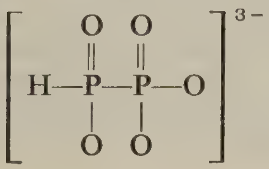
The sodium diphosphite, which is formed along with sodium phosphite, pyrophosphite and lesser amounts of phosphate and hypophosphate, is fractionally precipitated with alcohol and recrystallized from water. The main impurity is then hypophosphate which is removed as the sparingly soluble tetrasodium salt at pH 10–11, followed by further recrystallization of the diphosphite.

Phosphorus tribromide appears to give better yields of the diphosphite than does the trichloride.[8] Hydrolysis of diphosphorus tetraiodide and oxidation of $(P_4OH)_n$ with alkaline hypoiodite[37] give diphosphite, among other products.

Trisodium diphosphite crystallizes from water at 0°C. as the dodecahydrate, which is converted to a hexahydrate at 30°C. It becomes anhydrous on heating to 100°C. *in vacuo*[6,7]:

$$Na_3HP_2O_5,12H_2O \xrightarrow{30°C} Na_3HP_2O_5,6H_2O \xrightarrow[\textit{in vacuo}]{100°} Na_3HP_2O_5$$

Nuclear magnetic resonance[9] and Raman spectra[10] have shown that the structure of the anion is:



$$\left[H-\overset{\overset{O}{\|}}{\underset{\underset{O}{|}}{P}}-\overset{\overset{O}{\|}}{\underset{\underset{O}{|}}{P}}-O\right]^{3-}$$

The nuclear magnetic resonance spectrum is complicated because of close spin–spin coupling between the hydrogen and the two interconnected phosphorus atoms. It is therefore necessary to apply a quantum mechanical treatment to the interpretation of the results. This is given elsewhere.[9,43] A typical spectrum is shown in Fig. 1.

The Raman spectrum of trisodium diphosphite shows intense lines at 2271 and 312 cm.$^{-1}$ which indicate P–H and P–P bonds respectively. The P–H line at 2271 cm.$^{-1}$ is however weaker than that shown by sodium pyrophosphite.[10]

The diphosphite anion is fairly stable to alkali but is readily hydrolyzed to phosphite in acid solution. The hydrolysis in 0·5 N. HCl at 20°C. has been shown to follow the equation:

$$K = \frac{1}{t}\ln\frac{C_A}{C_A - C_X}$$

where $K = 29{\cdot}2$–$30{\cdot}8 \times 10^{-3}$ min.$^{-1}$.[7]

**Refs. p. 612**

Sodium diphosphite is virtually unchanged after heating for 1 hr. with 2 N. sodium hydroxide solution and is only 60% decomposed after six hours' boiling with 30% NaOH. Higher concentrations of alkali and higher temperatures decompose the diphosphite more readily according to two equations[11]:

$$HP_2O_5^{3-} + H_2O \rightarrow 2HPO_3^{2-} + H^+$$

$$HP_2O_5^{3-} + H_2O \rightarrow P_2O_6^{4-} + H_2 + H^+$$

The second reaction predominates at higher alkali concentrations (83% in 80% NaOH and 60% in 40% NaOH).

The diphosphite anion is oxidized quantitatively by iodine to hypophosphate in 0·01 N. HCl. At higher acid concentrations the oxidation rate increases, but hydrolysis also occurs to a significant extent.[11] In bicarbonate-buffered solution iodine oxidizes diphosphite to hypophosphate, whereas chlorine and bromine oxidize it to pyrophosphate:

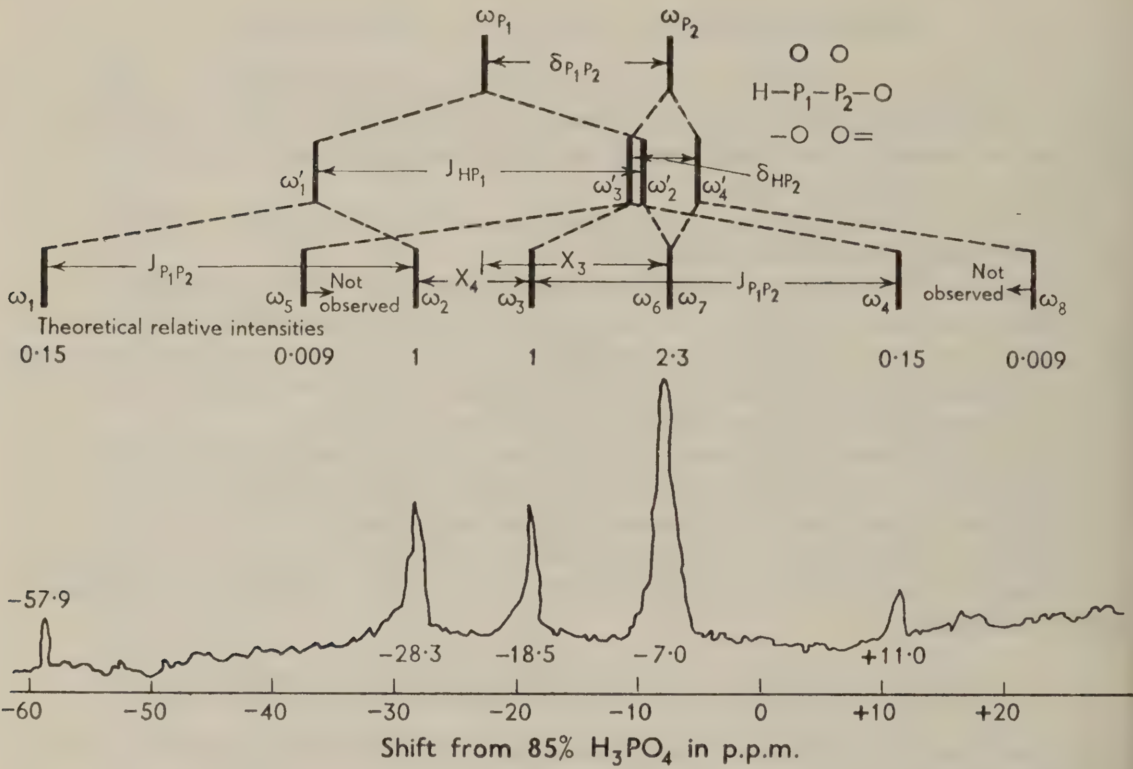


FIG. 1.—Zeeman levels and observed phosphorus spectrum for the diphosphite anion at a field of 9440 gauss. Because of saturation effects at the high r.f. field used to show up the small peaks, the peak areas are not strictly proportional to their predicted values. The measured values of $X_3$ and $X_4$ are 16·4 and 9·8 p.p.m. of the applied field as compared to the calculated values of 16·2 and 9·6 p.p.m., respectively. At the 7140 gauss field, the observed values of $X_3$ and $X_4$ are 21·9 and 9·5 p.p.m. compared to the calculated values of 21·6 and 10 p.p.m., respectively

$$HP_2O_5^{3-} + I_2 + H_2O \rightarrow P_2O_6^{4-} + 2I^- + 3H^+$$

$$HP_2O_5^{3-} + 2Br_2 + 2H_2O \rightarrow P_2O_7^{4-} + 4Br^- + 5H^+$$

## PYROPHOSPHOROUS ACID, $P^3$–O–$P^3$, $H_4P_2O_5$

Pyrophosphorous acid, which is isomeric with diphosphorous acid, and a few of its salts have been known since the late nineteenth century. The acid, however, was known only in the form of an unstable aqueous solution formed by the action of the stoicheiometric quantity of sulphuric acid on barium pyrophosphite. The pure acid has recently been prepared by reaction of phosphorus trichloride (or bromide) with phosphorous acid in the ratio of 1 : 5.[12–4] The product after removal of the halogen hydracid is claimed to have a purity of 99%.[12] It can be further purified by fractional crystallization from the melt. A closer study of the reaction shows that it is reversible:

$$5H_3PO_3 + PX_3 \rightleftharpoons 3H_4P_2O_5 + 3HX$$

Where phosphorus trichloride is used, the poor solubility of hydrogen chloride in the reaction mixture leads to a displacement of the equilibrium to the right, but in the case of phosphorus tribromide the reaction is both slower and less complete.[49] Earlier workers[15] claimed the formation of diphosphorus trioxide by this reaction.

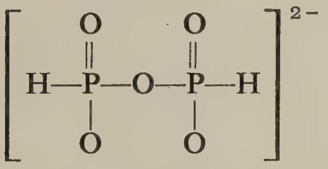
Pyrophosphorous acid is also formed during the thermal decomposition of phosphorous acid but itself undergoes further decomposition to form pyrophosphoric acid, metaphosphoric acid and phosphine.[17,49] Since these reactions occur to some extent simultaneously, this is not a practicable method of preparation:

$$2H_3PO_3 \rightarrow H_4P_2O_5 + H_2O$$

$$2H_4P_2O_5 \rightarrow H_4P_2O_7 + HPO_3 + PH_3$$

Under reduced pressure lower phosphorus hydrides, and even amorphous phosphorus, are formed, with a corresponding decrease in the yield of gaseous phosphine. Smaller quantities of pyrophosphorous acid also result from the hydrolysis of tetraphosphorus hexaoxide, or its reaction with phosphorous acid, and from the condensation of phosphorous acid by di*cyclo*hexylcarbodi-imide.[49] The P(III)(V) oxide $P_4O_{8\cdot13}$ also yields pyrophosphorous acid on hydrolysis.[50]

Nuclear magnetic resonance[9,12] and Raman spectra[14] of the acid and also the Raman spectrum of a saturated solution of the sodium salt[16] have shown that the structure of the anion is:



$$\left[\begin{array}{c} \mathrm{O} \quad\;\; \mathrm{O} \\ \| \qquad \| \\ \mathrm{H{-}P{-}O{-}P{-}H} \\ | \qquad | \\ \mathrm{O} \quad\;\; \mathrm{O} \end{array}\right]^{2-}$$

In the nuclear magnetic resonance spectrum two resonance peaks are observed at $-21$ p.p.m. and $+28$ p.p.m. (referred to the spectrum of 85% $H_3PO_4$ at 25°C.). The P–H splitting is 0·40 gauss, which is the same as that observed for phosphorous acid, and the chemical shift of 11 p.p.m. is approximately the same as that obtained in the change from phosphoric acid to pyrophosphoric acid.[12]

The Raman spectrum of the sodium salt[16] shows strong lines at 1107 $cm.^{-1}$ and 2412 $cm.^{-1}$ assignable to P–O–P and P–H vibrations respectively.

Melting points of 36°C.[12] and 39°C.[14] have been reported for pure pyrophosphorous acid.

Pyrophosphorous acid is stable to iodine in sodium bicarbonate buffered solution, but chlorine, under the same conditions, oxidizes pyrophosphorous acid to orthophosphoric acid (diphosphorous acid gives pyrophosphoric acid).[7]

Sodium pyrophosphite, $Na_2H_2P_2O_5$, is most conveniently prepared by heating monosodium phosphite at 110°–160°C. under reduced pressure[19,20]:

$$2NaH_2PO_3 \rightarrow Na_2H_2P_2O_5 + H_2O\uparrow$$

Under reduced pressure the pyrophosphite commences to decompose at about 225°C., decomposition being virtually complete by 350°C. when products are in approximately the following proportions: pyrophosphate 3%, phosphine 19%, tripolyphosphate 24% and trimetaphosphate 54%. At intermediate temperatures the ratios of the products formed differ from those quoted, and traces of orthophosphate and polyphosphates are found.[20]

Sodium phosphite reacts with phosphorus trichloride in an aqueous sodium bicarbonate buffered solution to give some sodium pyrophosphite. Hence pyrophosphite occurs among the hydrolysis products of phosphorus trichloride.[8]

Sodium pyrophosphite is also formed during the pyrolysis of disodium hypophosphate[22] and by heating disodium phosphite in a sealed tube at 180°C. for 1–2 hr. with iodine.[21] The latter reaction has been formulated as:

$$4Na_2HPO_3 + 2I_2 \rightarrow 4NaI + Na_2H_2P_2O_5 + Na_2H_2P_2O_7$$

Traces of a further unidentified species are also found.

The hydrolysis of the pyrophosphite ion is markedly dependent on the presence of other ions. Outside the range pH 5–8 it is rapidly hydrolyzed and this property is utilized analytically for the determination of mixtures of pyrophosphite and isohypophosphate. In 0·1 N. NaOH solution pyrophosphite is hydrolyzed to over 97% in half an hour, whereas isohypophosphate is decomposed to less than 1% in this time.[18, 47] The rate of hydrolysis is given by:

$$-R/[H_2P_2O_5^{2-}] = k_0 + \sum_a k_a[HA]_a + \sum_b k_b[B]_b$$

where $k_a$ and $k_b$ are catalytic coefficients, and $[HA]_a$ and $[B]_b$ are the concentrations of all Brönsted acids and Lewis bases respectively. The nuclear magnetic resonance spectra of partly hydrolyzed pyrophosphite solutions give evidence for the formation of intermediate species in the base catalyzed reaction.[51] The effects of some other ions on the hydrolysis are shown in Table II below.

*Table II.—Half-life of Pyrophosphite in* 0·05 *Molar Solution at* 30°C.

| Added salt | Concentration mole/litre | Half-life of pyrophosphite in hours |
|---|---|---|
| $NaHCO_3$ | 0·1 | 500 |
| | 1 | 24 |
| | 3 | 2 |
| $CH_3CO_2Na$ | 0·1 | 600 |
| | 1 | 70 |
| | 3 | 8 |
| $Na_2SO_4$ | 1 | 120 |
| $NaH_2PO_2$ | 1 | 110 |
| | 3 | 19 |
| NaCl | 1 | 250 |

There is some evidence to suggest that, in the presence of fluoride ions, pyrophosphite forms phosphite and a transient fluorophosphite which further decomposes to fluoride and more phosphite.

Pyrophosphite reacts with orthophosphate to form isohypophosphate in aqueous solution.[24–6, 47] This process has been termed interanhydrization. The reaction is dependent upon the phosphate concentration, high yields of isohypophosphate being favoured by high phosphate concentrations. The pH of the solution also affects the yield. Outside of the range pH 5–8 there is a marked fall in the isohypophosphate formed owing to hydrolysis of the pyrophosphite:

$$H_2P_2O_5^{2-} + PO_4^{3-} \rightarrow HPO_3^{2-} + HP_2O_6^{3-}$$

A similar reaction occurs between pyrophosphite and hypophosphate[24, 47] and possibly also between pyrophosphite and pyrophosphate[47]

$$H_2P_2O_5^{2-} + P_2O_6^{4-} \rightarrow HPO_3^{2-} + HP_3O_8^{4-} \qquad (P^4\text{—}P^4\text{—}O\text{—}P^3)$$

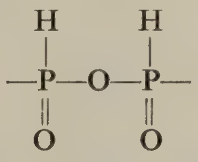
$$H_2P_2O_5^{2-} + P_2O_7^{4-} \rightarrow HPO_3^{2-} + HP_3O_9 \qquad (P^3\text{—}O\text{—}P^5\text{—}O\text{—}P^5)$$

Ammonium pyrophosphite has been prepared by heating monoammonium phosphite at 100–110°C. *in vacuo* over barium oxide. The product is a deliquescent, white solid which becomes yellow on prolonged heating above a temperature of 130°C.[27]

The hydrolysis of ammonium pyrophosphite has been shown to be similar to that of other pyrophosphites, i.e. it is slow at pH 5–7 but is very rapid outside the range pH 2–9.[28]

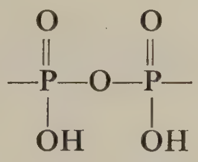
## HIGHER POLYPHOSPHOROUS ACIDS

No trace of polyphosphorous acids higher than pyrophosphorous could be detected by nuclear magnetic resonance spectroscopy or paper chromatography, either in molten pyrophosphorous acid, or in the products of other polycondensation reactions. Thus the reaction of phosphorous acid with excess of phosphorus trichloride, or the interaction of tetraphosphorus hexaoxide with phosphorous or pyrophosphorous acids, yielded only impure pyrophosphorous acid, together with some phosphate, and a yellow solid containing P–P and P–H bonds.[52] Similarly the thermal dehydration of a range of metal phosphites leads to coloured products of uncertain composition with lower oxidation equivalent. Very acid salts, such as $NaH_3(HPO_3)_2$, give pyrophosphite, but then lose phosphorous acid by volatilization.[53] This confirms that the theoretical arguments adduced[54] for the instability of polyphosphites are correct. It appears that the



$$-\overset{\overset{H}{|}}{\underset{\underset{O}{\|}}{P}}-O-\overset{\overset{H}{|}}{\underset{\underset{O}{\|}}{P}}-$$

grouping is not only more unstable to hydrolysis than pyrophosphate, but also disproportionates readily to –P–P– and

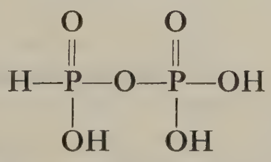


$$-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-$$

derivatives.[52]

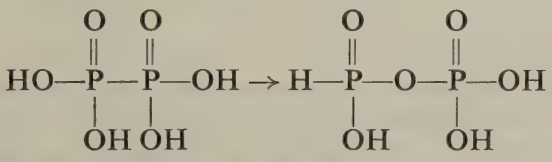
## ISOHYPOPHOSPHORIC ACID, $P^3$–O–$P^5$, $H_4P_2O_6$

In 1936 a study of the crystalline forms of hypophosphoric acid showed the presence of a hitherto unidentified species among their decomposition products. It was suggested[31] that this might be an isomer of hypophosphoric acid having the structure:



$$H-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-OH$$

It was not until much later, however, that the sodium salt of isohypophosphoric acid was isolated from this source[29] and other workers confirmed that the isomerization does take place by following the decomposition by observation of the Raman spectra.[16, 30]



$$HO-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-OH \rightarrow H-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-OH$$

There is no evidence for the reverse reaction.

Further support for the structure has come from the nuclear magnetic resonance spectrum.[9] This is shown below in Fig. 2.

Isohypophosphoric acid is itself unstable and disproportionates to pyrophosphorous and pyrophosphoric acids.[16]

There are four main methods available for the preparation of sodium isohypophosphate, three of which depend on the condensation of phosphorous and phosphoric acids or their residues.

(1) Mixtures of phosphorous and phosphoric acids are carefully dehydrated under reduced pressure. The phosphoric acid may be partially dehydrated before the reaction is commenced, i.e. a higher polyphosphoric acid or a mixture of phosphoric acid and phosphorus pentoxide may be employed. The oil obtained is then neutralized by dropwise addition to a cooled solution of an excess of sodium bicarbonate.[18]

(2) Halogen compounds of pentavalent phosphorus are hydrolyzed in a solution of sodium phosphite, buffered by an excess of sodium bicarbonate. The reaction may also be performed by hydrolysis of a halide of trivalent phosphorus in a solution of an orthophosphate or by hydrolysis of a mixture of a trihalide and a pentahalide of phosphorus in a bicarbonate buffered solution. Either chlorides or bromides may be used and the hydrolysis is best performed with cooling in the range 0–5°C.[5,29,32-4,44]

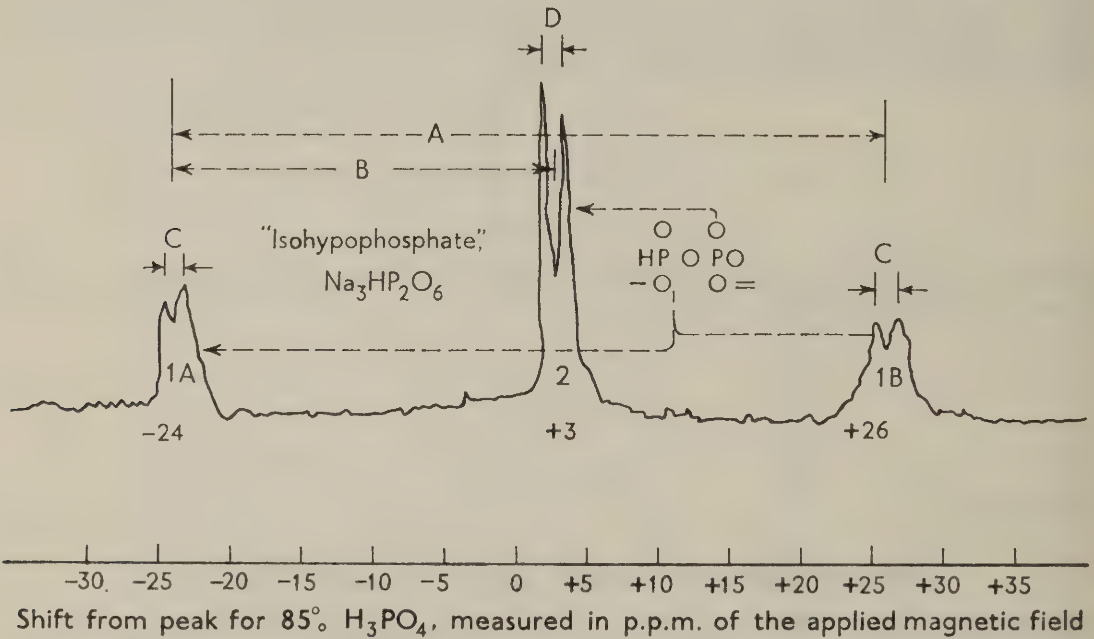


FIG. 2.—$^{31}$P magnetic resonance spectrum of the isohypophosphate anion at 7140 gauss and 12·3 Mc.: A = 620 c.p.s.; B = 27 p.p.m. or 328 c.p.s.; C = 17 c.p.s.; D = 17 c.p.s.

(3) Dehydration of a mixture of equivalent amounts of disodium orthophosphate and monosodium phosphite by heating *in vacuo* to constant weight at about 180°C. also gives a fair yield of anhydrous trisodium isohypophosphate.[26]

(4) High yields are claimed for a preparation depending upon interanhydrization between sodium pyrophosphite and disodium orthophosphate in neutral aqueous solution over a period of days[24-6,47]:

$$H_2P_2O_5^{2-} + PO_4^{3-} \rightarrow HP_2O_6^{3-} + HPO_3^{2-}$$

All the above reactions afford a mixture of salts containing, besides the isohypophosphate, phosphite, pyrophosphite, orthophosphate, pyrophosphate and sometimes lesser amounts of higher condensed phosphates. Separation depends on oxidation of the phosphite with iodine in bicarbonate-buffered solution after preferential hydrolysis of any pyrophosphite in weakly alkaline solution. The phosphates are removed by fractional precipitation with alcohol, the last few per cent. being preferentially precipitated as the lead salts.

The isohypophosphate anion has also been identified in small quantities when phosphorus trichloride or bromide is hydrolyzed in sodium bicarbonate buffered solution.[8]

Paper chromatography has been applied to the separation of the isohypophosphate anion, which in Thilo's ammoniacal solvent[8] has an $R_f$ value of 0·49–0·50.[26]

Trisodium isohypophosphate has been prepared anhydrous and also as octa- and tetrahydrates:

$$Na_3HP_2O_6{,}8H_2O \xrightarrow[\text{1 day}]{\text{in air}} Na_3HP_2O_6{,}4H_2O \xrightarrow[\textit{in vacuo}]{100^\circ C} Na_3HP_2O_6 \quad ^{29}$$

In addition to the nuclear magnetic resonance and Raman spectra mentioned earlier, *X*-ray powder photographs have been published for both hydrates. The anhydrous salt is said to be amorphous to *X*-rays.[29]

The salt is stable at room temperature in neutral aqueous solution but is hydrolyzed by both acid and alkali to a mixture of phosphite and orthophosphate. Hydrolysis is more rapid in acid solution, being virtually complete in 1 hr. in 0·1 N. $H_2SO_4$, whilst the half-life in 0·1 N. NaOH is given as 440 minutes at room temperature. The kinetics have been studied in 0·2 N. HCl at 0°C. and 1·0 N. NaOH at 34·2°C.; it was found that the values of the respective reaction constants $K$ were $1{\cdot}35–1{\cdot}43 \times 10^{-2}$ and $5{\cdot}39–5{\cdot}51 \times 10^{-3}$ min.$^{-1}$ where

$$K = \frac{1}{t} \ln \frac{C_A}{C_A - C_X} \quad ^{29}$$

Potentiometric titration shows two steps corresponding to the disodium and trisodium salts at pH 4·5 and pH 8·5, respectively. The disodium salt does not, however, appear to have been isolated.

The isohypophosphate anion is stable to iodine in the presence of sodium bicarbonate, but it is slowly and quantitatively oxidized to pyrophosphate by bromine under the same conditions.[29] Isohypophosphate, phosphite and pyrophosphite may be estimated iodometrically in the presence of one another. Only phosphite is attacked by iodine in the presence of sodium bicarbonate. Pyrophosphite is hydrolyzed to over 95% in 30 min. in 0·1 N. NaOH, whilst under these conditions the isohypophosphate anion is hardly affected:

$$H_2P_2O_5{}^{2-} + H_2O \rightarrow 2HPO_3{}^{2-} + 2H^+$$

The pyrophosphite may then be estimated by iodine oxidation of the phosphite liberated in this way. Hydrolysis in 0·1 N. mineral acid for 1 hr. converts isohypophosphate to phosphite and phosphate, after which it may be determined by an iodine oxidation of the liberated phosphite:

$$HP_2O_6{}^{3-} + H_2O \rightarrow PO_4{}^{3-} + HPO_3{}^{2-} + 2H^+$$

Alkaline earth and silver salts give colourless precipitates with solutions of sodium isohypophosphate. The precipitates consist of the tertiary salts but precipitation is not complete.[26, 29] The solubility of these salts, as might be expected from the structure of the anion, lies between those of the corresponding pyrophosphates and pyrophosphites.

The silver salt, which is white initially, darkens on standing. The lead salt, prepared by double decomposition between sodium isohypophosphate and lead acetate, hydrolyzes easily to phosphate and phosphite even in neutral solution.[26, 29] Lead pyrophosphite is similarly unstable.

## THE $P^4$–$P^3$–$P^4$ ACID, $H_5P_3O_8$

This acid was first observed among the products of oxidation by hypochlorite or hypobromite of red phosphorus in alkaline suspension, but may also be prepared by oxidation of both white and red phosphorus in acid solution.[38]

The acid itself has not been isolated in the pure state.

The highest yields of the pentasodium salt, $Na_5P_3O_8,14H_2O$, are obtained (up to 20%) by oxidation of the sodium potassium salt of the $(-P^3-)_6$ ring acid (*vide infra*) with iodine in the presence of sodium bicarbonate. Since the starting product itself can be obtained only in very small yield it is more convenient to prepare the sodium salt of the $P^4$–$P^3$–$P^4$ acid by oxidation of red phosphorus, either by hypochlorite or hypobromite in alkaline medium, or by hypochlorite or chlorite in acid solution. The main product of these oxidations is hypophosphate which is largely removed by crystallization of the reaction liquors at pH 10 after filtration of unreacted phosphorus. The traces of an anion containing four phosphorus atoms, which is probably the $P^4$–$P^3$–$P^3$–$P^4$ acid, are hydrolyzed much more rapidly than the $P^4$–$P^3$–$P^4$ acid and may be removed by making the solution approximately 0·3 N. with respect to hydrobromic acid and allowing the solution to stand for 1 hr. at room temperature. The $P^4$–$P^3$–$P^4$ acid and the remaining hypophosphate are separated from the other impurities, which are mainly phosphite and orthophosphate, by precipitation as their silver salts at pH 2·8. The silver salts are caused to react with sodium chloride and the hypophosphate and $P^4$–$P^3$–$P^4$ acid salt separated by fractional crystallization. This is possible since the pentasodium salt of the $P^4$–$P^3$–$P^4$ acid is soluble in its own weight of water at temperatures of 50°C. and above, whereas tetrasodium hypophosphate is only sparingly soluble. The yield of $Na_5P_3O_8,14H_2O$ is of the order of 2–3%.[35] This salt has also been isolated from phosphorus tribromide hydrolysates but only in yields of less than 1%. A further source of the $P^4$–$P^3$–$P^4$ acid is the polymer $(P_4OH)_n$ which can be oxidized by hypoiodite.[37]

When the lower phosphorus sulphides $P_4S_3$, $P_4S_5$ and $P_4S_7$ are hydrolyzed under alkaline conditions in the presence of hydrogen peroxide, the $P^4$–$P^3$–$P^4$ anion is formed together with phosphite, orthophosphate, pyrophosphate, hypophosphate and the $P^5$–O–$P^4$–$P^4$ anion.[45–6] Under the optimum conditions, the $P^4$–$P^3$–$P^4$ ion accounted for 15·5% of the phosphorus present. The yield increased in the order $P_4S_7 < P_4S_5 < P_4S_3$, other conditions being equal. Oxidative hydrolysis of diphosphorus tetraiodide gave a similar distribution of species. The hydrolysis of $P_2Cl_4$ or $P_2I_4$ in the absence of oxygen however, yields hypophosphite, phosphite, phosphate and (under basic conditions) diphosphine, but only traces of anions containing two or more phosphorus atoms.[58]

The salt obtained by crystallization from water is $Na_5P_3O_8,14H_2O$, which gives a unique *X*-ray powder photograph.[35] It may be converted to the anhydrous form by drying at 100°C. *in vacuo* over phosphorus pentoxide.

The $P^4$–$P^3$–$P^4$ acid is readily hydrolyzed by boiling with mineral acid to give phosphite and orthophosphate, but exhibits towards alkali a similar stability to that of other acids containing P–P bonds, i.e. diphosphorous acid and hypophosphoric acid. It shows very little decomposition even after boiling for several hours with 60% sodium hydroxide solution. The kinetics of hydrolysis in 1·5 N. nitric acid at 25°C. have been studied[35] and it was found that

$$K = \frac{1}{t}\ln\frac{C_A}{C_A - C_X} = 3{\cdot}09\times 10^{-3}\ \text{min.}^{-1}$$

so that the stability to acid hydrolysis lies between that of diphosphorous acid and that of hypophosphoric acid. Two mechanisms have been shown to be involved in the hydrolysis:

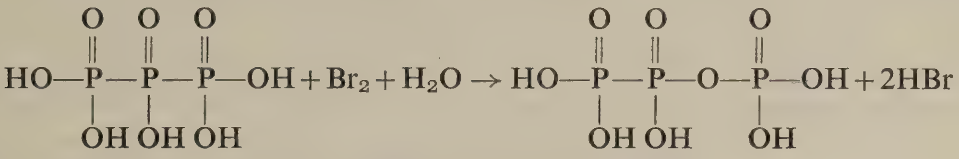
$$P_3O_8^{5-} + H_2O \rightarrow HPO_3^{2-} + P_2O_6^{4-} + H^+ \quad A$$

$$P_3O_8^{5-} + H_2O \rightarrow PO_4^{3-} + HP_2O_5^{3-} + H^+ \quad B$$

$$HP_2O_5^{3-} + H_2O \rightarrow 2HPO_3^{2-} + H^+ \quad C$$

Under the conditions of the above investigation, mechanism *A* occurred to the extent of 82% and mechanism *B*+*C* to 18%.

The $P^4$–$P^3$–$P^4$ acid is stable to halogens in acid solution and is stable to iodine in the presence of sodium bicarbonate over short periods, although considerable oxidation occurs over the period of a week. Bromine, in the presence of bicarbonate, oxidizes the $P^4$–$P^3$–$P^4$ acid quantitatively to the $P^4$–$P^4$–O–$P^5$ acid[35-6]:



$$\mathrm{HO{-}\underset{OH}{\overset{O}{P}}{-}\underset{OH}{\overset{O}{P}}{-}\underset{OH}{\overset{O}{P}}{-}OH + Br_2 + H_2O \rightarrow HO{-}\underset{OH}{\overset{O}{P}}{-}\underset{OH}{\overset{O}{P}}{-}O{-}\underset{OH}{\overset{O}{P}}{-}OH + 2HBr}$$

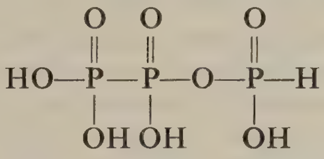
Potentiometric titration of the $P^4$–$P^3$–$P^4$ acid shows three steps, corresponding to the tri-, tetra- and penta-sodium salts. The trisodium salt, $Na_3H_2P_3O_8$,aq., has been prepared by adding acetic acid to a solution of the pentasodium salt and then precipitating the product with alcohol. The oil obtained is dissolved in water and reprecipitated with alcohol. It is finally dissolved in a little water which is allowed to evaporate spontaneously until the salt crystallizes.[35]

The silver salt is quantitatively precipitated from aqueous solution at pH 2·8 by the action of silver nitrate on the sodium salt. Even at this acidity, the pentasilver salt, $Ag_5P_3O_8$, is obtained as a white solid which slowly darkens on standing. It is slightly more soluble than the corresponding silver hypophosphate in the presence of phosphoric acid.

The sparingly soluble barium and magnesium salts have been prepared by double decomposition between the sodium salt of the $P^4$–$P^3$–$P^4$ acid and the alkaline earth halide. In the case of the barium salt, addition of barium hydroxide to pH 10·7 helps to prevent the formation of mixed salts.

### THE $P^4$–$P^4$–O–$P^3$ ACID, $H_5P_3O_8$

This acid, which is isomeric with the $P^4$–$P^3$–$P^4$ acid, and has the formula:



$$\mathrm{HO{-}\underset{OH}{\overset{O}{P}}{-}\underset{OH}{\overset{O}{P}}{-}O{-}\underset{OH}{\overset{O}{P}}{-}H}$$

is known only in the form of its well-crystallized salts.[38,47] The sodium salt has been prepared by interanhydrization between disodium pyrophosphite and hypophosphate in neutral aqueous solution.[5,24,47] The reaction takes place either on boiling for a few minutes or on standing at room temperature over a period of days:

$$H_2P_2O_5{}^{2-} + P_2O_6{}^{4-} \rightarrow HP_3O_8{}^{4-} + HPO_3{}^{2-}$$

There is some evidence, mainly chromatographic, for an acid being present in very small quantities among phosphorus trihalide hydrolysates, and it is believed to have both P–P and P–O–P bonds in the anion. This may be the $P^4$–$P^4$–O–$P^3$ acid or the $P^4$–$P^4$–O–$P^5$ acid.[8,39]

The $P^4$–$P^4$–O–$P^3$ acid is itself capable of entering into interanhydrization reactions. When a neutral aqueous solution of a mixture of the sodium salts of the $P^4$–$P^4$–O–$P^3$ acid and orthophosphoric acid is allowed to stand, reaction takes place with production of hypophosphate and isohypophosphate[5]:

$$HP_3O_8{}^{4-} + PO_4{}^{3-} \rightarrow P_2O_6{}^{4-} + HP_2O_6{}^{3-}$$

The $P^4$–$P^4$–O–$P^3$ anion is hydrolyzed in both acid and alkaline solutions to hypophosphate and phosphite. The stability to alkali lies between that of pyrophosphite and isohypophosphate. The half-lives of the three species in 0·5 N. KOH solution at 0°C. are:

| | |
|---|---|
| Pyrophosphite | 1–1·5 min. |
| $P^3$–O–$P^4$–$P^4$ | 110 min. |
| Isohypophosphate | 3400 min.[47] |

It is oxidized by bromine in the presence of sodium bicarbonate to the $P^4$–$P^4$–O–$P^5$ anion[36]:

$$HP_3O_8^{4-} + HCO_3^- + Br_2 \rightarrow P_3O_9^{5-} + CO_2 + 2Br^- + 2H^+$$

but is stable to iodine.

## THE $P^4$–$P^4$–O–$P^5$ ACID, $H_5P_3O_9$

This acid may be regarded as an anhydride between orthophosphoric acid and hypophosphoric acid. Like the $P^4$–$P^4$–O–$P^3$ acid, it is known only in the form of its salts.

There are several methods of preparation available for the sodium salt but, unfortunately, those that give high yields depend on starting materials that are themselves difficult to prepare.[36, 38] Bromine in the presence of sodium bicarbonate as buffer oxidizes the $P^4$–$P^3$–$P^4$ acid and the $P^4$–$P^4$–O–$P^3$ acid quantitatively to the $P^4$–$P^4$–O–$P^5$ acid. Under the same conditions the $(P^3)_6$ ring acid is also oxidized to the $P^4$–$P^4$–O–$P^5$ acid, but in this case orthophosphate and pyrophosphate are also produced.

Hydrolysis of phosphorus oxychloride in a solution of an alkali hypophosphate, buffered by sodium bicarbonate, gives small yields of the $P^4$–$P^4$–O–$P^5$ acid. Hypophosphates may also be phosphorylated in concentrated aqueous solution by the action of monoamidophosphates at pH 4·5–8.[36, 38] It is claimed that yields of up to 25% may be obtained by this method.

This acid is also formed during the oxidative hydrolysis of the lower phosphorus sulphides.[45, 46] The highest yield (up to 16% of the total phosphorus present) was with the lowest sulphide ($P_4S_3$) under only mildly alkaline conditions. Diphosphorus tetraiodide behaved similarly to the sulphides.

Potentiometric titration has indicated the existence of tri-, tetra- and penta-sodium salts but, so far, only the last has been obtained as a solid, and it crystallizes with difficulty. It is hygroscopic and has been shown to be amorphous to *X*-rays.[36] The penta-ammonium salt is, however, obtainable in a crystalline form with slightly variable water of crystallization $(NH_4)_5P_3O_9$,*ca.* 1·2–1·6 $H_2O$.

The white silver salt is precipitated quantitatively in neutral solution by the action of silver nitrate on a solution of the sodium salt.[36]

The $P^4$–$P^4$–O–$P^5$ anion is stable to bromine and iodine in acid, neutral and alkaline solution. It is, however, unstable to hydrolysis although it is more stable to alkaline solutions than it is to acid. Boiling the $P^4$–$P^4$–O–$P^5$ acid with 2–5 N. NaOH causes 5–10% hydrolysis in an hour, whilst boiling with 60% alkali causes complete and rapid hydrolysis to orthophosphate and hypophosphate:

$$P_3O_9^{5-} + H_2O \rightarrow P_2O_6^{4-} + PO_4^{3-} + 2H^+$$

Boiling the acid with aqueous mineral acid hydrolyzes it to phosphorous acid and orthophosphoric acid in the ratio of 1 : 2:—

$$P_3O_9^{5-} + 2H_2O \rightarrow HPO_3^{2-} + 2PO_4^{3-} + 3H^+$$

The half-life in 0·8 N. nitric acid has been determined as 95 minutes ($K = 7{\cdot}34 \times 10^{-3}$ min.$^{-1}$).[36]

## THE $P^4$–$P^3$–$P^3$–$P^4$ ACID, $H_6P_4O_{10}$

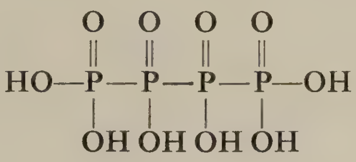
Although neither this acid nor any of its salts has yet been isolated, its existence has been postulated from chromatographic evidence.

It is believed to be formed in trace amounts during the oxidation of amorphous phosphorus by hypochlorite or hypobromite under alkaline conditions,[35] and also under some conditions during the degradation of the $(P^3)_6$ ring acid (*vide infra*).[40]

The anion, if it exists, is a homologue of the hypophosphate and $P^4$–$P^3$–$P^4$ anions and would be expected to show similar properties. As the $P^4$–$P^3$–$P^4$ acid is less stable to acid hydrolysis than hypophosphoric acid, so the $P^4$–$P^3$–$P^3$–$P^4$ acid would be expected to be still less stable and this appears to be true. If a solution containing the species believed to be the $P^4$–$P^3$–$P^3$–$P^4$ acid is made 0·3 N. with respect to hydrobromic acid, this species is completely destroyed in 2 hr., while much of the $P^4$–$P^3$–$P^4$ acid remains unchanged.[35] Similarly, by analogy with hypophosphoric acid and the $P^4$–$P^3$–$P^4$ acid, the $P^4$–$P^3$–$P^3$–$P^4$ acid would be expected to show considerable stability to alkali and have a silver salt insoluble at pH 2–8.

From chromatographic evidence for the decomposition of the $(P^3)_6$ ring acid, it appears that the $P^4$–$P^3$–$P^3$–$P^4$ anion is stable to iodine in acid and bicarbonate-buffered solution and to bromine in acid solution.[40] In this respect it is also exhibiting similar behaviour to that of its two homologues.

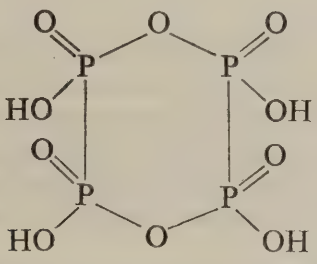
The structure of the acid would be:



$$\mathrm{HO}{-}\underset{\underset{\mathrm{OH}}{|}}{\overset{\overset{\mathrm{O}}{\|}}{\mathrm{P}}}{-}\underset{\underset{\mathrm{OH}}{|}}{\overset{\overset{\mathrm{O}}{\|}}{\mathrm{P}}}{-}\underset{\underset{\mathrm{OH}}{|}}{\overset{\overset{\mathrm{O}}{\|}}{\mathrm{P}}}{-}\underset{\underset{\mathrm{OH}}{|}}{\overset{\overset{\mathrm{O}}{\|}}{\mathrm{P}}}{-}\mathrm{OH}$$

## THE $(-P^4-P^4-O-)_2$ RING ACID

When tetrapotassium hypophosphate is treated with excess of acetic anhydride at 90°C. for periods up to 40 hr. it is converted to the salt of its cyclic anhydride acid $(-P^4-P^4-O)_2$[48]:



The product as obtained is amorphous but this can be converted to a tetraguanidinium salt which crystallizes readily in the form of a dihydrate. This can in turn be converted via metathetical reactions to the insoluble silver salt and finally to the sodium salt which crystallizes as a tetrahydrate. The barium salt is also insoluble.

Potentiometric titration shows only a single inflexion which is typical of the known cyclic phosphorus oxyacids.

The $(-P^4-P^4-O-)_2$ acid is readily hydrolyzed. When heated in the presence of mineral acids it decomposes, giving equimolecular amounts of orthophosphoric and phosphorous acids, but under strongly alkaline conditions (60% KOH at 150°) hypophosphate in the sole product. However under mildly alkaline conditions the ring is split across only one of the P–O–P bonds (*vide infra*).

The $(-P^4-P^4-O-)_2$ ring acid is stable to oxidation by iodine and bromine in the presence of sodium bicarbonate.

## THE $P^4$–$P^4$–O–$P^4$–$P^4$ ACID

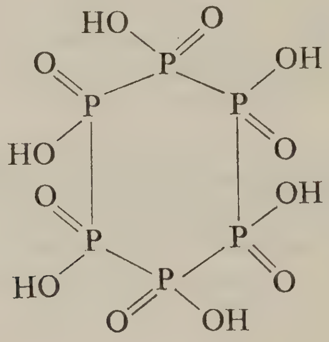
The anion of this acid is produced when the $(P^4-P^4-O)_2$ ring acid is hydrolyzed under mildly alkaline conditions (1·5 N. NaOH solution).[48] The sodium salt can be crystallized with approximately nine molecules of water of crystallization and is stable to oxidation by bromine in neutral solution. The potentiometric titration curve shows inflexions at pH 4·8–5·0 and pH 10·3 corresponding to the tetra- and hexa-sodium salts.

The acid is rather more stable to hydrolysis under alkaline conditions than the ring acid (e.g., 30 minutes reflux with 2 N. KOH solution only hydrolyzed 8·8% of a sample) but more vigorous conditions hydrolyze it completely to hypophosphate.

The insoluble silver and barium salts may be prepared from the sodium salt by metathetical reactions.

## THE $(P^3)_6$ RING ACID, $(HPO_2)_6$

It was found[5,38] that under alkaline conditions oxidation of amorphous phosphorus with either hypochlorite or hypobromite gave yields of up to 3% of a sparingly soluble sodium salt of a hitherto unknown oxyacid of phosphorus. This was identified as the salt of an acid containing six phosphorus atoms bonded in the form of a ring:



The free acid has not been prepared but several of the salts have been reported. If sodium ions are present during the oxidation of the phosphorus, the sparingly soluble sodium salt may be extracted with boiling water from the slurry of unreacted phosphorus at the end of the reaction. The potassium salt is more soluble but, such is the insolubility of the sodium salt, that even if the purest potassium salts available are used in the preparation the product obtained is usually found to contain up to 18 atom-% of sodium.[40-1]

The $(P^3)_6$ ring acid has also been prepared by oxidation of the polymer $(P_4OH)_n$ with an alkali metal hypoiodite.[37]

Three items of evidence suggest that the compound may have a ring structure. Firstly, analysis shows that the ratio of alkali metal to phosphorus is 1 : 1. Secondly, potentiometric titration shows only a single step and not a series of steps and, finally, the infra-red spectrum reveals no evidence for the presence of P–H bonds.

Crystallographic evidence has since confirmed that the anion is, indeed, cyclic in structure, the configuration being that of a buckled 6-membered ring of phosphorus atoms[42] (*vide infra*).

The pure sodium salt may be prepared from the crude product by recrystallization from an aqueous solution containing sodium bromide. The salt as crystallized contains 9·5–10·5 molecules of water per anion.

The pure potassium salt may be prepared from the mixed sodium potassium salt by first converting the latter to the thallium salt by double decomposition with thallous sulphate. The well-washed thallous salt is then suspended in water and treated with pure potassium iodide. After filtration of the precipitated thallous iodide, the pure potassium salt can be precipitated from the filtrate by alcohol and then recrystallized from water. The salt contains about 7·2 molecules of water for each anion.

The ammonium and cæsium salts have been prepared by a series of reactions similar to that which gives the potassium salt. The latter contains about 6·8 molecules of water for each anion.

The cæsium salt has been subjected to crystallographic investigation.[42] It crystallizes in the monoclinic system with $a = 9{\cdot}47$ A., $b = 9{\cdot}49$ A., $c = 16{\cdot}05$ A. and $\beta = 110{\cdot}5°$. The space group has been shown to be $C^5_{2h}$–$P2_1/C$ and there are two formula units to the unit cell. Figs. 3 and 4 show, respectively, a projection of the molecule onto the *ac*-plane and a three-dimensional representation of the anion.

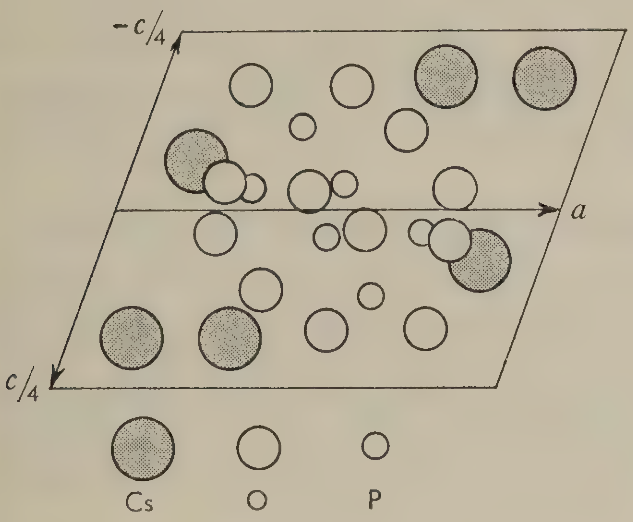


FIG. 3

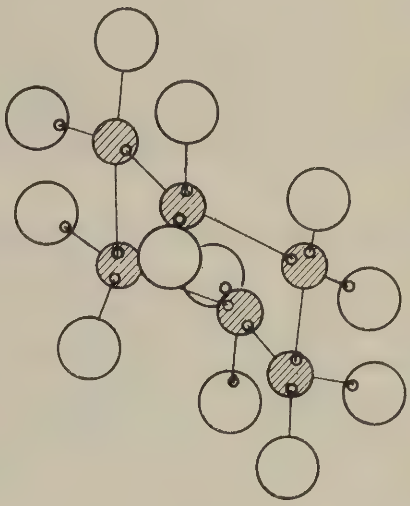

FIG. 4

Solubility measurements have been made[40] of the alkali metal salts, but the results are only approximate owing to the extreme sensitivity to the presence of even the slightest traces of sodium.

*Table III.—Solubility of Salts of the Acid* $(HPO_2)_6$

| Salt | Approximate solubility at room temperature (g. per 100 ml. $H_2O$) |
|---|---|
| $Cs_6P_6O_{12}$ | 170 |
| $K_6P_6O_{12}$ | 20 |
| $Na_6P_6O_{12}$ | 0·2 |
| $NaK_5P_6O_{12}$ (*ca.* 17 atom-% Na) | 2–2·5 |

The salts of the $(P^3)_6$ ring acid are readily hydrolyzed in acid and, unlike the other anions containing P–P bonds, also in alkaline solution. The hydrolysis is catalyzed by alkaline earth and heavy metal ions. For this reason, addition of gelatin to the suspension of amorphous phosphorus prior to oxidation increases the yield of the $(P^3)_6$ ring acid.

Acid hydrolysis yields mainly phosphorous acid with lesser amounts of hypophosphorous and orthophosphoric acid. Alkaline hydrolysis produces phosphorous and diphosphorous acids, although traces of hypophosphorous and hypophosphoric acids may also be formed. 50% sodium hydroxide at room temperature destroys the $(P^3)_6$ anion completely in 1 min., but with 1 N. or 2 N. NaOH the solution must be boiled to give the same result.

**Refs. p. 612**

The halogens oxidize the $(P^3)_6$ anion but the products formed vary according to the halogen used and the pH of the solution.

Iodine gives orthophosphoric, hypophosphoric, the $P^4-P^3-P^4$ and the $P^4-P^3-P^3-P^4$ acids. In acid solutions phosphorous acid is also found.

Bromine in the presence of sodium bicarbonate as buffer produces orthophosphate, pyrophosphate and the $P^4-P^4-O-P^5$ anion. There is also some chromatographic evidence that a species probably containing four phosphorus atoms per molecule is formed in traces. In acid media bromine gives orthophosphoric and hypophosphoric acids with traces of the $P^4-P^3-P^4$ and $P^4-P^3-P^3-P^4$ acids.[40]

Calcium, barium and magnesium halides all give precipitates with solutions containing the $(P^3)_6$ anion. The magnesium-containing compound has a Mg : P ratio of 1 : 2 and is probably the magnesium salt of the $(P^3)_6$ ring acid, but a zinc salt formed under similar conditions was shown to be partially hydrolyzed.

Silver nitrate also gives a colourless precipitate with an aqueous solution of the $(P^3)_6$ ring acid, but the precipitate rapidly darkens.

## THE ANALYSIS OF THE REDUCED OXYACIDS OF PHOSPHORUS

The lower oxyacids of phosphorus have been studied and separated primarily by paper chromatography.[8,26,55] A water–ammonia–methanol–dioxan solvent will separate all anions except $H_2PO_2^-/P^3-O-P^3$. A molybdenum spray reagent is used, with modifications for lower oxidation states.[55] Blue colours when obtained are due to $H_3PO_4$- heteropoly blue or $H_4P_2O_6$-heteropoly blue,[56] though $P^2-P^4$, $P^4-P^3-P^4$ and $(P^3)_6$ anions react with molybdate in acid solution to give a blue-green colour without any reducing agent.[57] The iodometric estimation of isohypophosphate–phosphite–pyrophosphite mixtures has been mentioned above.[29]

### SECTION XXI

# HYPOPHOSPHOROUS ACID AND THE HYPOPHOSPHITES

### BY H. A. J. CHAMP

ALTHOUGH hypophosphorous acid and its salts have been known since the beginning of the nineteenth century[1] the alkaline hydrolysis of white phosphorus, first described a few years after the discovery of the acid, remains the only mode of preparation of any commercial importance. Calcium hydroxide is the base normally used, and it has been claimed that lower aliphatic alcohols catalyze the reaction.[2] It is also said to be advantageous to use a slight excess of phosphorus in the reaction.[2] A study of the solution of red phosphorus in aqueous potassium hydroxide at 100° showed that the maximum yield of hypophosphite is obtained at a concentration of 200 g. KOH/l. Higher concentrations of alkali yield more phosphite. Using sodium hydroxide at the same concentration, hypophosphite formation is favoured by increasing phosphorus concentrations. The reaction could be represented by the equation[178]:

$$4P + 4NaOH + 3H_2O \rightarrow 2NaH_2PO_2 + Na_2HPO_3 + PH_3 + H_2$$

The free acid may be prepared from a solution of the calcium salt by reaction with oxalic acid.[6] Hypophosphorous acid may also be conveniently prepared on the laboratory scale by the oxidation of phosphine in an aqueous solution of iodine.[5] This method avoids the possibility of explosions which occasionally occur during the usual preparation.

Phosphine is also oxidized to hypophosphorous acid by alkali hypochlorite solution and this reaction is utilized for scrubbing gases contaminated by phosphine:

$$PH_3 + 2NaOCl \rightarrow H_3PO_2 + 2NaCl$$

The kinetics of this reaction have been studied in the pH range 12–13. It was found that

$$-\mathrm{d}[NaOCl] / \mathrm{d}t = k[PH_3][NaOCl] / [OH^-]$$

where

$$k = 3{\cdot}47 \times 10^{10}\, e^{-12{,}200/RT}\ \mathrm{sec.}^{-1}$$

and the following reaction mechanism was postulated[165]:

$$\begin{array}{rll} OCl^- + H_3O^+ \rightleftharpoons & HOCl + H_2O & \text{(fast)} \\ PH_3 + HOCl \rightarrow & [PH_3O] + H^+ + Cl^- & \text{(rate determining)} \\ [PH_3O] + OCl^- \rightarrow & H_3PO_2 + Cl^- & \text{(very fast)} \end{array}$$

Hypophosphorous acid is also formed by oxidizing phosphine with iodine in weakly acid aqueous solution, though in strongly acid solution the reaction proceeds further to phosphorous acid.[210]

Hypophosphorous acid is also formed when lead phosphate is reduced with hydrogen at 350–399°C. and 250–298 atm. Colloidal lead oxide is produced at the same time. At higher temperatures (400°C. and over) and pressures (416 atm.) phosphine is also formed.[3–4] Some hypophosphorous acid is formed on mild oxidation of tetraphosphorous oxide ($P_4O$)[166] and on hydrolysis of the $(P^3)_6$ ring acid[167] but only as a by-product. Neither reaction is a practical method of preparation.

The main impurities in commercial hypophosphorous acid are phosphorous and phosphoric acids, which are generally removed as the sparingly soluble calcium salts. Any excess of calcium may then be removed in the form of some other insoluble salt, e.g. calcium oxalate. A method has been described whereby very pure hypophosphorous acid may be prepared from the commercial product (containing 2–3% of phosphorous acid as the main impurity) by evaporation and crystallization in an inert atmosphere followed by fractional melting, the solid at each stage being retained.[7]

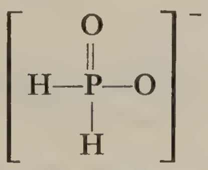
Early values for the melting point of hypophosphorous acid were 17·4°C. and 26·5°C.[3] Extrapolation of the water–hypophosphorous acid melting point diagram has given the value of $28{\cdot}8 \pm 0{\cdot}2$°C. for the melting point of the pure acid.[15] The same workers also determined the dissociation constant to be $5{\cdot}90 \times 10^{-2}$ from conductivity data measured at 25°C. and extrapolated to infinite dilution. A recalculation of Kolthoff's data[115] has given a value of $8{\cdot}0 \times 10^{-2}$ at 18°C.[149] Earlier workers in this field were Morton[16] and Bhagwat and Dhar.[17]

The results of a recent determination of the ionization constant of hypophosphorous acid are given in Table I.[161]

*Table I.—Ionization Constant of Hypophosphorous Acid*

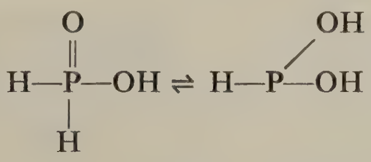
| Approximate ionic strength | Temperature °C. | Ionization constant $pK_1$ |
|---|---|---|
| 1·0 | 26·5 | 1·34 |
| 2·6 | 26 | 1·45 |
| 5·6 | 15·5 | 1·71 |

It is generally accepted[8–10] that the structure of the hypophosphite anion is



$$\left[\mathrm{H{-}\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle H}{|}}{P}}{-}O}\right]^-$$

although there is considerable evidence (*vide infra*) for tautomerism in the acid between the normal pentacovalent form and a tricovalent species:



$$\mathrm{H{-}\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle H}{|}}{P}}{-}OH} \rightleftharpoons \mathrm{H{-}\overset{\displaystyle OH}{P}{-}OH} \qquad \text{(‘active form’)}$$

From kinetic data on the oxidation of hypophosphorous acid by the halogens, it has been calculated that the equilibrium constant

$$K = \frac{[H_3PO_2 \text{ active}]}{[H_3PO_2 \text{ normal}]}$$

is of the order of $10^{-12}$.[163] The tautomeric change is said to have an activation energy of 18,200 g.-cal.[34] A comparison of the magnetic rotations and molar refractivities of esters $RP(OR)_2$ and $R_2P(O)OR$ with those of $H_3PO_2$ supports the $H_2P(O)OH$ structure for the latter.[179]

The Raman and infra-red spectra of the acid and its salts have been described by several workers.[9,72,125,150–5,168,180–3] Table II gives details of the frequencies observed for the potassium salt.

*Table II.—Raman and Infra-red Spectra of Potassium Hypophosphite*

| Frequency cm$^{-1}$ (approx.) | Infra-red spectrum | | | Raman spectrum | |
|---|---|---|---|---|---|
| | Aqueous solution | Crystalline salt | | Relative intensities | |
| | (Ref. 151) | (Ref. 155) | (Ref. 151) | (Ref. 151) | (Ref. 152) |
| 470 | (*m*) | — | (*m*) | 5 | 17 |
| 580 | — | — | — | — | 36 |
| 780 | — | — | — | — | 11 |
| 820 | (*s*) | 3 lines all (*s*) | (*s*) | 1 | 7 |
| 920 | — | — | — | 7 | 37 |
| 1050 | (*s*) | 3 lines all (*s*) | (*s*) | 10 | 100 |
| 1090 | (*m*) | (*s*) | (*w*) | 5 | 23 |
| 1160 | (*s*) | (*s*) | (*s*) | 7 | 33 |
| 1180–1230 | (*s*) | 4 lines (*s*), (*vs*) and 2 (*m*) | (*s*) | — | — |
| 1960 | — | (*vw*) | — | — | — |
| 2350 | (*w*) | (*s*) | (*m*) | 10 | 96 |
| 3400 | — | (*m*) | — | — | — |

(*s*) = strong, (*m*) = medium, (*w*) = weak.

From these spectra a non-planar $C_{2v}$ symmetry has been inferred, except possibly in the calcium salt where the symmetry appears to be $C_1$.[180]

The nuclear magnetic resonance spectra of hypophosphorous acid and some of its salts have also been studied[19,156–8] and again the results agree with those expected from the structure given above. Table III gives details of the $^{31}$P nuclear magnetic resonance spectra.[19]

*Table III.—Nuclear Magnetic Resonance Spectra of Hypophosphorous Acid and its Salts*

| Species | Chemical shift in p.p.m. relative to 85% $H_3PO_4$ | Line structure | Splitting in gauss |
|---|---|---|---|
| $H_3PO_2$ | $-13\pm2$ | 1–2–1 | 0·33 |
| $Ca(H_2PO_2)_2$ | $-8\pm2$ | 1–2–1 | 0·31 |
| $NaH_2PO_2$ | $-8\pm2$ | 1–2–1 | 0·31 |
| $KH_2PO_2$ | $-6\pm2$ | 1–2–1 | 0·31 |

Crystallographic examination of the hypophosphites of magnesium, nickel and cobalt has shown that the hypophosphite anion has a tetrahedral configuration.[122] From this work, the P–O bond distance was found to be 1·52 A. and the angle between the P–O bonds 109°. Similar investigations of ammonium hypophosphite give the P–O and P–H bond distances as 1·51 A. and 1·5 A. respectively,[124] whilst the angle between the P–O bonds is stated to be 120° and that between the P–H bonds to be 92°.

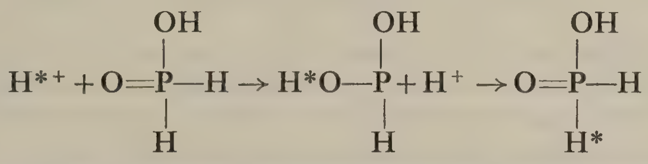
It has been observed that there is no exchange of phosphorus between hypophosphorous acid and either phosphorous or phosphoric acid in aqueous solution even in the presence of iodine.[11, 20, 39] There is, however, some exchange of oxygen in the free acid[21] and ready exchange of hydrogen for deuterium or tritium in acid, aqueous solution.[12–4, 22, 75, 169] There is no exchange of hydrogen in aqueous solutions of the hypophosphites unless free acid is present.[13–4, 22, 40]

The exchange of oxygen is thought to occur by addition of water to the P=O link forming $H_2P(OH)_3$.[21] The exchange has been shown to follow the equation:

$$-\ln(1-Z) = k(C_0+C_1)t$$

where $C_0$ and $C_1$ are the concentrations of water and acid respectively, $Z=y/y_\infty$ where $y$ = the excess of heavy oxygen and $y_\infty$ its content at equilibrium. The half-time of exchange at 40°C. is under 12 minutes.[21]

It is believed that the exchange of hydrogen occurs by addition of $H^+$ to the polar oxygen atom with simultaneous loss of $H^+$ from one of the P–H linkages followed by rearrangement, i.e.

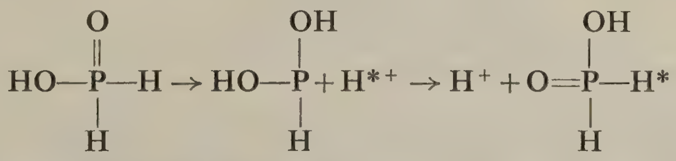


$$H^{*+} + O{=}\underset{H}{\overset{OH}{P}}{-}H \rightarrow H^{*}O{-}\underset{H}{\overset{OH}{P}} + H^{+} \rightarrow O{=}\underset{H^{*}}{\overset{OH}{P}}{-}H$$

The half-time of exchange at 25°C. is 16 min.[13] With no other acid present, the rate law is

$$R = k_{H^+}[H^+][H_3PO_2] + k_{H_3PO_2}[H_3PO_2]^2$$

At 30°C., $k_{H^+} = 3{\cdot}3 \pm 0{\cdot}15$ and $k_{H_3PO_2} = 2{\cdot}9 \pm 0{\cdot}14$.[12] It is possible that the tautomeric change occurs first, i.e.



$$HO{-}\underset{H}{\overset{O}{\overset{\|}{P}}}{-}H \rightarrow HO{-}\underset{H}{\overset{OH}{P}} + H^{*+} \rightarrow H^{+} + O{=}\underset{H}{\overset{OH}{P}}{-}H^{*}$$

The protonation of $H_2PO(OH)$ and $HPO(OH)_2$ in aqueous sulphuric acid has been studied by proton magnetic resonance. Calculations based on the variation of the P–H coupling constant with acid concentration did not yield $pK_a$ values consistent with the scales of Hammett function derived for other types of base. The results could best be interpreted in terms of a two-stage protonation:

$$H{-}O{-}H\cdots O{=}PH_n(OH)_{3-n} \xrightarrow{H^+} H_2O^+{-}H\cdots O{=}PH_n(OH)_{3-n}$$

$$\xrightarrow{H^+} H_3O^+ + H_nP(OH)^{+}_{4-n}$$ [211]

The oxidation of hypophosphorous acid by some oxidants (e.g. the halogens) obeys the same rate law and the catalytic coefficients are of the same order. Hence the two reactions probably follow a similar mechanism and provide support for the theory of tautomerism in hypophosphorous acid. There is also some evidence for dibasic character in the acid from conductivity data for the sodium salt.[18]

Hypophosphorous acid and the hypophosphites are very readily oxidized and many of their reactions involve oxidation–reduction processes. Although the oxidation potential of hypophosphorous acid does not seem to have been determined experimentally, the following values have been calculated[123]:

Under acid conditions,

$$H_2O + H_3PO_2 = H_3PO_3 + 2H^+ + 2e \qquad E^\circ = 0{\cdot}50 \text{ volts}$$

Under basic conditions,

$$3OH^- + H_2PO_2^- = HPO_3^{2-} + 2H_2O + 2e \qquad E^\circ_B = 1{\cdot}57 \text{ volts}$$

Hypophosphorous acid and also its salts undergo oxidation in aqueous solution, although some authorities state that catalysts must be present.[23] This oxidation may be inhibited by compounds with redox properties, such as hydroquinone.[24]

The free energies of disproportionation of hypophosphorous acid and of its oxidation by water have been stated to be[123]:

$$3H_3PO_2 \rightarrow PH_3 + 2H_3PO_3 \qquad \Delta F^\circ = -29{\cdot}9 \text{ kcal./ mole}$$

and

$$H_3PO_2 + H_2O \rightarrow H_3PO_3 + H_2 \qquad \Delta F^\circ = -23{\cdot}0 \text{ kcal./ mole}$$

The oxidation of hypophosphorous acid by atmospheric oxygen may be initiated by ozone or fluorine dioxide and a chain mechanism has been proposed for the reaction[25]:

$$HPO_2^- + O_2 \rightarrow HPO_4^-; \qquad HPO_4^- + H_2PO_2^- \rightarrow H_2PO_4^- + HPO_2^-$$

This reaction is accelerated by decrease in pH, increase in concentration, increase in temperature and by small amounts of heavy metal salts, although larger concentrations tend to inhibit the oxidation.[25] The order of reaction and the temperature coefficient of the rate of oxidation have been determined over the temperature range 20–40°. The activation energy of the reaction is 17·8 kcal./mole.[184]

Metallic palladium, copper, cobalt and nickel catalyze the aqueous oxidation of hypophosphorous acid and it has been suggested that under these conditions the first stage is the loss of hydrogen, followed by the addition of water.[27–8] However, isotope studies have shown that, of the hydrogen evolved in neutral solution, half is derived from the hypophosphite and half from the water.[27] A possible mechanism is:

$$\begin{aligned}&H_3PO_2 \rightarrow [H_2PO_2] + H\cdot\\&[H_2PO_2] + H_2O \rightarrow H_3PO_3 + H\cdot\\&2H\cdot \rightarrow H_2\end{aligned}$$

In the anodic oxidation of hypophosphorous acid on a palladium plated gold anode, the rate determining step is claimed to be the electrochemical ionization of the atomic hydrogen arising from a catalytic dehydrogenation such as that shown above.[185] It has been claimed, in fact, that hypophosphite is oxidized only at palladium anodes[186] although other authors have observed the formation of phosphite, phosphate and pyrophosphate at lead or copper anodes.[187] Cathodic reduction led only to phosphine formation.[187]

Hypophosphorous acid is quantitatively oxidized by iodine to phosphorous acid under acid conditions.[29–33] The most probable mechanism is that both the normal and active forms of hypophosphorous acid are in equilibrium with hypophosphite and $H_3PO_2.H^+$ ions. The iodine reacts with the hypophosphite ion and the active form of the acid. The latter reaction is subject to a general acid–base catalysis and the catalytic coefficients have been determined for several acids.[32] The same work claims that the transformation to the active form of hypophosphorous acid requires an activation energy $E_{k_1^\circ}$ of 20,000 g.-cal. and that for the reaction of iodine with the acid at 30°C. the catalytic coefficients are $k_1^\circ = 0{\cdot}35$ min.$^{-1}$ and $k_1^{H_3PO_2} = 0{\cdot}13$ min.$^{-1}$

The acid is oxidized by bromine and chlorine,[33–4, 38] the reaction being similar to that with iodine. Iodine monochloride and iodine trichloride also oxidize hypophosphorous acid.[35]

Chloramine reacts slowly but quantitatively with hypophosphorous acid in the presence of 0·24 N. sulphuric acid to form phosphorous acid.[36] It is said that in the presence of two equivalents of acetic acid the oxidation proceeds further to phosphoric acid.[37]

Iodic acid and the alkali metal iodates oxidize hypophosphorous acid to phosphorous acid, but it is not practicable to use this reaction for the quantitative analysis of hypophosphites, because of considerable interference from the iodate–iodide and iodine–phosphorous acid reactions.[41–3] There is also a considerable induction period which can be affected by temperature, concentration of the reactants and the presence of other species.[44] Both bromates and chlorates react similarly, again after an induction period,[45–6] though the chlorates oxidize hypophosphorous acid only in fairly concentrated solution. Bromate, or rather bromine monochloride formed *in situ* therefrom, has been used for the determination of hypophosphorous acid.[45]

When hypophosphorous acid is oxidized by hydrogen peroxide,[8] addition of ferrous ions increases the initial oxidation rate, although after this, the rate is the same whether ferrous or ferric ions are present.[47] Cuprous ions do not have this effect. Dihydroxymaleic, dihydroxytartaric and thioglycollic acids increase the activation by ferrous ions; this is believed to be due to some form of complex formation between the ferrous ion and the hypophosphorous acid, which renders the latter more readily oxidizable.[47]

Hydrochloric acid solutions of the arsenates are reduced by hypophosphorous acid to arsenic according to a second-order reaction[48–9, 148]:

$$\frac{-\mathrm{d}C_{\mathrm{As(OH)_3}}}{\mathrm{d}t} = KC_{\mathrm{As(OH)_3}}C_{\mathrm{H_3PO_2}} = KC_{\mathrm{As(OH)_3}}(B-(C_0-C))$$

where $B$ and $C_0$ are the initial concentrations of the hypophosphorous and arsenic acids respectively and $C$ is the concentration of the latter at time $t$. The velocity coefficients of the reaction vary with the initial concentrations of the reactants[49] and addition of potassium iodide accelerates the reaction.[129] The arsenic contains a little phosphorus (0·5–2%), the phosphorus content rising with increasing hypophosphite concentration and decreasing temperature.[188]

Some anomalous results were obtained when mixtures of arsenates and methylarsonates were reduced together. Highly coloured precipitates were formed instead of the expected brown mixture of arsenic and methylarsine. From mixtures rich in organic arsenate a yellow precipitate was obtained which was partially soluble in carbon disulphide, leaving a residue of arsenic. The solution slowly deposited more arsenic, eventually becoming colourless and containing methylarsine oxide.[48]

The kinetics of the reduction of arsenic trihalides by hypophosphorous acid have been studied and show that the rate of reaction decreases in the order $AsI_3 > AsBr_3 > AsCl_3$.[48]

When phosphorus or phosphine is oxidized by nitric acid under mild conditions, considerable quantities of hypophosphorous acid are formed, although hot nitric acid oxidizes it completely to phosphoric acid.[50]

Sulphuric acid is reduced by hypophosphorous acid in the presence of hydrogen iodide and this reaction has been developed into a method for the quantitative determination of sulphur in steel.[53] The seleninic acids are also reduced by hypophosphorous acid in dilute hydrochloric acid solution. The products are either seleninous acids or selenides depending on the reaction conditions.[51]

Ferricyanides are reduced by hypophosphites in alkaline solution and osmium tetroxide is said to catalyse the reaction.[52]

Hypophosphorous acid also reduces solutions of many of the heavy metals although under carefully controlled conditions the hypophosphites of some of the metals, which are normally reduced, may be prepared. Silver, gold and under some conditions copper, mercury and palladium, are reduced to the metal. The reaction has been proposed as a method of gravimetric analysis for all these metals except copper,[54–6] although some workers have used the reduction of mercuric salts to mercurous chloride by hypophosphorous acid as a method of analysis.[57–8, 127]

The complex of mercury with ethylenediamine tetraacetic acid (EDTA) is reduced to the metal and EDTA and this has been utilized as an indirect method of determining hypophosphorous acid.[170]

The kinetics of the reduction of cupric salts by hypophosphorous acid have been studied[60–1] and it has been proposed that copper hypophosphite may be formed as an intermediate product, which then decomposes under the reaction conditions. A moderately stable solution of copper hypophosphite has been prepared by some investigators.[61] It decomposes at 70°C. to form the unstable copper hydride CuH and reacts with cupric chloride to give cuprous chloride. Other workers have also obtained copper hydride by reduction of copper sulphate with hypophosphorous acid at 50–55°C. in an atmosphere of hydrogen.[26] For the reduction to copper metal according to the reaction:

$$2CuSO_4+2H_2O+H_3PO_2 \rightarrow 2Cu+2H_2SO_4+H_3PO_4$$

the empirical equation $C=at^{-m}$ has been deduced from kinetic data measured at 47°C. In the equation, $C$ is the concentration of cupric ions, $t$ is the time of reaction, and $a$ and $m$ are constants. This equation reduces to $\log C=2{\cdot}2932-0{\cdot}48 \log t$.[60]

Although some investigators have observed the formation of hydrogen when silver salts are reduced by hypophosphorous acid,[159] more recent studies failed to confirm this when equimolar concentrations of the reactants were mixed under a wide range of conditions.[59] The later workers suggest that silver hypophosphite first formed then decomposes to form silver and hypophosphite radicals. The latter react with water to form hypophosphorous acid and oxygen, which then oxidizes the acid to phosphorous and phosphoric acids.

The reduction of mercuric salts has been shown to involve four reactions[62]:

$$\begin{aligned}
&(1)\ 2Hg^{++}+H_2PO_2^-+H_2O \rightarrow Hg_2^{++}+H_2PO_3^-+2H^+\\
&(2)\ Hg_2^{++}+H_3PO_2+H_2O \rightarrow 2Hg^\circ+H_3PO_3+2H^+\\
&(3)\ Hg^\circ+Hg^{++} \rightarrow Hg_2^{++}\\
&(4)\ H_3PO_3+2Hg^{++}+H_2O \rightarrow Hg_2^{++}+H_3PO_4+2H^+
\end{aligned}$$

In the presence of chloride ions a fifth reaction takes place:

$$(5)\ Hg_2^{++}+2Cl^- \rightarrow Hg_2Cl_2\downarrow$$

Reaction (1) is the main rate-controlling reaction and the velocity constant for this step is given as $k=11{\cdot}42$ min.$^{-1}$ at 25°C. and $1{\cdot}42$ min.$^{-1}$ at 0°C. From these figures an activation energy of 13,600 g.-cal. has been derived.

Reaction (2) is believed to involve a preliminary tautomeric change in the hypophosphorous acid similar to that occurring in the exchange of hydrogen and oxidation by iodine.

Reaction (3) is so rapid that no mercury metal appears until after the removal of all the mercuric ions from the system.

Reaction (4) makes a significant contribution to the rate of removal of mercuric ions towards the middle of the overall reaction.

Germanium(IV) compounds are reduced to germanium(II) by hypophosphorous acid, or even further depending on the conditions.[63, 148] The reduction of uranyl sulphate is photocatalyzed and yields a mixture of products including hypophosphite, phosphite and phosphate with uranous sulphate.[64]

The reduction of cerium(IV) by hypophosphite may be utilized for the determination of the latter.[171] The rate of the reaction is about 1/200 of that which would be expected from strong acid catalysis theory, and the mechanism appears to involve Ce(IV) complex ions, as suggested by the rate expression[189]:

$$-\tfrac{1}{2}\mathrm{d}[\mathrm{Ce(IV)}]/\mathrm{d}t = [H^+]_{n=1}^{n=3} kH_n^+[Ce(H_2PO_2)_n^{(4-n)+}]$$

Bismuth salts are also reduced, usually to the metal, although bismuth hypophosphites may be formed as unstable intermediates.[65–6] An empirical equation has been derived for this reaction at 50°C.:

$$\log C = -2{\cdot}523-0{\cdot}10 \log t$$

where $C$ is the concentration of bismuth and $t$ is the time of reaction.[66]

The kinetics of the reaction between hypophosphorous acid and dichromate ion in sulphuric acid have been studied and show that the reaction is first order with respect to hypophosphorous acid and second order with respect to dichromate. The following mechanism was proposed[172]:

$$H_3PO_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} H_3PO_2 \qquad \text{(active form)}$$

$$H_3PO_2\ \text{(active form)} + H^+ + 2HCrO_4 \xrightarrow{-k_3} H_3PO_3 + HCr_2O_6^- + H_2O$$

where $HCr_2O_6^-$ rapidly reduces to Cr(III).

$$\frac{k_1k_3}{k_2} = 466\ \text{sec.}^{-1}\ \text{at}\ 25°\text{C.}$$

A Mn(III) phosphate, prepared from Mn(IV) and Mn(II) in phosphoric–sulphuric acid solution, quantitatively oxidizes hypophosphite to phosphate.[190]

Molybdic acid and tungstic acid sols are reduced by hypophosphorous acid, the reaction involving photochemical initiation.[90] The reaction is complex and the velocity constant is said to depend on the temperature, reactant concentrations, pH of the medium and even the polarization of the incident light, although not all these factors apply to both reactions.

Hypophosphorous acid also reduces aryl diazonium salts. Investigations using hypophosphorous acid labelled with deuterium have shown that the mechanism involves the transfer of a hydrogen from a P–H bond to the aromatic nucleus.[67–9] The yield in this reaction is improved by the addition of copper sulphate or, in the case of certain aryl groups, ferrous sulphate.[70]

The reaction of hypophosphorous acid with hydroborate in acid solution gives only traces of phosphine whereas under similar conditions arsenic, antimony, germanium and tin oxyacids give good yields of their hydrides.[173]

Hypophosphorous acid is used as a colour stabilizer in the preparation of polymers, fatty materials and other organic products. It is used in plating without current,[134] particularly of nickel, although its salts are more often employed. It also has uses in the steel industry, the preparation of emulsifying agents and as a catalyst in the preparation of polyamides.[135–44, 191]

The addition of hypophosphites to radioactive waste solutions greatly reduces the volatility of ruthenium contained therein and thus prevents its escape when such solutions are concentrated for disposal.[174]

Hypophosphorous acid solution at 85°C. acts as a reducing agent for the disulphide linkage in cystine or oxidized glutathione, but does not reduce wool.[192] The crystalline acid reacts with orthocarbonates (orthocarboxylates) or ketals, yielding hypophosphite esters or 1-hydroxyalkyl phosphinates respectively.[193] A review of the chemistry and applications of hypophosphorous acid and its salts has appeared.[194]

## THE HYPOPHOSPHITES

The alkali metal hypophosphites are prepared by reaction of white phosphorus with an aqueous solution of alkali metal hydroxide usually with the addition of sufficient calcium hydroxide to remove the phosphite formed as calcium phosphite. They may also be prepared by double decomposition reactions with calcium hypophosphite, e.g. ammonium hypophosphite by reaction of the calcium salt with ammonium carbonate.[160] The reaction of phosphorus with hydroxides is strongly exothermic:

$$4P + 3OH^- + 3H_2O \rightarrow PH_3 + 3H_2PO_2^-; \qquad \Delta F° = -80{\cdot}0\ \text{kcal.}^{123}$$

The technique of paper chromatography has been applied to the identification and determination of hypophosphites as for the other oxyacids of phosphorus.[73–4, 195] The solvents most often employed are those described by Volmar, Ebel and Yacoub.[73] The $R_f$ values of the hypophosphite anion in their acid and alkaline solvents are 0·84 and 0·75 respectively.[73–4] The chromatograms are normally developed by molybdate reagent. Hypophosphite itself does not give a colour with this reagent, but can be quantitatively oxidized to orthophosphate by acid sodium sulphite at 95°C.[196] Thin layer chromatography has also been used for the separation.[197–98]

The heats of solution of some of the hypophosphites have been determined and the values found are recorded in Table IV below.[71]

*Table IV.—Heats of Solution of Hypophosphites in Water*

| Salt | $-\Delta H$ in kcal./mole at $29 \pm 1$°C. | | |
|---|---|---|---|
| | Dilution in moles of water per mole of solute | | |
| | 100 | 1000 | ∞ |
| Ammonium hypophosphite | −2·20 | −1·66 | −1·60 |
| Sodium hypophosphite | +2·60 | +2·85 | +2·88 |
| Calcium hypophosphite | +1·70 | +3·90 | +4·20 |
| Barium hypophosphite | +0·20 | +0·68 | +1·05 |
| Barium hypophosphite monohydrate | −0·30 | −0·50 | −0·53 |

The alkali metal, alkaline earth and many other hypophosphites are soluble in water and the alkali metal salts are soluble in alcohol. The solubility of sodium hypophosphite over a range of temperatures is given below.

| Temperature °C. | 0° | 10° | 20° | 30° | 40° | 50° | 60° | 70° | 80° |
|---|---|---|---|---|---|---|---|---|---|
| Solubility in g. $NaH_2PO_2$ per 100 g. water | 104·7 | 107·5 | 112·3 | 120·3 | 131·0 | 145·1 | 163·9 | 188·2 | 220·5 |

Potassium hypophosphite has a solubility of 170·3 g. $KH_2PO_2$/100 g. water at 20°C. and 335 g./100 g. water at 100°C. Solubility data over a wider range of temperatures have been recorded for sodium and potassium hypophosphite, together with values of the density of solutions of various concentrations.[199] The figures for calcium hypophosphite are 15·3 g. $Ca(H_2PO_2)_2$/100 g. water at 25°C. and 12·5 g./100 g. at 100°C.[164] The solubilities at 20°C. of sodium and calcium hypophosphite in 100 g. of 98·2% and 86·5% aqueous glycerol have been given as 42·2 and 32·7 g. of sodium salt and 3·2 and 2·5 g. of calcium salt, respectively.[126]

Ammonium hypophosphite crystallizes as orthorhombic bipyramids and has a density of 1·634. There are four molecules to the unit cell which has the dimensions $a = 3{\cdot}98$ Å., $b = 7{\cdot}57$ Å. and $c = 11{\cdot}47$ Å. The space group is $Acmm(V_h^{21})$.[124] Ammonium hypophosphite decomposes when heated to 250°, giving ammonia and orthophosphoric acid in good yield. At higher temperatures the orthophosphoric acid loses water with the formation of polyphosphoric acid.[200]

Sodium hypophosphite, when heated, begins to decompose at about 310°C. giving, initially, phosphine, sodium phosphite, 'metaphosphate' and pyrophosphate. The bulk of the reaction proceeds according to the equations quoted below, although small amounts of phosphorus and phosphides of sodium are also formed.[76, 199, 201]

Water can be removed from the hydrate below 200° without decomposition occurring.[201]

At 310°C. $14NaH_2PO_2 \rightarrow 6PH_3 + 4Na_2HPO_3 + 2NaPO_3 + Na_4P_2O_7 + 3H_2O$
At 370°C. $4Na_2HPO_3 \rightarrow PH_3 + 2Na_3PO_4 + \frac{1}{2}Na_4P_2O_7 + \frac{1}{2}H_2O$
At 500°C. $NaPO_3 + Na_3PO_4 \rightarrow Na_4P_2O_7$

The reaction of hypophosphorous acid or hypophosphites with acetic anhydride has long been known to give a phosphorus suboxide, $(P_4OH)_n$,[175] but recently it has been found that potassium hypophosphite gives as a by-product a small amount of potassium acetophosphinate $K[HPO_2(COCH_3)]$.[176]

The sodium and lithium salts have also been prepared by neutralization of the acid (formed by ion exchange from the potassium salt).

The potassium salts of propionophosphinic and butyrophosphinic acid have been obtained similarly.

In aqueous solution hypophosphorous acid acts as a monobasic acid, the tautomeric tricovalent form being present only in trace amounts. However, a dipotassium compound has been prepared by causing a suspension of monopotassium hypophosphite to react in liquid ammonia with two equivalents of potassamide. The crystalline suspension is slowly converted to a white powdery solid which is extremely hygroscopic. On moistening the powder with a drop of water it decomposes with spontaneous combustion[146]:

$$KNH_2 + H_2PO.OK \rightarrow NH_3 + KHPO.OK$$

Although it is probable that the dipotassium compound contains a potassium–phosphorus bond, it is possibly a salt of the tautomeric form, viz. $HP(OK)_2$.

The hypophosphites of rubidium and cæsium are similar to those of the other alkali metals. The densities and solubilities of the salts increase with the atomic weight of the alkali metal. The cæsium salt crystallizes as a hemihydrate, $CsH_2PO_2,\frac{1}{2}H_2O$, with a density of 2·81 g./c.c. at 18°C. The rubidium salt is anhydrous and has a density of 2·32 g./c.c. at 17°C. Both salts are extremely deliquescent and have similar thermal decomposition reactions to those of the sodium salt.[95]

Like the acid, the alkali metal hypophosphites are powerful reducing agents. In fact, Latimer's figures[123] show hypophosphorous acid to be a much stronger reductant in basic solution than in acid solution. Again, many of the transition metal salts are reduced. Copper salts are reduced to the metal or the unstable hydride, unless chloride ions are present when cuprous chloride is formed.[77–9] Cobalt salts are similarly reduced but the product is more complex, being usually a mixture of the metal with metal phosphides.[80–1] Some workers, however, claim that unless ammonia is present a catalyst, such as palladium, is necessary for reaction to occur.[82] When palladium is present it is possible to obtain cobalt metal uncontaminated by phosphides. It is possible that, in this case, the reduction is effected by nascent hydrogen formed by the palladium-catalyzed aqueous oxidation of the hypophosphite. The volumetric determination of the hydrogen evolved from this catalytic dehydrogenation has been used for the estimation of sodium hypophosphite.[202]

The reduction of nickel salts is likewise dependent on the reaction conditions, the product being largely the metal, together with varying amounts of nickel phosphide. Palladium, again, can act as a catalyst and the presence of ammonia enhances the reaction rate besides decreasing the proportion of phosphide formed.[83–4] This reaction is utilized for the chemical deposition of nickel and there are many references of a technological nature.[85–7,96,130–4] It has been claimed that the mechanism represented by the equations:

$$H_2PO_2^- + H_2O \rightarrow HPO_3^{--} + 2H^+ + H^-$$
$$Ni^{++} + 2H^- \rightarrow Ni + H_2$$
$$H^+ + H^- \rightarrow H_2$$

is consistent with earlier data on the rate of hydrogen evolution during the reaction.[203] Other authors have invoked the reaction of hydroxyl radicals from the metal surface with partly dehydrogenated hypophosphite[204]:

$$H_2PO_2^- \rightarrow HPO_2^- + H$$
$$HPO_2^- + {\cdot}OH \rightarrow H_2PO_3^-$$
$$2H + Ni^{++} \rightarrow 2H^+ + Ni$$

Alloys of iron, nickel, chromium, cobalt and vanadium may be deposited on steel by reducing mixtures of salts of these metals with hypophosphites.[132, 162]

Although palladium and nickel salts are normally reduced to the metal (or a phosphide), if the metal is present in the form of a complex ion reduction may not be complete. Potassium tetracyanonickelate (II) and the corresponding palladate are both reduced to the monovalent cyanide by sodium hypophosphite in neutral or alkaline solution. The platinum analogue is not reduced.[88] Ruthenium, as halide or complex cyanide, is also reduced to the monovalent state but iridium and osmium salts show little or no change.[88]

Sodium hypophosphite can also reduce ferric iron to the ferrous state and this reaction has been employed for the colorimetric determination of iron by 2,2′-bipyridine or *o*-phenanthroline.[145]

Hypophosphite has been used as a precipitating agent for the gravimetric determination of scandium. The precipitate obtained consists of scandium trihypophosphite, $Sc(H_2PO_2)_3$,[177] $d$ 1·93, $n$ 1·56–1·58, sol. $3{\cdot}3 \times 10^{-4}$ M. at 25°.[209] The following transition metals are also said to give similar precipitates: Zr(IV), Hf(IV), Th(IV) and Ta(V).[177]

Sodium hypophosphite is also oxidized under conditions of glow-discharge electrolysis.[89] The reaction of iodine with solid anhydrous sodium hypophosphite at 50°C. is violently exothermic, and leads to inflammation. White, yellow or orange products of indeterminate composition are formed.[205] Nitrogen dioxide reacts with saturated alcoholic sodium hypophosphite solution at 20°C. giving a white precipitate. The water-soluble portion of this contains hypophosphite and phosphite, while the insoluble portion is assumed to be the sodium salt of the $(P^3)_6$ acid. Solid dinitrogen tetroxide at −10° oxidizes hypophosphite to phosphite, phosphate and condensed phosphates.[206]

Besides the uses already mentioned, the alkali metal hypophosphites are used in certain polymerizations[91–93] and the removal of oxygen from boiler water,[94] whilst the sodium, ammonium and the calcium salts have been used in the production of flameless, gas-producing charges.[128]

The alkaline earth hypophosphites are prepared similarly to the alkali metal salts. They are more soluble in water than the corresponding salts of most of the other oxyacids of phosphorus. These salts appear to have been little studied in recent years. Calcium hypophosphite has been reported to be phosphorescent after exposure to ultra-violet radiation.[97]

Aluminium hypophosphite may be prepared by reaction of aluminium hydroxide with hypophosphorous acid[98] or by heating an aluminium salt with 50% acid at 80–90°C. for 1 hr.[99] It can also be produced by double decomposition between sodium hypophosphite and an aluminium salt, but the precipitation is said to be slow. It is insoluble in water, sodium hypophosphite solution and hypophosphorous acid, but is dissolved by sodium hydroxide, hydrochloric acid and dilute sulphuric acid. The salt, as formed, is anhydrous and decomposes at 220°C. No double salts with aluminium chloride have been reported.[99]

Two gallium hypophosphites, the normal salt and an acid salt, have been reported.[100–1] The normal salt, which was claimed to have the formula $GaPO_2,H_2O$, was obtained as a white precipitate by adding sodium hypophosphite to a solution of gallium nitrate. It is insoluble in water, alcohol and ether, but is dissolved by dilute hydrochloric acid. The acid salt, given as $GaH_3(PO_2)_2$, is prepared by dissolving freshly precipitated gallium hydroxide in hypophosphorous acid. It is a white powder, soluble in warm water but insoluble in alcohol or ether.

Indium hypophosphite is obtained by double decomposition between a soluble indium salt and sodium hypophosphite. From the solution which remains after filtration of the precipitate, a basic indium hypophosphite is obtained by further concentration and addition of sodium hydroxide. This is a white, curdy precipitate corresponding to $In(H_2PO_2)_3,2In(OH)_3$. The normal salt is a white, crystalline powder readily soluble in mineral acids, but rather unstable to hydrolysis.[102]

Thallous hypophosphite is obtained as white, needle-like crystals by treating thallous carbonate with hypophosphorous acid and concentrating the solution. When heated for five days at 90–95°C. this compound gave a liquid, thought to be thallous phosphite.[103] The melting point of thallous hypophosphite has been reported to be 110°C.[103] although earlier workers gave 150°C.[98] The system thallous hypophosphite–water has a eutectic point at $-25$°C. with a composition of 13·5 mole-% of the salt.[104]

When a hydriodic acid solution of germanium dioxide is treated with a little hypophosphorous acid, a double hypophosphite-iodide, $3Ge(H_2PO_2)_2,GeI_2$, is obtained together with germanous phosphite and a phosphate, $Ge_3(PO_4)_2,2GeHPO_4$.[105] Double hypophosphite halides are also formed when germanium dioxide is heated with 50% hypophosphorous acid in the presence of hydrochloric or hydrobromic acid. The formulæ assigned to the two compounds are $Ge(H_2PO_2)_2,GeCl_2$ and $3Ge(H_2PO_2)_2,GeBr_2$.[106] The double hypophosphite-chloride and -bromide are fairly stable in air but are hydrolyzed to germanous hydroxide. Their respective melting points are 124° and 129°C. They are soluble in concentrated halogen acids and in phosphoric and hypophosphorous acids.[106] Reduction of germanium dioxide by hypophosphorous acid in 2–3% hydrochloric acid is said to give germanium or, possibly, a suboxide.[63] Other workers, however, found that germanium tetrachloride is reduced only to the divalent state by sodium hypophosphite under acid conditions.[148] There is also some evidence for the formation of germanic hypophosphite, $Ge(H_2PO_2)_4$, when germanous iodide is heated with 90% hypophosphorous acid in contact with the atmosphere, although this would appear to be at variance with other results.[105]

Stannous hypophosphite is prepared by cooling a solution of stannous hydroxide in hot 25% hypophosphorous acid. The hexahydrate, m.p. 66–67°C., which is formed is converted to the dihydrate by standing for 12 hr. at room temperature *in vacuo*. This melts at 70–90°C. and is converted to the anhydrous compound, m.p. 105°C., *in vacuo* at 45–50°C.[107]

When stannous hypophosphite in warm 25% hypophosphorous acid is treated with a little hydrochloric acid, the compound $3Sn(H_2PO_2)_2,SnCl_2$ (m.p. 130°C.) is obtained. Stannous chloride in 3N. hydrochloric acid gives a precipitate with hypophosphorous acid. This, dissolved in 50% hypophosphorous acid and made 10 N. with respect to hydrochloric acid, reacts with metallic tin to give crystals of the compound $Sn(H_2PO_2)_2,SnCl_2$ (m.p. 181°C.).[107] All these compounds of tin hydrolyze to stannous hydroxide and are decomposed by concentrated acids.

Stannic hydroxide is soluble in hypophosphorous acid but the solution does not yield any solid compound. The double salt, $Sn(H_2PO_2)_4,SnCl_4,3H_2O$, may be obtained by precipitation from a solution of stannic chloride with sodium hypophosphite[98] or by reaction of stannic chloride with 50% hypophosphorous acid in 3 N. hydrochloric acid solution.[107] It is insoluble in most solvents and is fairly readily hydrolyzed. It is decomposed by concentrated acids and, when heated, decomposes at 195°C. before melting. The anhydrous compound may be prepared by drying the hydrate *in vacuo* at 50–60°C. The corresponding iodide is obtained by the action of hypophosphorous acid on an alcoholic solution of stannic iodide. The solid darkens at 100°C., melts at 319°C., and decomposes above this temperature. It is insoluble in most solvents but dissolves in concentrated phosphorous acid, alkalis and hot hydrochloric acid solution. It is readily attacked by concentrated oxidizing acids.[108]

The hypophosphites of zinc and cadmium form loose addition compounds with

**Refs. p. 626**

hydrochloric and hydrobromic acids.[114] Although the addition is not completely stoicheiometric the compounds formed approximate to $Cd(H_2PO_2)_2,2HCl$; $Cd(H_2PO_2)_2,2\frac{1}{2}HBr$; $Zn(H_2PO_2)_2,HCl$ and $Zn(H_2PO_2)_2,HBr$.

A titanium hypophosphite has been prepared by causing a solution of titanium oxide in sulphuric acid to react with sodium hypophosphite. The amorphous white precipitate is easily hydrolyzed and is insoluble in most solvents. It may be dehydrated at 100°C. *in vacuo* over concentrated sulphuric acid. It is suggested that the two compounds are $H_2[Ti(OH)_4(H_2PO_2)_2]$ and $H_2[TiO_2(H_2PO_2)_2]$.[113] They are soluble in hot, concentrated acids and their aqueous suspensions have an acid reaction.

Recently thermometric titration of ferric chloride with sodium hypophosphite has provided evidence for complexes in which the iron:hypophosphite ratios are 1:1, 1:3 and 2:3.[118] Transport experiments by the same workers indicate that the 1:3 compound previously formulated[116, 117] as $[Fe_3(H_2PO_2)_6](H_2PO_2)_3$ should be regarded as being $Fe[Fe(H_2PO_2)_6]$ instead. However, the 1:1 complex of Cr(III) and hypophosphite has been shown to contain the $[CrH_2PO_2]^{2+}$ ion.[207]

Ferric, lead and copper hypophosphites have all been used in ammunition priming mixtures[109–12, 119–21] and sodium, calcium and ferric hypophosphites are much used in tonics.

Besides the scandium hypophosphite already mentioned[177, 208–9] the hypophosphites of other lanthanide and actinide elements have been described, including those of Th(IV), $UO_2$(II), Sm(III), Tm(III), Yb(III), La(III) and Y(III).[183,208] Their infra-red and Raman spectra are similar to those of hypophosphites of uni-and bivalent cations[183, 208] and their thermal decomposition appears to follow a similar course.[208–9]

## SECTION XXII

# PHOSPHOROUS ACID AND THE PHOSPHITES

BY R. A. SMITH

## PHOSPHOROUS ACID

### Preparation

THE methods for the preparation of phosphorous acid described in Mellor, VIII, 900, remain in common use, although several innovations have been reported. The oxidation of phosphorus by water vapour under pressure[1] in the presence of 1·0–9·75 N. NaOH yields phosphoric, phosphorous and hypophosphorous acids, depending on the amount of sodium hydroxide present and the temperature. Use of the calculated quantity of sodium hydroxide results in the formation of disodium phosphite alone at temperatures below 225°C.; the phosphate is formed at temperatures above 250°C. With only the requisite quantity of sodium hydroxide to form the mono-sodium salt, a mixture of phosphite and hypophosphite is produced at temperatures below 225°C. It was also shown that sodium hypophosphite can be oxidized completely to phosphite or phosphate without the evolution of phosphine, by regulation of the amount of sodium hydroxide and the temperature.

The preparation of phosphorous acid of approximately 100% strength has been patented.[2] The preferred method is to mix phosphorus trichloride and 80–98% phosphorous acid at 86–90°C.; the product contains very little free water. Good yields have also been claimed to result from the hydrolysis of a mist of phosphorus trichloride droplets by steam at 150–200°C. in an inert atmosphere.[100]

A laboratory-scale preparation of this acid[3] has been described, based on the well-established reaction of phosphorus trichloride and water. This procedure has been claimed to give phosphorous acid of high purity, providing the phosphorus trichloride is freshly distilled and is hydrolyzed in an inert atmosphere with cooling.[101] An alternative method is to hydrolyze trialkyl phosphites under conditions such that any trialkyl phosphate is unaffected and may be removed by solvent extraction.[102] Phosphorous acid is also observed among the products of the electrochemical oxidation of white phosphorus at a porous anode,[103] or of the hydrolysis of the lower oxides of phosphorus,[104] though these are not suitable as preparative methods. The oxidation of phosphine by iodine in strong aqueous acid affords pure phosphorous acid in high yield.[134]

Attempts to prepare and isolate the two possible forms of phosphorous acid have occupied the attention of several workers. It was thought[4] that the presence of hydrochloric acid converted the $P(OH)_3$ form of phosphorous acid into the $HP:O(OH)_2$ form; therefore phosphorus trichloride was hydrolyzed in the presence of pyridine which would remove any hydrogen chloride formed. Despite this precaution no $P(OH)_3$ was obtained. Kolitowska[5] claimed that the highest yield of $P(OH)_3$ was obtained by hydrolysis of phosphorus tribromide and the lowest by hydrolysis of phosphorus trichloride. An optimum pH of 5·7, coupled with a low temperature during the hydrolysis, was said to favour a high yield of $P(OH)_3$.

A peroxy derivative[6] of phosphorous acid, having the formula $HP(:O)(OOH)(OH)$, is reported to be made by treatment of sodium hypophosphite solution with ozone.

**Refs. p. 641**

## METAL PHOSPHITES

### Preparation

The method of preparing alkali metal phosphites by addition of alkali to phosphorous acid was studied by Ebert,[7] who found it necessary to cause the acid to react with a solution of the appropriate alkali in ethanol to obtain a 98–99% yield, since the reaction in aqueous solution is hindered by the precipitation of phosphite.

The neutralization of phosphorous acid by sodium hydroxide dissolved in the minimum amount of water[2] gives, in addition to the already known sodium phosphites, two further compounds: $2NaH_2PO_3,H_3PO_3,\frac{1}{2}H_2O$, which dehydrates at 200°C., and $NaH_2PO_3,H_3PO_3$ which melts at 165°C. The existence of these compounds has also been confirmed by measurements of the specific electrical conductivity of the system $Na_2HPO_3$–$H_3PO_3$–$H_2O$.[105,106] Hydrolysis of phosphorus halides under alkaline, and mildly alkaline, conditions has been studied by Thilo and Heinz.[8] Chromatographic and iodometric analyses show that sodium phosphite is only one of a number of products. These authors obtained no evidence for the existence of $P(OH)_3$ and attributed the anomalous behaviour of the sodium bicarbonate hydrolysis to the formation of sodium pyrophosphite, $Na_2H_2P_2O_5$, the amount of which increases as more $PCl_3$ is added to the bicarbonate solution. A study of the $Li_2HPO_3$–$H_3PO_3$–$H_2O$ system at 25° disclosed three congruent phosphites, $LiH_2PO_3$, $LiH_2PO_3,H_3PO_3$ and $2LiH_2PO_3,H_3PO_3$, the last two compounds being white crystals, very soluble in water.[107]

The ternary system $K_2HPO_3$–$H_3PO_3$–$H_2O$[79] at 25°C. was studied by the solubility method. The phase diagram shows the existence of two acid phosphites with the formulæ $2KH_2PO_3,H_3PO_3$ and $KH_2PO_3,H_3PO_3$. These compounds have been isolated and their composition verified by *X*-ray and chemical analysis. A later study of the specific electrical conductivity of the system $K_2HPO_3$–$H_3PO_3$–$H_2O$ confirmed the existence of these compounds, and disclosed in addition the compound $KH_2PO_3,2H_3PO_3$. The formation of the more acid phosphites increases with rising concentration, temperature having a negligible effect. $KH_2PO_3,H_3PO_3$ is the most, and $KH_2PO_3,2H_3PO_3$ the least stable of the series.[108] A study of the rubidium and cæsium systems showed the presence of the series $MH_2PO_3,H_3PO_3$, $MH_2PO_3,2H_3PO_3$ (most stable), $2MH_2PO_3,H_3PO_3$ and $4MH_2PO_3,H_3PO_3$ (least stable): $(M = Rb, Cs)$. In each case the rubidium compound was more stable than the cæsium compound.[109]

In a study of the copper phosphites Nassler[80] characterized copper(II) phosphite dihydrate, $CuHPO_3,2H_2O$, copper(II) hydrogen phosphite, $Cu(H_2PO_3)_2$, copper(II) tetraminophosphite, $Cu(NH_3)_4HPO_3$, its dihydrate, and the di- and tri-hydrates of copper(II) pyridine phosphite, $CuHPO_3,2C_5H_5N,2$ or $3H_2O$. Pictorial representations of the *X*-ray powder photographs of these compounds are included in the paper. The thermal decompositions[81] of these compounds have been described and the results discussed in terms of loss of water, ammonia and pyridine.

Alkaline earth phosphites[9] are prepared by adding 82% of the calculated amount of carbonate or hydroxide to molten phosphorous acid at 80°C., stirring the mixture for several hours in ethanol or acetone in order to remove excess moisture and drying at 60°C. Good yields of pure products are reported. A similar method[13] is used to prepare ammonium phosphite which is also formed, together with mono- and diammonium phosphates, in the hydrolysis of $P_4N_6$.

Methods for preparing gallium[10–11] and thallium[12–13] phosphites have been described; there is some difference of opinion about the degree of hydration of $GaH_3(PO_3)_2$. Thallous phosphite is obtained on neutralizing phosphorous acid with aqueous thallous carbonate to the methyl-orange end point and evaporating the solution over phosphorus pentoxide *in vacuo*. The resultant oily product is dried by ethanol to give an amorphous, very hygroscopic solid, m.p. 30–50°C. A technique similar to that employed in the preparation of the alkaline earth phosphites is claimed to give a product of high purity. Normal thallium phosphite is a white crystalline substance which is stable in air up to 115°C.; its solubility at 20°C. is 23·80 g. per 100 g. of water. Acid phosphites, $TlH_2PO_3$ and $2TlH_2PO_3,H_3PO_3$, have been identified. Both are white compounds, congruently soluble in water. The compound $TlH_2PO_3,H_3PO_3$ was sought for, but could not be detected.[110]

Stannous phosphite[82] is prepared by adding tin(II) oxide to molten phosphorous acid. Water is added to the viscous solution; this results in the precipitation of transparent crystals which are washed with dry ethanol and dried in a vacuum.

A crystalline germanium phosphite,[14] $GeHPO_3$, has been observed as one of the products of the reduction of a solution of germanium dioxide in hydrochloric or hydrobromic acid with hypophosphorous acid.

Red-brown crystals of samarium phosphite[15] are prepared by metathesis of samarium chloride and a phosphite.

Rosenheim[16] drew attention to the similarity in crystal structure between complex phosphites and pyrophosphates, as for example in the complex dialkali uranium phosphites $R_2[UO_2(HPO_3)_2]$, which were similar to dialkali uranium pyrophosphates $R_2[UO_2(P_2O_7)]$; the analogy was, however, lacking with bivalent metal salts. A number of complex metal phosphites, including those of uranium, chromium, iron, cobalt and nickel, were prepared from solutions of the dialkali phosphite and the appropriate metal salt.

Addition[17] compounds are formed when hydrogen chloride is passed over dry phosphites; $CdHPO_3,2HCl$ and $PbHPO_3,2HCl$ have been prepared by this method.

A number of chromium phosphites have been reported. When phosphite ions[18] react in aqueous solution with $Cr^{++}$ cations, three types of compound are formed with Cr/P ratios of 1:1, 1:2 and 1:3. $CrHPO_3,H_2O$, $(NH_4)_2[Cr(HPO_3)_2],3H_2O$, $(NH_4)_2[Cr(HPO_3)_2]$ and $(NH_4)_4[Cr(HPO_3)_3],5H_2O$ have all been prepared and shown to be stable in air and slightly soluble in water. Chromic phosphite[19] is produced when sodium dichromate and phosphorous acid are mixed with a solution of alkali or ammonium sulphite at pH 6·2.

Triphosphitochromic acid[20, 83] may be prepared by dissolving chromium phosphite or chromium hydroxide in boiling aqueous phosphorous acid, followed by crystallization of the product. The proposed structure of the acid is shown in Fig. 1.

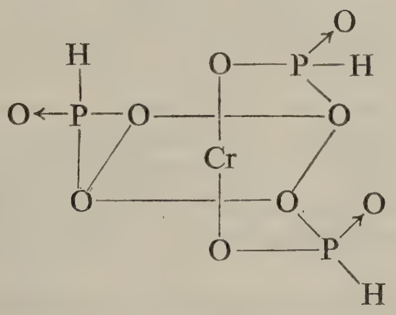

FIG. 1.—Proposed structure of triphosphitochromic acid

Its solubility in water and methanol at 15°C. is 11·70 g. per 100 g. and 3·82 g. per 100 g. solvent respectively. The density of the decahydrate at 20°C. is 2·03 g./c.c.; it is paramagnetic ($\chi = +7{\cdot}8 \times 10^{-3}$ at 20°C.) with a magnetic moment $\mu_{\text{eff}} = 3{\cdot}43$ which corresponds approximately to three unpaired electrons. The values of the pH after the addition of 0·5, 1·5 and 2·5 equivalents of alkali were used to calculate the dissociation constants:

$$pK_1 = 2{\cdot}65 \qquad K_1 = 3 \times 10^{-3}$$
$$pK_2 = 5{\cdot}42 \qquad K_2 = 4 \times 10^{-6}$$
$$pK_3 = 6{\cdot}44 \qquad K_3 = 4 \times 10^{-7}$$

The decahydrate was shown to lose ten molecules of water at 40°C. As the acid has a co-ordination number of six and three dibasic ligands it might be expected to be optically active. This has been confirmed by preparing the (+) tri-*d*-strychnine salt which has a molecular rotation of $[\alpha]^{M}_{Hg} = +420°$.

Aqueous ammonium triphosphitochromite shows optical density maxima at 435 and 590 mμ; this property has been used in estimating the instability constant which is $3{\cdot}4 \times 10^{-11}$. Ammonium and sodium triphosphitochromites are made by dissolving the bisphosphitochromites[16] in a solution of the alkali phosphites. Other triphosphitochromites can be prepared by metathesis from solutions of the sodium salt and the following cations: $Ba^{2+}$, $Cu^{2+}$, $Ca^{2+}$, $Sr^{2+}$, $Mg^{2+}$, $Zr^{2+}$, $Cd^{2+}$, $Hg^{2+}$, $Hg_2^{2+}$, $Al^{3+}$, $Ce^{3+}$, $Tl^{3+}$, $Sn^{2+}$, $Pb^{2+}$, $Cr^{3+}$, $UO_2^{2+}$, $Mn^{2+}$, $Fe^{2+}$, $Fe^{3+}$, $Co^{2+}$ and $Ni^{2+}$. The chromium salt is identical with chromium phosphite, $Cr_2(HPO_3)_3,7H_2O$.

A study of the system vanadium–phosphite[84] in water and acetic acid showed the existence of compounds with V:P mol. ratios of 2:3 and 1:2. These compounds have been isolated as $V_2(HPO_3)_3,7H_2O$ and $H[V(HPO_3)_2],3H_2O$.

The simple phosphite is prepared by mixing aqueous solutions of vanadium(III) perchlorate and ammonium phosphite, whilst the reaction of vanadium(III) acetate and phosphorous acid in 90% acetic acid produces the complex phosphite. Some properties of these compounds are tabulated below.

*Table I.—Properties of Vanadium Phosphites at* 20°*C.*

| Compound | Density g./c.c. | Magnetic moment $\mu_{eff}$B.M. | Solubility in water mol./l. |
|---|---|---|---|
| $V_2(HPO_3)_3,7H_2O$ | 1·89 | — | $<10^{-5}$ |
| $H[V(HPO_3)_2],3H_2O$ | 2·07 | 2·91 | $\sim10^{-3}$ |

The complex salt dissolved in excess phosphorous acid shows an absorption maximum at 685 mμ. A later study revealed the existence of complexes formed in solution with V:P mol. ratios of 1:1 and 1:2. The compound $VHPO_3,H_2O$ was isolated as pink-violet crystals insoluble in water or organic solvents, and slightly soluble in phosphorous acid or alkali metal phosphites. It was very sensitive to oxidation by traces of atmospheric oxygen.[111]

The reaction between anhydrous manganese(III) acetate[84] and a concentrated methanol solution of phosphorous acid produces a complex manganese salt, $H[Mn(HPO_3)_2],3H_2O$. Crystals of this compound have a density of 2·95 g./c.c. at 20°C. and a solubility in methanol of $10^{-4}$ mol./l. at 20°C. A solution of the compound in 0·5 molar methanolic phosphorous acid showed an absorption maximum at 500 mμ.

A series of iron phosphites has been prepared and examined.[85] The salts are mostly prepared from phosphorous acid and ferric nitrate phosphite, which in its turn is prepared from anhydrous ferric nitrate and phosphorous acid. The properties of the compounds prepared are given in Table II.

The existence of the complex ions $Fe(H_2PO_3)_n^{(3-n)+}$ ($n=1$ or 2) has been demonstrated. The stepwise instability constants of $Fe(H_2PO_3)_2^+$ (corrected to zero ionic strength) are $10^{-5}$ and $6{\cdot}7 \times 10^{-3}$ respectively.[112]

Nickel phosphite, $NiHPO_3,2H_2O$, and cobalt phosphite, $CoHPO_3,2H_2O$, have been described. They are sparingly soluble, and have an inverse temperature–solubility relationship (solubilities $5{\cdot}1 \times 10^{-3}$ and $2{\cdot}2 \times 10^{-3}$ mol./l. at 25°C., and $3{\cdot}0 \times 10^{-3}$ and $1{\cdot}6 \times 10^{-3}$ mol./l. at 85°C. respectively), probably due to the decomposition of complex ions.[113]

Complex platinum phosphites[21] are prepared by heating together potassium platinic chloride and phosphorous acid in a little water; compounds of the type

$Pt[P(OH)_3]_2[P(OH)_2O]_2$ and $Pt[P(OH)_3]_4Cl_2$ are produced after addition of alcohol.

### Reactions of Phosphites and Phosphorous Acid

The use of paper chromatography for the separation of phosphorus-containing anions[22-4] has assisted in identifying the products of the thermal decomposition of sodium phosphite.

*Table II.—Properties of Iron(III) Phosphites at 20°C.*

| Compound | Density g./c.c. | Magnetic moment $\mu_{eff}$,B.M. | Solubility mol./l. | |
|---|---|---|---|---|
| | | | Water | Methanol |
| $[FeHPO_3]NO_3$ | 1·99 | 5·89 | $7{\cdot}1\times10^{-5}$ | $2\times10^{-6}$ |
| $[FeHPO_3]Cl,6H_2O$ | 1·91 | — | $3{\cdot}0\times10^{-5}$ | $1\times10^{-6}$ |
| $Fe_2(HPO_3)_3$ | 2·40 | — | (a) | — |
| $Fe_2(HPO_3)_3,7H_2O$ | 2·27 | 5·83(b) | (a) | $5\times10^{-7}$ |
| $Fe_2(HPO_3)_3,9H_2O$ | 2·21 | — | (a) | — |
| $H[Fe(HPO_3)_2],3H_2O$ | 2·37 | 5·80 | (a) | $1{\cdot}17\times10^{-3}$ |
| $Fe(H_2PO_3)_3,H_2O$ | 2·38 | 5·81 | (a) | — |

[a] Hydrolyses.
[b] Calculated for one iron atom.

The dehydration of phosphorous acid or its salts does not lead to chain polyanions as considerable breaking or rearranging of the P–H bonds present in the phosphites occurs. There is no definite evidence to show the existence of anything more complex than pyrophosphite. Attempts to dehydrate beyond the pyrophosphite stage have resulted in the elimination of phosphine or hydrogen.

The results of a systematic examination[86] of the decomposition temperatures of various phosphites of the form $M^{I}_{2}HPO_3$ in air are given in Table III.

*Table III.—Decomposition Temperatures of Metal Phosphites in Air*

| | Temp. °C. |
|---|---|
| $Li_2HPO_3,2H_2O$ | 344 |
| $Na_2HPO_3,5H_2O$ | 292 |
| $K_2HPO_3,\frac{2}{3}H_2O$ | 250 |
| $Rb_2HPO_3$ | 350–400 |
| $Cs_2HPO_3,2{\cdot}5H_2O$ | 320 |
| $BeHPO_3,H_2O$ | ~400 |
| $MgHPO_3,5H_2O$ | 350 |
| $CaHPO_3,H_2O$ | 375 |
| $SrHPO_3,H_2O$ | 330 |
| $BaHPO_3$ | 475 |
| $ZrHPO_3,2H_2O$ | 255 |
| $CdHPO_3$ | 200 |
| $SnHPO_3$ | 320 |
| $PbHPO_3$ | 300 |
| $Tl_2HPO_3$ | 350 |

The products obtained after limited heating are never completely soluble in water, a result also noted by Ebel *et al.*[25] with disodium phosphite. Infra-red evidence shows that during heating the P–H bond disappears, but there is some evidence for the formation of the P–P bond.

Cæsium phosphite, $Cs_2HPO_3$, is the only phosphite for which the expected course of reaction, oxidation to phosphate followed by condensation to pyrophosphate, is largely followed. In the case of other phosphites radicals formed by the primary fission of P–H bonds rearrange or eliminate hydrogen or water. Certain hydrates eliminate water, passing through a series of intermediate hydrates before undergoing oxidative degradation.

The hydrogen phosphites,[86] of formula $M^{I}H(HPO_3)$ or $M^{II}H_2(HPO_3)_2$, give pyrophosphites on heating accompanied, or followed, by oxidative breakdown. The hydrated salts lose their water of crystallization before breakdown. Only lithium, sodium and strontium phosphites give well defined pyrophosphites. The temperatures at which the various hydrogen phosphites condense and then oxidize are given in Table IV.

*Table IV.—Decomposition Temperatures of Metal Hydrogen Phosphites in Air*

| | Temp. of condensation to pyrophosphite °C. | Temp. of breakdown °C. |
|---|---|---|
| $LiH_2PO_3$ | 205 | >300 |
| $NaH_2PO_3,2{\cdot}5H_2O$ | 158 | 330 |
| $KH_2PO_3$ | 180–200 | ~200 |
| $RbH_2PO_3$ | 220 | ~230 |
| $CsH_2PO_3$ | 280 | ~300 |
| $MgH_2(HPO_3)_2,3{\cdot}5H_2O$ | 230 | 250 |
| $CaH_2(HPO_3)_2,6H_2O$ | ~200 | 360 |
| $SrH_2(HPO_3)_2$ | 223 | 370 |
| $BaH_2(HPO_3)_2$ | 230 | ~250 |

A study of ammonium dihydrogen phosphite[87] shows that it decomposes to the pyrophosphite only when calcined barium oxide is present to remove the water liberated. Sodium acid phosphite, $NaH_3(HPO_3)_2$, if heated to 130°C. gives an acid pyrophosphite $NaH(H_2P_2O_5)$. Further heating to about 190° leads to a complex decomposition.

The transformations which take place when disodium phosphite is heated in the absence of oxygen have been described.[88] The author postulated an autoxidation–reduction above 400°C., $8P^{3+}H^{+} \rightarrow 4H_2 + P^{3-} + 7P^{5+}$. In the presence of alkali hydroxides this reaction is modified, since there is no autoreduction and up to 75% of phosphate is formed. The product on heating a mixture of monosodium phosphite and disodium phosphate dodecahydrate is $Na_3(HP_2O_6)$. The pyrolytic oxidation of phosphites has been investigated by Kolitowska.[26] When the disodium salt is heated in the range 300–400°C. in the presence of phosphoric acid[114] phosphine is evolved and acid sodium phosphate, which in turn condenses to polyphosphates, is formed. On boiling sodium phosphites with 85% aqueous sodium hydroxide, hydrogen is evolved[115–6] and orthophosphate is formed. Under milder alkaline conditions with trisodium phosphate,[117] sodium pyrophosphate is the product. In another study, a number of metal phosphites, $M_2(I)HPO_3$, $M(II)HPO_3$ and $M(I)H_2PO_3$, were heated at 200–475°. The normal phosphites decomposed to coloured products of uncertain composition in which the infra-red P–H stretching absorption had vanished, but which exhibited a reduced oxidation equivalent against acid Ce(IV), and hence might contain P–P bonded material. Acid phosphates dehydrated smoothly to pyrophosphites, but thereafter breakdown of the P–H structure occurred. Very acid salts such as $NaH_2PO_3,H_3PO_3$ also gave pyrophosphite, but then lost phosphorous acid by volatilization.[135] A mixture of disodium phosphite and iodine heated in a sealed tube at 180°C. gives acid sodium pyrophosphite and acid sodium hypophosphate, together with an unidentified phosphite. Analysis[27] of a solution of the product which is obtained by heating a mixture of disodium phosphite and a silver halide at 380°C. shows that it contains sodium trimetaphosphate, sodium triphosphate, metaphosphoric acid and the appropriate halogen acid.

Sodium phosphite reacts with sulphur[89] in an inert atmosphere to produce a mixture which contains monothiopyrophosphate. This may be separated by selective precipitation of the lead salt.

Sodium hypophosphate[90] is formed when sodium phosphite is made to react with lithium hydride at 330°C. under a nitrogen atmosphere.

A fluorine-substituted phosphorous acid[91] is produced by the interaction of phosphorous and hydrofluoric acids, $H_3PO_3 + 4HF \rightarrow HPF_4 + 3H_2O$. The total water content of the reaction mixture should not exceed 10% by weight.

Thermal decomposition of phosphorous acid in liquid medium[28] was shown to proceed via the following reactions: $4H_3PO_3 \rightarrow 3H_3PO_4 + PH_3$ and $H_3PO_3 + H_2O \rightarrow H_3PO_4 + H_2$ in the temperature range 275–350°. Below 325°C. the composition of the evolved gases depends on the concentration of the solutions used and is independent of time. However when the duration exceeds fifteen hours at above 325°C. a secondary reaction sets in which decreases the proportion of phosphine. With concentrations below 50% of phosphorous acid nearly pure hydrogen is evolved, whilst above this concentration the phosphine content of the gases increases with increasing temperature. Bushmakin and Frost[29] confirmed these results and postulated that the reaction $PH_3 + 4H_2O \rightarrow H_3PO_4 + 4H_2$ takes place when the concentration of phosphorous acid is high.

More recent work on heating phosphorous acid[86] in a vacuum has shown that pyrophosphorous acid is initially formed. Decomposition in the presence of small partial pressures of water vapour leads to the formation of some phosphine, and red material comprising substantially phosphorus and pyrophosphoric acid. The proportions of these components are dependent on the temperature and time of heating. It was also noted[30] that the oxidation is catalyzed by the presence of colloidal platinum, silver and copper.

The reaction between phosphorous acid and iodine in aqueous solution has attracted the attention of a number of workers.[31–3] The work of Mitchell was reported in Mellor, VIII, 906. The system was re-investigated by Berthoud and Berger,[31] who found no need to postulate the existence of two forms of acid to account for the reaction. Nylén's investigations show that in weakly acid media (pH 3·2–6·8) the reaction is much faster than in strongly acid media and proceeds between $HPO_3^{--}$ and iodine. If iodine reacts with $H_2PO_3^-$ its specific rate is many times smaller than that with $HPO_3^{--}$. Iodine and $I_3^-$ react with $HPO_3^{--}$, the specific rate of the former being 1000 times that of the latter. Nylén also thought that the reaction is not subject to general acid catalysis, a view not supported by Griffith *et al.*,[34] who determined the catalytic coefficients of a few moderately strong acids. They concurred with the majority of Nylén's findings, but doubted whether the slow reaction between $HPO_3^{--}$ and $I_3^-$ could be detected. Similar reasoning to that of Nylén has been used by several authors to account for the mechanism of oxidation of phosphites with chlorine and bromine.

Blaser and Matei[35] showed that nitric acid free from oxides of nitrogen has no action on phosphorous acid. If, however, these oxides are present,[36] oxidation to phosphoric acid is rapid when the phosphorous acid concentration is greater than 44%. Other authors[37] consider this method to be unpractical for use on a commercial scale, because of the large quantities of nitric acid required.

The rate of oxidation of phosphorous acid by chromates[38] is more rapid in the presence of perchloric acid than in the presence of sulphuric acid or phosphoric acid.

The rate is much lower in acetate buffers, where $HCrO_4^-$ is the oxidizing species, and the reaction follows a complex rate law. The reaction is inhibited by chloride ion, which forms $CrO_3Cl^-$.[118] Oxidation of phosphite by permanganate, on the other hand, can be catalyzed either by 0·01% $OsO_4$, or by a 5% solution of Ni(II), Co(II), Cu(II) and $(NH_4)_2MoO_4$, an observation which has been applied to the analysis of phosphites.[101] Phosphite is also oxidized rapidly by persulphates. In neutral solutions the kinetics follow the rate law:

$$-\mathrm{d}(S_2O_8{}^{2-})/\mathrm{d}t = k_1+k_2[\textstyle\sum H_3PO_3]^{1/2}[S_2O_8{}^{-2}]^{3/2}$$

The oxidation is a chain reaction, propagated by the species $SO_4{}^-$, and initiated by the two parallel reactions:

$$S_2O_8{}^{2-} \rightarrow 2SO_4{}^-$$

and

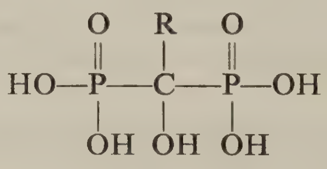
$$S_2O_8{}^{2-}+H_2PO_3{}^- \rightarrow SO_4{}^-+HSO_4{}^-+HPO_3{}^-(\text{ref.}^{119}).$$

The autoxidation of phosphorous acid[39] is induced by ozone and $O_2F$.

Several workers have reported on the anodic oxidation of phosphites. Lead anodes have been claimed as the most efficient, the sole detectable product being orthophosphate.[120] On a platinum anode the optimum conditions are 1–1·5 N. NaOH, 20°, c.d. 4–6 amp./dm.$^2$, when phosphite yields 30–40% orthophosphate, while hypophosphite is unaffected.[121] On palladium the rate-determining step of the oxidation is an initial catalytic dehydrogenation and not, as with hypophosphite, the ionization of the atomic hydrogen thus formed.[122]

Pyrophosphorous acid[40] is produced when phosphorus trichloride or tribromide reacts with phosphorous acid. The reaction $PX_3+5H_3PO_3 \leftrightarrows 3H_4P_2O_5+3HX$ is reversible and its rate appears to be governed by the solubility of the halogen acid in phosphorous acid.

The reaction of phosphorous acid[92–3] with organic acids, acid chlorides and anhydrides has been the subject of several patents. Compounds of the type



$$HO{-}\overset{O}{\overset{\|}{P}}(OH){-}\overset{R}{\overset{|}{C}}(OH){-}\overset{O}{\overset{\|}{P}}(OH){-}OH$$

are formed by refluxing the reactants. A simple equation cannot be written for the reaction which is very sensitive to temperature. Optimum yields are obtained if 1 g. mol. of acid reacts with 1·1 g. moles of acylating agent. The product from acetic anhydride is very soluble in water but may be recrystallized from glacial acetic acid. Anhydrous sodium formate, however, reacts with sodium phosphite at 370°C. according to the equation:

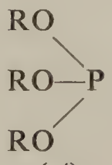
$$Na_2HPO_3+HCOONa \rightarrow H_2+CO+Na_3PO_4{}^{123}$$

Contrary to previous statements, good yields of alkyl iodides can be obtained by the action of alcohols and iodine upon phosphorous acid.[124]

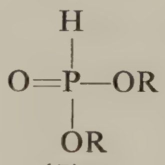
Dioxan and phosphorous acid[41] form a eutectic containing 52 mol.-% of acid with a freezing point of $-12$°C.; there is no evidence of interaction between the components.

## Structural and Physical Properties

The structure of phosphorous acid and the phosphites has attracted considerable interest because of the two possible alternatives:



and



$$O{=}\overset{H}{\overset{|}{P}}(OR){-}OR$$

(*A*) (*B*)

where R = hydrogen or an alkali metal.

*X*-Ray structure studies of crystalline phosphorous acid[42] and magnesium phosphite hexahydrate $MgHPO_3,6H_2O$ showed that the solids exist in form (*B*). Magnesium phosphite is isomorphous with magnesium sulphite hexahydrate $MgSO_3,6H_2O$ in which the positions of anions, cations and water molecules are probably very similar.

Further evidence for the structure of phosphorous acid and its salts is presented by Stelling[44] and Nylén.[45] The position of the absorption edge of the *K* line in the *X*-ray spectrum of phosphorus compounds has been found to depend on the number and type of the atoms connected directly to the phosphorus atom. The absorption edge for triply connected phosphorus atoms lies near 5·77 A. and for quadruply connected atoms near 5·75 A. According to evidence from this source it appears that phosphorous acid and its salts have a phosphorus atom connected to four neighbouring atoms.

The Raman spectra of phosphorous acid and its salts and esters[46–8] suggest a structure in the form of a distorted tetrahedron with the phosphorus atom connected to one hydrogen and three oxygen atoms. Tsuboi[49] obtained infra-red spectra of the phosphite ion both in the solid state and in solution. He assigned 980 and 1100 cm.$^{-1}$ as corresponding to $PO_3^{--}$ stretching vibrations and considered these to be characteristic of the $PO_3^{--}$ group. The nuclear magnetic resonance spectrum of phosphorous acid[50] also corresponds to one hydrogen atom being directly attached to the phosphorus atom in all phosphites except the triesters. The structural interpretations of the ultra-violet absorption spectra[51–4] of phosphites agree with the conclusions derived from other physico-chemical methods.

The literature on chemical evidence for the existence of one or the other form of phosphite has been reviewed by Nylén.[45] Arbuzov[55] used the formation of addition compounds with cuprous halides to demonstrate which of the phosphites has a triply connected phosphorus atom; the results agree with physico-chemical studies described above. Recent papers on this topic are by Voigt,[56] who attempted to prepare the form of phosphorous acid depicted as (*A*) in the diagram, and Kolitowska,[57] who stated that under identical conditions mild oxidants convert the 'enol' form of the acid to hypophosphoric acid and the 'keto' form to phosphoric acid.

Cryoscopic and molecular magnetic susceptibility studies of phosphorous acid dissolved in acetic acid suggest that in this solvent a dimeric form of $P(OH)_3$ is present, while in aqueous solution the $HPO(OH)_2$ form exists, also probably as a dimer.[125] The rate of exchange of $^{18}O$ between water and $H_3PO_3$ increases continuously with increasing acidity from pH 10 to 9·4 N. perchloric acid. Rate constants for exchange between water and various ionic species present were derived, but it was not possible to distinguish between several possible exchange mechanisms.[126]

The diameter of the $[H_2PO_3^-]$ ion in aqueous solutions of monosodium or potassium phosphite at 25° is 2·24 A.,[127] while that of the $[HPO_3^{--}]$ ion in solutions of the neutral salt is 2·66–3·04 A., the value decreasing with increasing dilution over the range 1 g. equiv./10–100 moles $H_2O$.[128]

Recalculation and new determinations of the ionization constants have led to a variety of results depending on the temperature and concentration of the solutions. Some of the results are given in Table V.

In highly acid solution phosphorous acid behaves as a very weak base ($[H_3PO_3][H^+]/[H_4PO_3^+] = 10^5$). The third dissociation constant, $[PO_3^{3-}][H^+]/[HPO_3^{2-}] = < 10^{-14}$. The same workers observed the following ionic mobilities: $l_{H_2PO_3^-} = 43{\cdot}4$; $l_{1/2HPO_3^{2-}} = 47{\cdot}8$; $l_{NaHPO_3^-} = 41{\cdot}5$; $l_{KHPO_3^-} = 39{\cdot}6$, while the instability constants of complexes at zero ionic strength are $KH_2PO_3$ 0·18; $NaH_2PO_3$ 0·11; $KHPO_3^-$ 0·16; $NaHPO_3^-$ 0·09.[129]

The protonation of phosphorous acid in aqueous sulphuric acid has been studied by proton magnetic resonance, though the p*Ka* values derived were not consistent with the scales of Hammett function derived for other types of base. Results could be interpreted in terms of a two-stage protonation:

$$H{-}O{-}H\cdots O{=}PH(OH)_2 \xrightarrow{H^+} H_2\overset{+}{O}{-}H\cdots O{=}PH(OH)_2 \rightarrow H_3\overset{+}{O} + H\overset{+}{P}(OH)_3 \text{ }^{136}$$

**Refs. p. 641**

In methanol, phosphorous acid behaves as a monobasic acid with a dissociation constant $k_1 = 3{\cdot}30 \times 10^{-5}$. The mobility of the dihydrophosphite ion in this medium, $l_{H_2PO_3^-} = 43{\cdot}0$.[130]

Using Kolthoff's data the free energies of formation of the ions have been calculated[59] to be: $H_2PO_3^-$ $-202{\cdot}35$ kcal. and $HPO_3^{--}$ $-194{\cdot}0$ kcal.

These values lead to the following potentials for the phosphorous–phosphoric acid couple:

$$H_2O + H_3PO_3 \rightleftharpoons H_3PO_4 + 2H^+ + 2e^- \qquad E^\circ = 0{\cdot}276 \text{ volts}$$
$$3OH^- + HPO_3^{--} \rightleftharpoons PO_4^{---} + 2H_2O + 2e^- \qquad E^\circ_\beta = 1{\cdot}12$$

The estimated entropies of $H_3PO_3$ and $H_2PO_3^-$ are 40 and 19 calories per degree respectively.

*Table V.—Ionization Constants of Phosphorous Acid*

| Temp. °C. | $K_1 \times 10^2$ | Solution concentration (molarity) | $K_2 \times 10^7$ | Solution concentration (molarity or ionic strength) | Reference |
|---|---|---|---|---|---|
| 0 | 0·97 | $5 \times 10^{-2}$ | 6·6 | $5 \times 10^{-2}$ ($\mu = 1$) | 32 |
| 17 | — | — | 82·5–179 | — | 94 |
| 18 | 1·6–6·2 | $10^{-3} - 10^{-1}$ | 2 | $\mu = 0$ | 95 |
| 18 | 1 | — | 2·6 | — | 96 |
| 20 | — | — | 8 | $\mu = 1{\cdot}15$ | 34 |
| 24 | — | — | 4·7 | — | 94 |
| 25 | 5 | — | 240 | — | 97 |
| 25 | 2–3 | $3 \times 10^{-2} - 10^{2}$ | 1·5 | $3 \times 10^{-2} - 10^{-2}$ | 58 |
| 30 | — | — | 5·9 | $\mu = 0{\cdot}4$ | 34 |
| — | ~6 | — | ~2 | $\mu = 0$ | 129 |

The conductivities of the system $Na_2HPO_3$–$H_3PO_3$–$H_2O$ have been measured[98] at 25, 35 and 45°C.

The heat of formation of sodium dihydrogen phosphite is $\Delta H^\circ_{298} = -338{\cdot}0$ kcal./mole[131] and of the disodium salt $\Delta H^\circ_{298} = -684{\cdot}2$ kcal./mole.[132] The heats of solution are as follows:

| | |
|---|---|
| $Na_2HPO_3,5H_2O$ | $\Delta H_{291} = +4{\cdot}54$ kcal./mole |
| $NaH_2PO_3$ | $\Delta H_{291} = -0{\cdot}90$ kcal./mole |
| $NaH_2PO_3,2{\cdot}5H_2O$ | $\Delta H_{291} = +5{\cdot}26$ kcal./mole |

All these heats of solution were determined at the concentration of one mole of crystals in 550 moles of water.

The solubility of disodium hypophosphite[133] in water at 25°C. has been found to be 38·4 g./100 g. solution. This determination was made in connection with an investigation of the system $Na_2HPO_3$–$NaH_2PO_2$–$H_2O$.

## Uses

Phosphorous acid and phosphites have been recommended as stabilizers for plastics. Incorporation of phosphites into several vinyl plastics[60–4] is claimed to stabilize them against heat and ultra-violet light; furthermore, it was found that washing these plastics with an acidified aqueous solution of phosphite removed iron impurities. In a review[65] of the action of polyvinyl chloride stabilizers it is suggested that evolution of HCl, with its catalytic action in degrading the polymer chain, forming carbonyl groups and conjugated double bonds, is followed by oxidation to the peroxide.

Experiments showed that when 2% of a basic lead phosphite is present in the polyvinyl chloride, evolution of hydrogen chloride, even on heating to 175°, is only slight and maximum retardation of opalescence occurs. Polyamides are also stabilized[66] by the addition of lead phosphite. Mixtures of lead phosphite[99] and boron compounds are also recommended as polyvinyl chloride stabilizers.

Lead phosphite has been used[67] in conjunction with sulphur, zinc oxide and accelerators when co-vulcanizing butyl rubber with a highly unsaturated rubber. The presence of the lead salt prevents blistering, porosity, inhomogeneity, delamination, cracking and peeling. The addition of up to 20% w/w of lead phosphite[68] to fluorine-containing elastomers increases the tensile strength but does not affect the percentage elongation. Phosphites are claimed[69] to be superior to other catalysts in condensing polyamides, 3% of phosphorous acid being optimal.

Corrosion by phosphorous acid vapours,[70] used to catalyze reactions such as the ethylation of benzene with ethane, can be prevented by passing the hot products over alkaline earth carbonate. The treatment of metal surfaces with phosphites to prevent rusting has been described in a number of patents. Kebrich[71] and Chiaudano[72] gave particulars of the use of basic lead phosphite as a pigment; details of the preparation of di- and mono-basic lead phosphites are given in Kebrich's patent. Treatment of the metal surface with mixtures containing phosphorous acid is claimed[73-5] to give good protection against rust formation and in one instance to improve lacquer adhesion of ferrous metal.[75] The addition of phosphites to boiler water[78] reduces the oxygen content and in doing so forms phosphates which are useful for the control of scale.

Various metals, including aluminium, copper, brass, cadmium and nickel, can be electro-polished anodically in a bath of 60–100% $H_3PO_3$ at 20–100°C. with an anodic current density of 5–100 amp./sq. dm.; to electro-polish zinc about 2% of hydrofluoric acid (40% w/w) must be added to 88% phosphorous acid.

A novel use of phosphorous acid[77] is its addition to fish water to prevent the formation of scale in the evaporator when the liquid is being boiled down.

## SECTION XXIII

# HYPOPHOSPHORIC ACID AND THE HYPOPHOSPHATES

BY D. R. PECK

## THE PREPARATION OF HYPOPHOSPHORIC ACID

SEVERAL methods, which give better yields than the oxidation of white phosphorus previously reported (Mellor, VIII, 924), for preparing hypophosphoric acid and hypophosphates have been described.

In an early method[1] red phosphorus (5 g.) was oxidized by 10% bleaching powder solution (1 l), 64% oxidation being obtained. After filtering off the excess phosphorus, calcium hypophosphate and small amounts of calcium ortho-, pyro-, and metaphosphates were precipitated by neutralizing the filtrate with calcium carbonate. Treatment of the precipitate with dilute sulphuric acid gave a dilute solution of hypophosphoric acid.

The phosphorus recovered from the initial filtration was reddish-black in colour and was thought to be a new form of phosphorus. There is, however, very little evidence to support this[2] and the effect appears to be due to the particle size of the phosphorus. The smaller, light-red particles react more quickly with oxidizing agents, leaving behind the larger, darker particles.

A modification of the above procedure has been described[3] in which the oxidation is carried out at 25°C. The hypophosphate is first separated as the calcium salt, $Ca_2P_2O_6,2H_2O$. This is converted to the free acid by reaction with sulphuric acid and then to the tetrasodium salt, $Na_4P_2O_6,10H_2O$. Half the phosphorus is oxidized in the initial reaction and the yield is 16% based on the weight of phosphorus originally taken. This yield can be increased by 15% by oxidation of red phosphorus with an aqueous extract of bleaching powder at 12–15°, or better still, by the use of sodium chlorite containing a small proportion of hypochlorite, when $Na_4P_2O_6,10H_2O$ can be isolated.[100]

A similar reaction in which red phosphorus is stirred with sodium hypochlorite solution at 5°C. gives a 25% yield of disodium hypophosphate, $Na_2H_2P_2O_6,6H_2O$.[4] Oxidation of red phosphorus with iodine in solution at pH 4·6 to 5·7 gives a 34% yield of hypophosphoric acid.[5]

Strongly alkaline solutions of potassium permanganate or neutral alkaline solutions of hydrogen peroxide oxidize red phosphorus to orthophosphate and hypophosphate.

Yields of up to 40% of disodium hypophosphate, $Na_2H_2P_2O_6,6H_2O$, based on the phosphorus oxidized are obtained when sodium chlorite solution reacts with excess of red phosphorus. The equation given for the reaction is[6]:

$$2P + 2NaClO_2 + 8H_2O \rightarrow Na_2H_2P_2O_6,6H_2O + 2HCl$$

The reaction mixture is reported to contain 42% of hypophosphate, 35% of phosphite, 19% of orthophosphate and 2% of hypophosphite.[7] An apparatus in which the temperature of the reaction can be controlled has been described.[8] This gives slightly higher yields of sodium hypophosphate. The free acid was obtained by ion-exchange from solutions of the disodium ($Na_2H_2P_2O_6,6H_2O$) or the trisodium salt ($Na_3HP_2O_6, 9H_2O$), the latter being the more soluble in water.[8] The free acid may also be prepared by precipitating solutions of the sodium salts with lead acetate solution containing a little acetic acid. The resulting lead salt ($Pb_2P_2O_6$) is suspended in water and hydrogen sulphide is bubbled through the suspension for 7 hr. at 0°C. After removal of the lead sulphide, the filtrate is vacuum-evaporated at 10° to 20°C. under 3–7 mm. until the dihydrate of the acid crystallizes.[9,101]

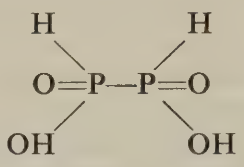
The reaction of an aqueous suspension of red phosphorus with sodium chlorite solution is strongly exothermic. If the temperature of the reaction mixture rises above 50°C., chlorine and chlorine dioxide are evolved and the yield of hypophosphate decreases. The reaction is catalyzed by hydrogen ions and there is usually an induction period on first mixing the reactants. During this period no apparent reaction takes place and the temperature rises but slightly. This may be followed by a sudden and almost explosive stage, particularly if more than 20% of the required amount of sodium chlorite has already been added to the phosphorus suspension. When more than 50 g. of phosphorus is taken initially, the reaction is best carried out by making a 15% wt.-vol. suspension of red phosphorus in 1% hydrochloric acid solution. This is cooled to 10–15°C. and a 25–30% wt.-vol. solution of sodium chlorite is slowly added with vigorous stirring of the reaction mixture, keeping the temperature below 30°C. The $NaClO_2/P$ weight ratio should be about 1·5. At the end of the reaction the excess phosphorus is filtered off, the filtrate is heated to 50° to 60°C. and is carefully adjusted to pH 5·0–5·5 by addition of pellets or a concentrated solution of sodium hydroxide. Any turbidity (due to the presence of iron and calcium) which forms is removed by filtration. On cooling the filtrate to room temperature, crystals of $Na_2H_2P_2O_6,6H_2O$ are quickly deposited. These should be purified from traces of other phosphorus compounds (mainly phosphite) by recrystallizing once or twice from water.

The preparation of hypophosphoric acid by the oxidation of red phosphorus with alkaline solutions of hydrogen peroxide, potassium permanganate, sodium hypobromite or sodium hypochlorite has been described. A similar oxidation occurs with acid solutions of sodium chlorate, sodium bromate or potassium persulphate. All these oxidations form phosphite, phosphate, pyrophosphate and polyphosphates as well as hypophosphate.[10] In addition the $P^5$–O–$P^4$–$P^4$ and $P^4$–$P^3$–$P^4$ anions are formed by the oxidation of red phosphorus by hydrogen peroxide in sodium carbonate solution, although from a medium made alkaline with sodium hydroxide a 23% yield of pure $Na_2H_2P_2O_6,6H_2O$ can be isolated.[102]

The oxidation of white phosphorus with dilute nitric acid in the presence of copper (Mellor, VIII, 925) gives yields of hypophosphoric acid accounting for not more than 15% of the phosphorus oxidized. This reaction has been shown to be violent if much phosphorus is used.[11] It is best carried out by adding the phosphorus in small pieces to a mixture of copper and dilute nitric acid heated to 100°C. It is reported that in addition to hypophosphoric acid the nitric acid oxidation forms acids of pentavalent and trivalent phosphorus, but no phosphorous acid. The oxidizing agent in the system is postulated to be copper nitrate, and this is partly reduced to copper and copper phosphides. The latter are then oxidized to oxy-acids of phosphorus by the excess copper nitrate.[12]

The hydrolysis of a number of phosphorus halides under mild oxidizing conditions yields hypophosphoric acid or its sodium salts in varying proportions with other tri- and penta-valent phosphorus compounds. A 45% yield of hypophosphoric acid is obtained by hydrolyzing diphosphorus tetraiodide and then oxidizing with iodine in solution at pH 5·7. Under similar conditions phosphorus tri-iodide gives a 37% yield of the acid.[13] Hydrolysis of diphosphorus tetraiodide at 0°C., followed by immediate oxidation with 30% hydrogen peroxide solution under alkaline conditions, converts 24% of the phosphorus to hypophosphate. If the oxidation is delayed for 24 hr. the yield falls to 10%. The initial product of the hydrolysis appears to be $P_2(OH)_4$ and this on oxidation yields hypophosphoric acid. The final products include hydrogen iodide, $P_{12}H_6$, phosphine, hypophosphorous, phosphorous and phosphoric acids.[14]

More recent work confirms that the initial product in the hydrolysis of diphosphorus tetraiodide is the acid $P_2(OH)_4$ or $H_4P_2O_4$. The structure of this is as follows:



and it is more stable at pH 7 than in acid or alkaline solution. Oxidation by atmospheric oxygen, or by iodine in acid or alkaline solution readily converts it to hypophosphoric and pyrophosphoric acids.[15] On the basis of the newer nomenclature for the reduced acids of phosphorus, $H_4P_2O_4$ is referred to as $\overset{2}{P}$–$\overset{2}{P}$ acid[16] (see also page 596).

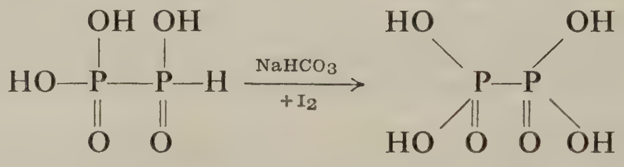
At 20°C. solutions of diphosphorus tetraiodide in carbon disulphide readily absorb oxygen to give phosphorus tri-iodide and the polymeric compound $(P_3I_2O_6)_n$. The reaction may be written:

$$7P_2I_4+6O_2 = 8PI_3+\frac{2}{n}(P_3I_2O_6)_n$$

Hydrolysis of the polymer gives some hypophosphoric acid, together with phosphine and phosphorous and phosphoric acids.[17]

A 55% yield of hypophosphoric acid is obtained by slowly adding phosphorus tribromide to an ice-cold solution of sodium acetate and acetic acid at pH 5·7. The product is then oxidized in the presence of sodium bicarbonate with sufficient 0·10 N. iodine solution to convert 60% of the trivalent phosphorus to the pentavalent form. Orthophosphate and hypophosphate are then precipitated by adding barium nitrate. Hypophosphate is recovered as the silver salt by dissolving the precipitate in dilute phosphoric acid and adding silver nitrate.[18] A similar reaction using phosphorus trichloride gives a 10% yield of hypophosphoric acid.[19]

The mechanism of the hydrolysis of the phosphorus trihalides has been explained in terms of the two isomers of phosphorous acid. The less stable form, $P(OH)_3$,[20] is said to give hypophosphoric acid, whereas the more stable form, $HO.P(OH)_2$, gives phosphoric acid.[21] Phosphorus tribromide is reported[21] to give more of the unstable isomer on hydrolysis. The opposite view, i.e. that hypophosphoric acid is formed by oxidation of the $HO.P(OH)_2$ isomer, has also been used[19] to explain the mechanism. However, it is more likely that the reaction involves the intermediate formation of a lower oxyacid of phosphorus. For example, diphosphorous acid has been isolated from the hydrolysis products of phosphorus tribromide.[22] This acid is readily oxidized by iodine in sodium bicarbonate solution to form hypophosphoric acid:



When phosphorus trichloride vapour is passed into sodium bicarbonate solution at 0°C. the disodium salts of phosphorous and pyrophosphorous acids are formed, together with phosphine and other oxyacids in smaller amounts. The initial product is disodium phosphite and this reacts with more phosphorus trichloride to give disodium pyrophosphite:

$$Na_2HPO_3+PCl_3+2H_2O \rightarrow Na_2H_2P_2O_5+3HCl$$

Smaller amounts of pyrophosphite and larger quantities of the other products are formed by hydrolyzing the trichloride under more alkaline conditions. When the hydrolysis products are oxidized with iodine in sodium bicarbonate solution, the pyrophosphite is oxidized extremely slowly, whereas the diphosphite rapidly forms hypophosphate. The latter is stable under these conditions of oxidation.

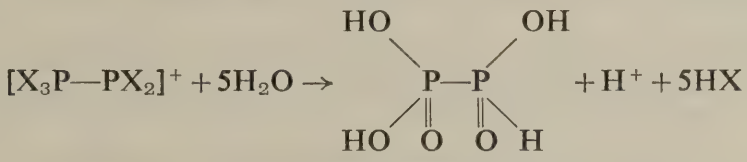
Liquid phosphorus tribromide and sodium carbonate solution at 0°C. react to give much larger quantities of diphosphite, but no pyrophosphite is formed. A similar reaction between sodium bicarbonate solution and phosphorus tri-iodide dissolved in carbon disulphide gives a smaller proportion of diphosphite than in the products obtained from phosphorus tribromide. Again no pyrophosphite is formed.

No evidence was found to indicate the presence of an unstable form of phosphorous acid, $P(OH)_3$, in these reactions. It seems reasonably certain therefore that hypophosphoric acid results from the formation and subsequent oxidation of diphosphorous acid. The experimental observations suggest that P–P bonds are more easily formed as the phosphorus–halogen bond (P–X) becomes less polar. The mechanism can be interpreted in terms of a proton transfer reaction as follows:

$$PX_3 + H^+ \rightarrow [HPX_3]^+ \rightarrow [PX_2]^+ + HX$$

The $PX_2{}^+$ radical then reacts with a further halide molecule to form an intermediate compound which is hydrolyzed by water to form diphosphorous acid.[23]

$$[PX_2]^+ + PX_3 \rightarrow [X_3P—PX_2]^+$$



$$[X_3P—PX_2]^+ + 5H_2O \rightarrow (HO)_2P(O)—P(O)(OH)H + H^+ + 5HX$$

Hypophosphoric acid is also formed by oxidizing diphosphorous acid with iodine in 0·01 N. hydrochloric acid solution, but the oxidation proceeds more slowly than in weakly alkaline solution. Increasing the acidity decreases the yield of hypophosphate and, with concentrations above normal, increasing hydrolysis of the product occurs. The oxidation also decreases in strongly alkaline solutions.

Hypophosphoric and phosphorous acids are formed when diphosphorous acid is decomposed by heating with sodium hydroxide alone:

$$H_4P_2O_5 + H_2O \rightarrow 2H_3PO_3$$
$$H_4P_2O_5 + H_2O \rightarrow H_4P_2O_6 + H_2$$

No phosphine is formed in these reactions and the proportions of the two acids produced are influenced by the sodium hydroxide concentration as shown in Table I.[24]

*Table I.—The Decomposition of Diphosphorous Acid with Concentrated Sodium Hydroxide Solutions*[24]

| Time (hr.) | Temp. °C. | NaOH % | % P as $H_3PO_3$ | % P as $H_4P_2O_6$ |
|---|---|---|---|---|
| 6 | 118 | 30 | 29·7 | 26 |
| 3 | 130 | 40 | 33 | 59·6 |
| 6 | 130 | 40 | 36 | 60 |
| 12 | 130 | 40 | 35·6 | 61 |
| 1 | 160 | 60 | 14·5 | 81 |
| 1 | 160 | 60 | 19·2 | 81 |
| 0·3 | 180–190 | 80 | 11·5 | 84 |

Finely powdered disodium phosphite and excess of lithium hydride when heated at 330°C. in a nitrogen atmosphere form a mixture of phosphorus compounds and lithium nitride. About 30% of the phosphite is converted to hypophosphate. The reactions are given as:

$$
\begin{gathered}
2Na_2HPO_3+2LiH \rightarrow NaPO_2+Na_3PO_4+2Li+2H_2 \\
Na_2HPO_3+7LiH \rightarrow Li_3P+2Li_2O+Na_2O+4H_2 \\
6Li+N_2 \rightarrow 2Li_3N \\
2Na_2HPO_3+2LiH \rightarrow Na_4P_2O_6+2Li+2H_2
\end{gathered}
$$

The last of the above reactions is supposed to proceed by the formation of the free radical $Na_2PO_3\cdot$:

$$Na_2HPO_3+LiH = Na_2PO_3\cdot+Li+H_2$$

This radical can then dimerize to form hypophosphate or disproportionate to orthophosphate or to metaphosphite ($NaPO_2$).[25]

Hydrolysis of diphosphorus tetraiodide, or of the phosphorus sulphides $P_4S_3$, $P_4S_5$ and $P_4S_7$, with hydrogen peroxide in solutions of sodium bicarbonate, carbonate or hydroxide gives 15–30% yields of hypophosphate. The major product is phosphate (30–60%) and minor amounts of phosphite and the $\overset{4}{P}–\overset{3}{P}–\overset{4}{P}$ and $\overset{5}{P}–O–\overset{4}{P}–\overset{4}{P}$ acids are also formed. The reaction with phosphorus pentasulphide is given as[26]:

$$P_4S_7+30H_2O_2+22NaOH \rightarrow Na_4P_2O_6+2Na_2HPO_4+7Na_2SO_4+40H_2O$$

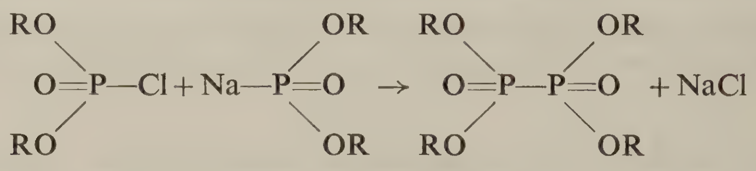
It is reported that at 300°C. a mixture of disodium phosphate and ammonium nitrate gives a product having the formula $Na_4P_2O_6,4H_2O$. Similarly, potassium nitrate and monopotassium phosphate are said to give $K_4P_2O_6,4H_2O$.[27] There is, however, little evidence that these are hypophosphates and the compounds would seem to be either poly- or meta-phosphates.

No exchange of radioactive phosphorus between phosphorous and phosphoric acids according to the mechanism:

$$H_3{}^{32}PO_4+H_3PO_3 \rightleftharpoons H_4{}^{32}PPO_6 \rightleftharpoons H_3PO_4+H_3{}^{32}PO_3$$

was found in acid or alkaline solution. In 5·6 N. HCl the equilibrium constant for the formation of hypophosphoric acid from phosphorous and phosphoric acids is less than $8\times10^{-5}$ l. mole$^{-1}$ at 25°C.[28]

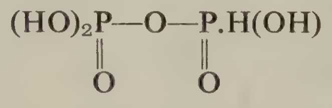
Esters of hypophosphoric acid have been obtained by reaction of the sodium salts of esters of phosphorous acid with phosphorochloridites according to the equation[29]:



The menthyl ester obtained in this way dissociates into menthene and hypophosphoric acid.[30] A general method for preparing tetra-alkyl hypophosphates in 40–70% yield is to cause dialkyl sodium phosphites to react with sulphuryl chloride at 5° to 10°C. according to the equation[31]:

$$2(RO)_2NaPO+SO_2Cl_2 \rightarrow (RO)_2OP.PO(OR)_2+2NaCl+SO_2$$

Isohypophosphoric acid, the isomeric form



$$(HO)_2\underset{\displaystyle O}{\underset{\|}{P}}—O—\underset{\displaystyle O}{\underset{\|}{P}}.H(OH)$$

of the acid has been obtained in 27% yield by neutron bombardment of disodium orthophosphate at low temperature. Smaller amounts of ordinary hypophosphate, pyro- and tripoly-phosphate and some unknown species are also formed.[32]

Isohypophosphates have also been obtained by dehydrating mixtures of phosphoric and phosphorous acids under reduced pressure or by heating mixtures of mono- and di-sodium phosphites at 180°C. *in vacuo*. Trisodium hypophosphate is the main product of the reaction between phosphorus trichloride and phosphorous and phosphoric acids in the absence of added water at 50°C. The reaction mixture is then neutralized with sodium bicarbonate and crystallized[23]:

$$PCl_3 + 3H_3PO_4 + 2H_3PO_3 \rightarrow 3H_3(HP_2O_6) + 3HCl$$

Oxidative hydrolysis of phosphorus tribromide gives some isohypophosphate, but apparently in lower yield than the trichloride reaction with phosphorous and phosphoric acids.[22] However, when both halides are oxidized and hydrolyzed under alkaline conditions, the bromide gives the better yield.[23]

At 150° to 160°C. in the presence of silica gel as catalyst 1 mol. of bromine reacts with 2 mol. of disodium phosphite to give isohypophosphate as the primary product:

$$2Na_2HPO_3 + Br_2 \rightarrow Na_3HP_2O_6 + NaBr + HBr$$

However, further reaction occurs to give phosphite, pyrophosphite, ortho-, meta-, pyro- and poly-phosphates and phosphorus hydrides. As a result the final yield of isohypophosphate is only about 5%.[33]

Several reactions are known in which isohypophosphates are formed by exchange processes between phosphorous acids of different complexity. For example, neutral aqueous solutions containing equimolar proportions of sodium pyrophosphite and disodium phosphite react slowly at room temperature according to the equation[34]:

$$Na_2HPO_3 + Na_2H_2P_2O_5 \rightarrow Na_3HP_2O_6 + NaH_2PO_2$$

These are mentioned under the properties of hypophosphoric acid and are discussed in more detail in Section XX (page 604). As methods of preparation the more suitable reactions are as follows.

A 12% yield of the sodium salt, $Na_3HP_2O_6,8H_2O$, is obtained by adding 3 mol. of phosphorus trichloride to a mixture of 1 mol. of monosodium phosphate and 2 mol. of disodium phosphate dissolved in 1900 ml. of water, in the presence of 1400 g. of sodium bicarbonate at 0°C. A somewhat better yield results when dipotassium phosphate and potassium bicarbonate are used. Phosphorus oxychloride reacts at 0°C. with a 40% wt.-vol. solution of phosphorous acid in the presence of excess of sodium bicarbonate to give a yield of about 20% of isohypophosphate.[35] Very high yields are obtained by heating together concentrated aqueous solutions of orthophosphates and pyrophosphites. 95 g. of $Na_2H_2P_2O_5$ are added to 537 g. of $Na_2HPO_4,12H_2O$ dissolved in 100 ml. of water at 100°C. The mixture is heated for 3 min., 300 ml. of water are added and the mixture quickly cooled and filtered. The filtrate is treated with iodine in sodium bicarbonate solution to oxidize unwanted reduced acids and the isohypophosphate is purified by conversion with lead acetate to the lead salt and subsequent decomposition with sodium sulphide. The yield is 112 g. (58%) of $Na_3HP_2O_6,8H_2O$. If the reaction is carried out at 30°C. the yield is 75% and this can be increased to 96% by using 6 molar dipotassium phosphate solution. The optimum acidity is pH 5–8 and yields decrease as the temperature is raised or the orthophosphate concentration is lowered.[36] The pyrophosphite may be prepared by neutralizing phosphorous acid with one equivalent of sodium hydroxide. The crystalline product ($NaH_2PO_3,2\frac{1}{2}H_2O$) is then dried *in vacuo* at 60°C. and the anhydrous salt is further heated *in vacuo* at 150°C.[37–8]

$$2NaH_2PO_3 \rightarrow Na_2H_2P_2O_5 + H_2O$$

Suitable methods of preparation for hypophosphoric acid and its mono-, di-, tri- and tetra-sodium salts have been given.[101]

The mechanism of the formation of hypophosphates has been reviewed.[39]

## THE PREPARATION OF SALTS OF HYPOPHOSPHORIC ACID

Many of the known salts of hypophosphoric acid were prepared during the last century, following the discovery of the acid in 1792 by Pelletier.[40] Detailed information on the methods of preparation of the earlier known salts is to be found in the work of Salzer,[41] and this has already been summarized (Mellor, VIII, 931–40). Later work has substantially confirmed the previous findings and has extended the number of salts. Table II lists the salts which have already been described. Those which have since been reported are discussed below.

Magnesium hypophosphate, $Mg_2P_2O_6,12H_2O$, is reported to be converted to the di-, tri- and hexa-hydrates on crystallizing from acetic acid containing a little hydrochloric acid.[42] The optical properties and crystal morphology of the dodecahydrate are stated to be almost identical with those of a substance formulated as $Mg_2H_2P_2O_7,11H_2O$.[43] A silver salt, $Ag_4H_2P_2O_7$, is said to exist. Addition of magnesium powder to a solution of disodium hypophosphate is reported to form, in acetic acid solution, a product having the apparent composition $Mg_2P_2O_6,Mg_2H_2P_2O_7,13H_2O$ from which the salt $Ag_4P_2O_6,Ag_4H_2P_2O_7$ is derived.[44]

Lead hypophosphate, $Pb_2P_2O_6$, and acid barium hypophosphate, $BaH_2P_2O_6,2H_2O$, have been prepared in the pure state by reaction of disodium hypophosphate solutions with lead acetate and with barium chloride in the presence of hydrochloric acid. An aqueous suspension of the barium salt reacts with ammonium sulphate solution to form diammonium hypophosphate. A solution of this forms the monoammonium salt on stirring with a 48% solution of the free acid and then evaporating *in vacuo* over phosphorus pentoxide.[9]

$ZrP_2O_6,H_2O$

* Guanidine salt.

The silver, mercurous, copper, lead, cobalt and nickel salts have all been made by mixing equimolar proportions of solutions of the metal acetate and disodium hypophosphate. All the salts decompose on heating to give the metal. The decomposition of the mercurous salt is explosive. In a nitrogen atmosphere at temperatures below 200°C. the silver, mercury and copper salts give the following products[45]:

$$Ag_4P_2O_6 \rightarrow Ag + (PO_3)_3 + (PO_3)_n$$
$$Hg_2P_2O_6 \rightarrow Hg + (PO_3)_3 + (PO_3)_n + PO_4 + P_2O_7 + P_3O_{10}$$
$$Cu_2P_2O_6 \rightarrow Cu + PO_4 + P_2O_7 + P_3O_{10} + P_4O_{13} + P_5O_{16}$$

Ceric hypophosphate, $CeP_2O_6,xH_2O$, has been obtained as a yellow gel by reaction of a solution of ceric ammonium nitrate, $(NH_4)_2Ce(NO_3)_6$, in N. nitric acid with a solution of sodium hypophosphate.[3] The substance is stable at 100°C. but at 150°C. it becomes colourless, owing to the decomposition:

$$6CeP_2O_6 \rightarrow 2Ce(PO_3)_3 + Ce_4(P_2O_6)_3$$

Thorium hypophosphate, $ThP_2O_6,2H_2O$, is formed by controlled precipitation of a hot thorium nitrate solution with a solution of disodium hypophosphate.[46] The neodymium salt, $Nd_4(P_2O_6)_3$, and the yttrium salt, $Y_4(P_2O_6)_3$, have been obtained in a similar manner.[47] Protoactinium salts give a precipitate with tetrasodium hypophosphate. The product is also insoluble in 5 N. sulphuric acid.[48]

A sesqui-hydrated tetrasodium hypophosphate, $Na_4P_2O_6,1\frac{1}{2}H_2O$, has been reported and the transition temperature between this and the decahydrate is given as 74·6°C. Anhydrous tetrasodium hypophosphate is stable to heat above 400°C., but the acid salts decompose at lower temperatures, giving a mixture of condensed phosphates and a trace of a brown product of high phosphorus content.[101] The sodium ammonium salt, $Na_2(NH_4)_2P_2O_6,7H_2O$, has been made. Copper and nickel form the complex salts $NH_4CuP_2O_6,4H_2O$ and $Na_2NiP_2O_6,12H_2O$. Electrolysis of solutions of these two salts shows that the heavy metal atom is in the anion.[49]

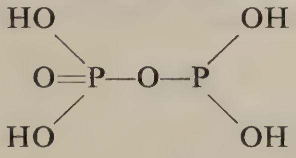
Tripotassium isohypophosphate has been prepared from dipotassium orthophosphate and phosphorus trichloride[35] in a manner similar to the trisodium salt (see p. 604):

$$K_2HPO_4 + 4KHCO_3 + PCl_3 \rightarrow K_3HP_2O_6 + 3KCl + 2H_2O + 4CO_2$$

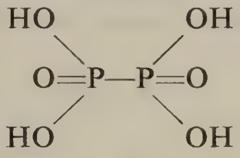
## THE STRUCTURE OF HYPOPHOSPHORIC AND ISOHYPOPHOSPHORIC ACID

With the information which was available in the earlier literature it was not possible to give a precise structure or formula for hypophosphoric acid. The evidence used to support the various structures which were proposed has previously been given in some detail (Mellor, VIII, 926–8). Many of the facts and observations known at that time were apparently contradictory and the formula of hypophosphoric acid was confused with those of other lower acids of phosphorus. In the light of present and more certain knowledge, the main features of the earlier work are as follows.

Before 1933, argument was largely concerned with the question as to whether the molecular formula of the acid was $H_2PO_3$ or the double one $H_4P_2O_6$. Salzer[41] had originally adopted the double formula on the basis of being able to prepare four different salts with monovalent cations. He concluded that the structure was represented by I or II, of which he favoured the first.



I

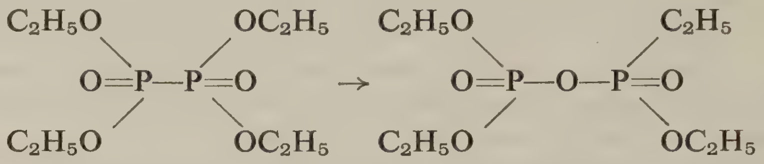


II

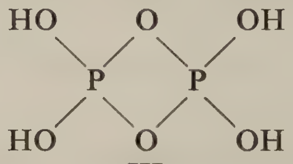
In 1894 Bansa[50] accepted the double formula and the symmetrical structure II because he was unable to form isomeric sodium and potassium salts.

The double formula agreed with conductivity and transport number measurements,[51] depression of the freezing point of aqueous solutions of sodium, potassium and ammonium hypophosphates[52] and the rate of hydrolysis of hypophosphates in acid solution.[53-4]

On the other hand some measurements of the elevation of the boiling point of ethyl iodide, ethyl bromide and chloroform by dissolved methyl hypophosphate appeared to show that the single formula was the correct one.[55] The same observations were found with solutions of the methyl ester in methyl iodide, the ethyl ester in ethyl iodide[56] and of the benzyl ester in diethyl ether.[57] However, the esters used for the molecular weight measurements were made by reaction of silver hypophosphate with the appropriate organic iodide, and later work has shown[58] that this method of preparation is not valid for hypophosphates, even though it is valid for the corresponding pyrophosphates. Silver halides react with organic hypophosphates to form addition compounds and organic iodides, e.g. ethyl iodide, cause hypophosphate esters to rearrange and form pyrophosphate[59-60]:



A re-examination of the rate of hydrolysis of hypophosphate in acid solution[49] confirmed the earlier findings[53] supporting the double formula. Further evidence in favour of this was provided in 1933 by measurements of the magnetic susceptibility of $Na_2H_2P_2O_6,6H_2O$, $Na_2H_2P_2O_6,Ag_4P_2O_6$ and guanidine hypophosphate. At 20°C. the respective values were found to be $-0{\cdot}41\times10^{-6}$, $-0{\cdot}38\times10^{-6}$, $-0{\cdot}41\times10^{-6}$ and $-0{\cdot}25\times10^{-6}$. The salts are therefore all diamagnetic and must be derived from an acid of the formula $H_4P_2O_6$. The $H_2PO_3$ molecule would have an odd number of electrons surrounding the phosphorus atom in the outer valency shell.[61] Structure III,

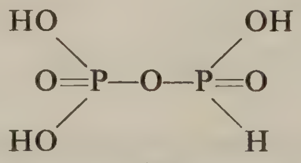


III

like the $H_2PO_3$ molecule, also has an odd number of electrons round each phosphorus atom. Both of them can therefore be rejected since such compounds would be paramagnetic.[62]

When non-electrolytes are added to ice–salt mixtures a normal molecular lowering of the eutectic point temperature is observed. The addition of electrolytes, however, gives a molecular lowering of the temperature which is proportional to the number of ions formed, other than common ions. When disodium hypophosphate or tetrapotassium hypophosphate is used in this technique the observed molecular lowering agrees with the formulæ $Na_2H_2P_2O_6$ and $K_4P_2O_6$.[63]

*X*-Ray absorption measurements on hypophosphoric acid and its sodium and barium salts strongly supported the symmetrical structure II. This also agreed with the tetra-basicity of the acid, its resistance to oxidation by nitric acid and the halogens, and with cryoscopic measurements.[64] On the other hand the ease of oxidation of hypophosphate to pyrophosphate by bromine at pH 5–11 favoured structure I, III or IV,



IV

of which I was considered to be the most probable.[65] However, although this oxidation could not be readily explained by a symmetrical acid containing a P–P bond, structure II was generally favoured at this time.[66–8]

Raman spectra of the free acid and its dipotassium salt showed too many lines for the monomeric formula $H_2PO_3$, and showed also that more complex units must be present. Although the experimental results agreed more closely with a dimeric formula, they were insufficient to establish structure II completely.[69] A later examination[9] showed the presence of a P–P bond and the absence of a P–H link. The $P_2O_6^{4-}$ ion comprised two equal $PO_3$ pyramids joined by a P–P bond, the $PO_3$ groups being staggered at an angle of 60° to each other. The six oxygen atoms were found to be equivalent.

*X*-Ray exmination of diammonium hypophosphate gives unit cell dimensions of $a=7{\cdot}26$, $b=11{\cdot}47$ and $c=9{\cdot}38$ A. Only structure II agrees with the data.[70] The unit cell size and space-group symmetry of the hypophosphate ion are very similar to those of ammonium bicarbonate.[71]

The di-, tri- and tetra-sodium salts of hypophosphoric acid are all monoclinic and each has four molecules in the unit cell. The trisodium salt has space group $P2_1/a$ and the other two are $C2/c$. The cell dimensions are given in Table III.[72]

*Table III.—The Cell Dimensions of Sodium Hypophosphates*[72]

| Salt | Cell dimensions—A. | | |
|---|---|---|---|
| | *a* | *b* | *c* |
| $Na_2H_2P_2O_6,6H_2O$ | 14·12 | 7·00 | 12·71 |
| $Na_3HP_2O_6,9H_2O$ | 26·96 | 6·00 | 9·26 |
| $Na_4P_2O_6,10H_2O$ | 16·97 | 6·97 | 14·50 |

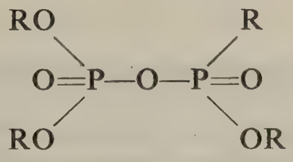
Infra-red absorption spectra in the 650 to 4000 cm.$^{-1}$ region have been tabulated for the sodium, ammonium, calcium, strontium, barium and lead hypophosphates.[73] Far ultra-violet absorption spectra of hypophosphates have been recorded.[110]

Nuclear magnetic resonance studies prove that structure II is the only possible one for hypophosphate. Only one resonance peak is shown and there is no evidence for P–H bonds. If the molecule contains two phosphorus atoms it must therefore have a symmetrical structure.[74]

By the same technique structure IV is the only one possible for isohypophosphoric acid.[75] The N.M.R. diagram is shown in Section XX, Fig. 2, p. 604. Peaks 1A and 1B in this are due to the P–H bond and peak 2 corresponds to the phosphorus atom which has no hydrogen atom directly attached to it.

Equations have been derived which enable the calculation of the A translations for the conditions $J_{XX'}=0$. Using these, the $^1H$ and $^{31}P$ spectra of the tetramethyl and tetraethyl esters of hypophosphoric acid were calculated, and shown to be in good agreement with observation.[103]

Chromatographic and Raman spectra data agree with the above structure for isohypophosphate.[34] Raman spectra also show that the structure of alkyl isohypophosphates is:



where R is an alkyl group.[76]

**Refs. p. 662**

## THE PROPERTIES OF HYPOPHOSPHORIC ACID AND THE HYPOPHOSPHATES

### Thermal Decomposition

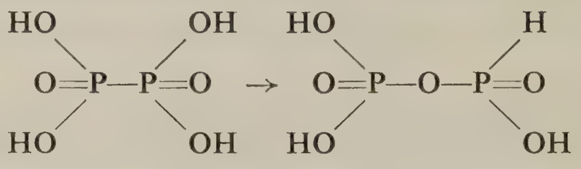
Hypophosphoric acid exists as an anhydrous material, and as a mono- and dihydrate. The melting points of these have been given as 70°C., 79·5° to 81·5°C. and 62° to 62·5°C. respectively. However, careful observation of the melting process shows that these are not true melting points. Rapid heating of the anhydrous acid gives an apparent m.p. of 55°C., but on slow heating, the melting temperature can vary between 70° and 95°C. The residue from the melting consists of phosphorous acid and a polymetaphosphoric acid, indicating the decomposition:

$$H_4P_2O_6 \rightarrow H_3PO_3 + \frac{1}{n}(HPO_3)_n$$

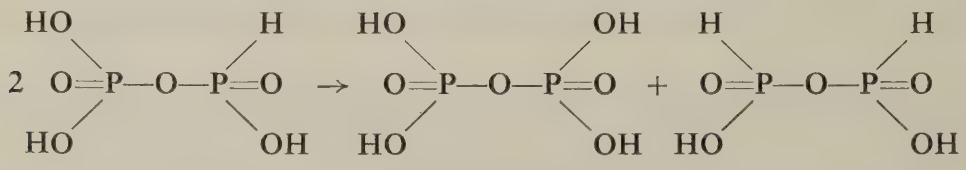
The dihydrate shows an apparent m.p. at 62° to 64°C., but on heating for 15 min. at 65°C. considerable decomposition into phosphoric and phosphorous acid occurs[9]:

$$H_4P_2O_6,2H_2O \rightarrow H_3PO_4 + H_3PO_3 + H_2O$$

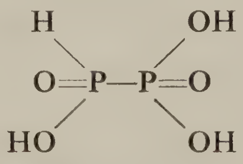
The dihydrate is stable for at least 2 months at −15°C.[9] but slowly decomposes at room temperature to become a clear liquid in 1–2 months. The anhydrous acid changes in 5 days to a viscous liquid which solidifies, but does not crystallize, at low temperature.[77] The final products of the spontaneous decomposition of hypophosphoric acid in the presence of water are phosphorous and phosphoric acids. However, a number of intermediate acids have been detected and under anhydrous conditions it appears that the first stage in the decomposition is the isomerization of hypophosphoric acid to isohypophosphoric acid[34–5,78]



Oxidation and reduction can then occur, leading to the formation of pyrophosphoric and pyrophosphorous acid:



Hypophosphorous acid $H_3PO_2$ and diphosphorous acid



have not been detected in this decomposition.[78]

### Hydrolysis and Oxidation

Hypophosphoric acid is very stable in alkaline solutions and is not hydrolyzed by heating for 1 hr. at 200°C. in 80–90% sodium hydroxide. In 80% potassium hydroxide solution less than 5% hydrolysis occurs on heating for 40 hr. at 200°C. Molten sodium hydroxide oxidizes, rather than hydrolyzes, hypophosphoric acid. At 320°C. in 30 min. a quantitative conversion to orthophosphate occurs. Hydrogen, but no phosphine, is evolved[24]:

$$H_4P_2O_6 + 6NaOH \rightarrow 2Na_3PO_4 + 4H_2O + H_2$$

In acid solutions the hydrolysis of hypophosphate is catalyzed by hydrogen ions, the rate of reaction being much slower than that for pyrophosphate or other polyphosphates under similar conditions. The products of the hydrolysis are phosphorous and phosphoric acids. Some data for the hydrolysis of $Na_2H_2P_2O_6,6H_2O$ in sulphuric acid solutions are given in Table IV.[49]

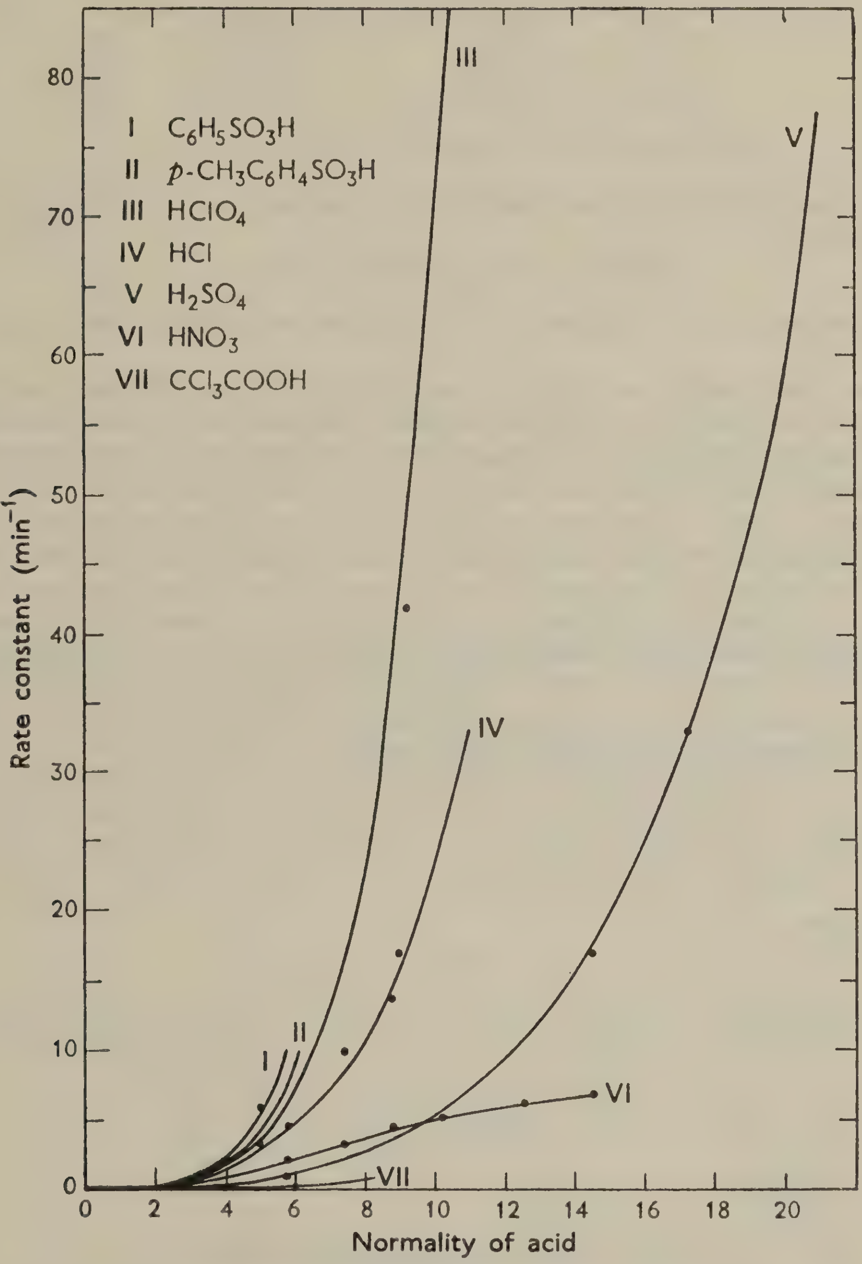


FIG. 1.—Hydrolysis of disodium hypophosphate in concentrated acid solutions[79]

At 25°C. in N.-acid solution the half-life is estimated to be approximately 180 days, i.e. $k = 2{\cdot}7 \times 10^{-6}$ min.$^{-1}$. These data are consistent with an activation energy of 20–25 kcal. mole$^{-1}$ for the hydrolysis in N.-acid solutions.[75] The first order rate constants for isohypophosphoric acid are $1{\cdot}4 \times 10^{-2}$ min.$^{-1}$ in 0·2 N. hydrochloric acid at 0°C.[35], $2\times10^{-4}$ min.$^{-1}$ in 0·5 N. potassium hydroxide at 0°C.[36] and $5{\cdot}4\times10^{-3}$ min.$^{-1}$ in N. sodium hydroxide at 34°C.[35]

Measurements of the rate of hydrolysis at 40°C. of $Na_2H_2P_2O_6{,}6H_2O$ in concentrated solutions of strong acids show that the reaction is of first order. The relevant data are shown graphically in Fig. 1, from which nitric acid is seen to be much less effective than the other mineral acids.[79] This acid has virtually no oxidizing action on hypophosphates. It behaves like the other acids as a hydrogen ion catalyst for the reaction[80]:

*Table IV.—Hydrolysis of Disodium Hypophosphate in Sulphuric Acid Solution*[49]

| Temp. °C. | Normality of $H_2SO_4$ | Rate constant min.$^{-1}$ |
|---|---|---|
| 60 | 0·5 | $1{\cdot}18\times10^{-4}$ |
| 60 | 1·0 | $2{\cdot}51\times10^{-4}$ |
| 100 | 0·25 | $4{\cdot}30\times10^{-3}$ |
| 100 | 0·50 | $6{\cdot}80\times10^{-3}$ |

$$H_4P_2O_6 + H_2O \rightarrow H_3PO_3 + H_3PO_4$$

The phosphorous acid is oxidized only if nitrogen oxides are present in the nitric acid.[81]

Reference has already been made to the stability of hypophosphoric acid towards oxidation by the halogens, hydrogen peroxide and acid solutions of potassium dichromate and potassium permanganate (Mellor, VIII, 930–1). The material appears to be oxidized slowly in cold acid solutions and more rapidly when hot, but this is not a direct oxidation to pyrophosphate. This is shown by the action of iodates, which have virtually no effect on hypophosphates in neutral or alkaline solution. In strong acid solutions the reaction is slow in the cold, but is complete in a few hours at 100°C. The initial action is one of hydrolysis which proceeds with a measurable velocity, and is followed by a rapid oxidation of phosphorous to phosphoric acid.[82]

The rate of reaction with 0·001 N. potassium permanganate in 0·1 N. sulphuric acid at 80°C. varies with the hypophosphate concentration as shown in Fig. 2; maximum velocity occurs at 0·015 M. $Na_2H_2P_2O_6$.[83]

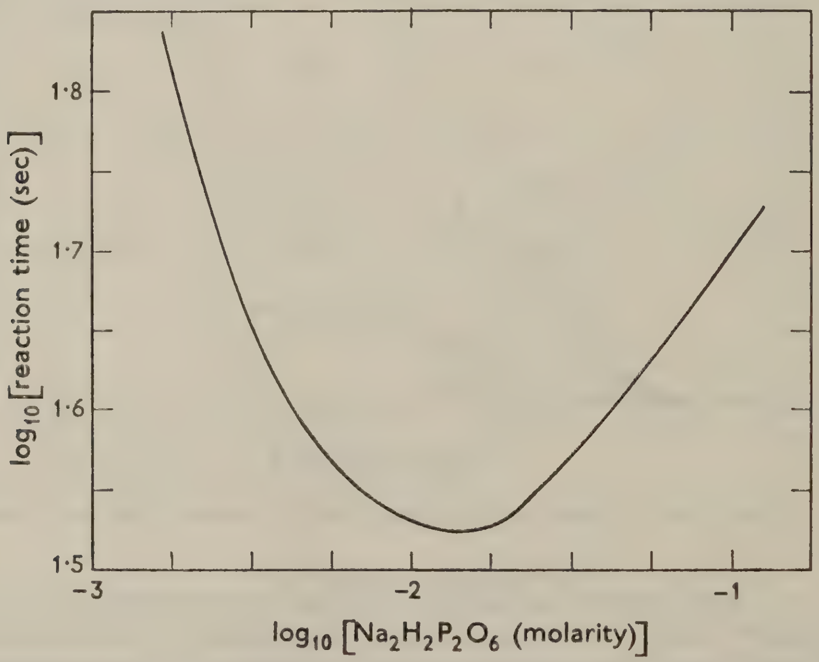

FIG. 2.—Rate of reaction of $Na_2H_2P_2O_6$ with 0·001 N. $KMnO_4$ at 80°C.

Bromine is one of the few reagents which oxidize hypophosphate directly to pyrophosphate without intermediate hydrolysis. The tetrasodium salt reacts according to the following equation[41]:

$$Na_4P_2O_6 + Br_2 + H_2O \rightarrow Na_2H_2P_2O_7 + 2NaBr$$

For the other sodium salts and the free acid the rate of oxidation depends on the pH, as shown in Fig. 3. The data for this were obtained by measuring the extent of oxidation by 0·1 N. aqueous bromine in 1 min. at 25°C. In the presence of excess of sodium bicarbonate at 20°C., the oxidation is at least 98% complete in 15 min. Less than 0·5% of orthophosphate is formed.[65]

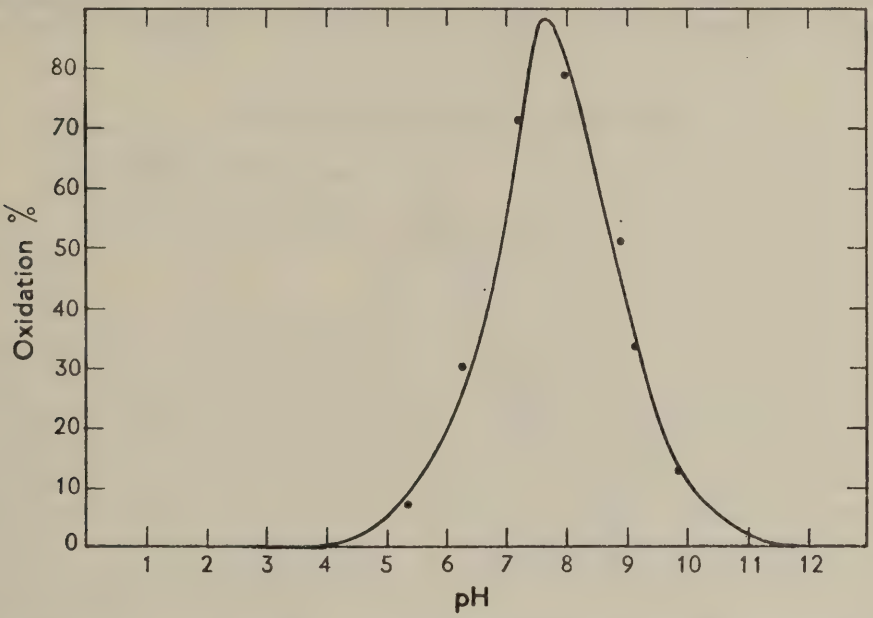

FIG. 3.—Effect of pH on the oxidation of hypophosphoric acid by 0·1 N.-$Br_2$ (aq.) at 25°C.[65]

More recently[3] a calculation of the variation in the hypobromous acid concentration with pH indicates that this is the oxidizing agent in the reaction. Fig. 4 shows the hypobromous acid concentration superimposed on the oxidation curve. The calculated values are based on the value $2{\cdot}1 \times 10^{-9}$ for the ionization constant of hypobromous acid[84] and the value $5{\cdot}8 \times 10^{-9}$ for the hydrolysis of bromine according to the equation[85]:

$$Br_2 + H_2O \rightleftharpoons HBrO + H^+ + Br^-$$

Bromite appears to be less effective as an oxidizing agent. A mechanism postulated for the hypobromite oxidation is[3]:

$$HP_2O_6^{3-} + HBrO \rightarrow 2PO_3^- + Br^- + H_2O$$
$$2PO_3^- + H_2O \rightarrow H_2P_2O_7^{2-}$$

## Dissociation and Solubilities in Water

The ionization constants of hypophosphoric acid have been given as $K_1 = 10^{-2{\cdot}2}$, $K_2 = 10^{-2{\cdot}81}$, $K_3 = 10^{-7{\cdot}27}$ and $K_4 = 10^{-10{\cdot}03}$, the first value being approximate. More recent values are $K_2 = 10^{-2{\cdot}1}$, $K_3 = 10^{-6{\cdot}77}$ and $K_4 = 10^{-9{\cdot}48}$ at 20°C.[87] These were obtained by electrometric titration using a hydrogen electrode in 0·10 N. potassium chloride solution. For comparison the results obtained in this way for pyrophosphoric acid gave $K_2 = 10^{-2{\cdot}5}$, $K_3 = 10^{-6{\cdot}08}$ and $K_4 = 10^{-8{\cdot}45}$.

Some solubility data for the ammonium, lithium, sodium, potassium, calcium, magnesium and hydrazine salts of hypophosphoric acid have been recorded previously (Mellor, VIII, 931–40). A more recent determination of the solubility diagrams for tetrasodium, trisodium and disodium hypophosphate shows that the tetrasodium salt undergoes an inversion of solubility at 66·5°C. This is interpreted as a change in the stable phase from $Na_4P_2O_6,10H_2O$ at low temperatures to the anhydrous salt above 66·5°. The trisodium salt $Na_3HP_2O_6,9H_2O$ shows a similar inversion at 58·5°C. and the disodium salt $Na_2H_2P_2O_6,6H_2O$ an inflection at 80·5°C. corresponding to a similar phase change to the anhydrous salts.[109] At 20°C., 48 g. of monoammonium hypophosphate, $NH_4H_3P_2O_6$, dissolve in 100 ml. of water.[9]

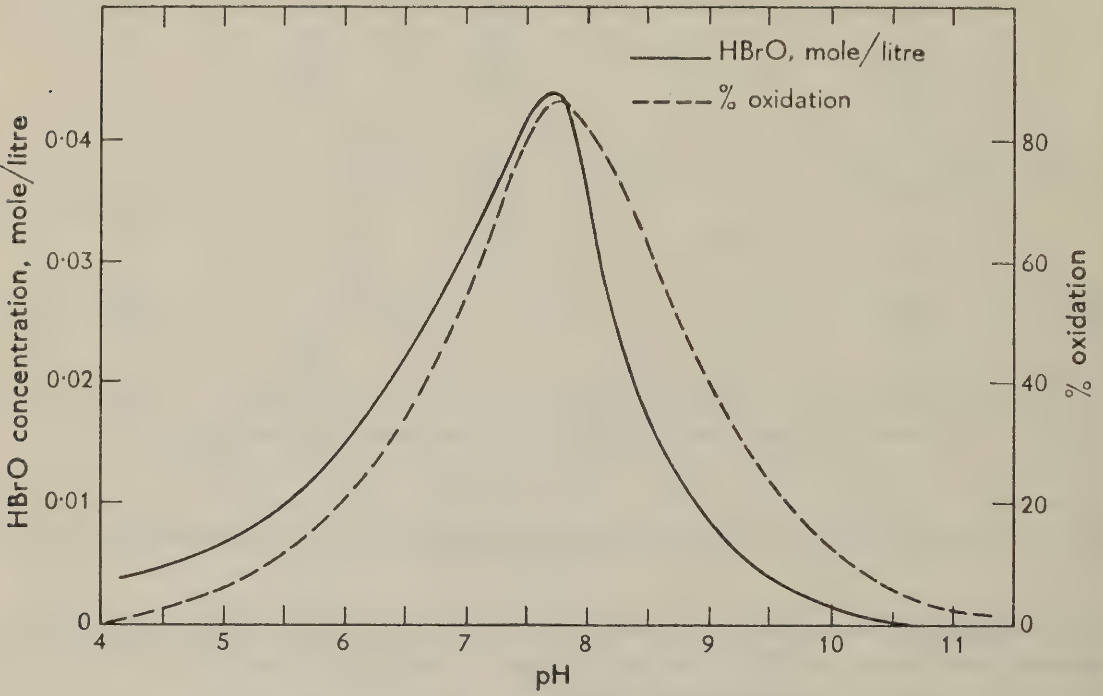

FIG. 4.—Oxidation of hypophosphate by hypobromite. (*cf.* Fig. 3)

The solubilities of the thorium, neodymium and yttrium salts in hydrochloric acid solutions at 25°C. are given in Table V.[47] The data for thorium hypophosphate agree with the figure of $0{\cdot}41 \times 10^{-4}$ mol./l. previously given for the solubility of $ThP_2O_6,11H_2O$ in N. hydrochloric acid (Mellor, VIII, 939).

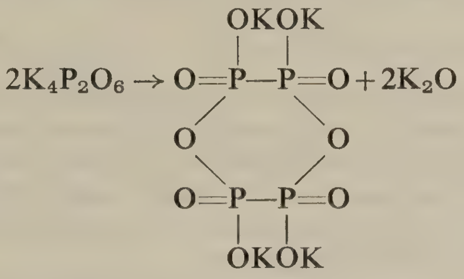
*Table V.—The Solubilities of Thorium, Neodymium and Yttrium Hypophosphates in Hydrochloric Acid Solutions at 25°C.*[47]

| HCl normality | Solubility (mol./l.) | | |
|---|---|---|---|
| | $ThP_2O_6$ | $Nd_4(P_2O_6)_3$ | $Y_4(P_2O_6)_3$ |
| 0·05 | — | $0{\cdot}11 \times 10^{-4}$ | — |
| 0·10 | — | $0{\cdot}48 \times 10^{-4}$ | — |
| 0·20 | — | $1{\cdot}60 \times 10^{-4}$ | $3{\cdot}02 \times 10^{-4}$ |
| 0·30 | — | $2{\cdot}0 \times 10^{-4}$ | $5{\cdot}52 \times 10^{-4}$ |
| 1·0 | $0{\cdot}25 \times 10^{-4}$ | $14{\cdot}46 \times 10^{-4}$ | $26{\cdot}90 \times 10^{-4}$ |
| 2·0 | $0{\cdot}47 \times 10^{-4}$ | $34{\cdot}7 \times 10^{-4}$ | — |
| 4·0 | $1{\cdot}65 \times 10^{-4}$ | — | — |
| 6·0 | $2{\cdot}10 \times 10^{-4}$ | — | — |

### Other Chemical Reactions of Hypophosphates involving conversion to other Phosphorous Acids

Several reactions involving hypophosphates have been referred to above. Those discussed below show the relationship between hypophosphoric acid and the other reduced acids of phosphorus which are described in more detail in Section XX (page 596).

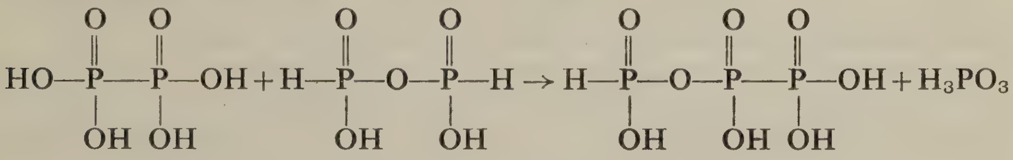
Tetrapotassium hypophosphate when heated with acetic anhydride for 40 hr. at 90°C. is converted to the potassium salt of the cyclic acid $(\overset{4}{P}\text{–}\overset{4}{P}\text{–}O)_2$



Somewhat higher yields are obtained in 68 hr. at 90°C. using a mixture of equal weights of propionic acid and propionic anhydride. The product is separated as the dihydrated guanidine salt, from which the sodium salt, $Na_4P_4O_{10},4H_2O$, is obtained by successive reaction with silver nitrate and sodium chloride. The sodium salt is also formed by heating disodium hypophosphate with a mixture of acetic acid and acetic anhydride, but separation from the unchanged hypophosphate is more difficult.[88] Properties of the material are given in Section XX. The free acid is monobasic and when heated at 150°C. with 60% potassium hydroxide it is quantitatively converted to hypophosphate.

Reaction with 1·5 N. sodium hydroxide at room temperature for a few hours converts the sodium salt into the sodium salt of the acid $\overset{4}{P}\text{–}\overset{4}{P}\text{–}O\text{–}\overset{4}{P}\text{–}\overset{4}{P}$. The latter is hydrolyzed by 0·2 N. nitric acid at 20°C. to give hypophosphoric acid. The first order rate constant for this reaction is $13{\cdot}3 \times 10^{-3}$ min.$^{-1}$

Hypophosphates react in aqueous solution with pyrophosphites to form salts of the acid $\overset{3}{P}\text{–}O\text{–}\overset{4}{P}\text{–}\overset{4}{P}$ by a process of trans-anhydrization. Under suitable conditions the yield is almost quantitative, but the rate of reaction depends on the temperature and on the concentration and pH of the solution[36].



$$HO\text{—}\underset{OH}{\overset{O}{\overset{\|}{\underset{|}{P}}}}\text{—}\underset{OH}{\overset{O}{\overset{\|}{\underset{|}{P}}}}\text{—}OH + H\text{—}\underset{OH}{\overset{O}{\overset{\|}{\underset{|}{P}}}}\text{—}O\text{—}\underset{OH}{\overset{O}{\overset{\|}{\underset{|}{P}}}}\text{—}H \rightarrow H\text{—}\underset{OH}{\overset{O}{\overset{\|}{\underset{|}{P}}}}\text{—}O\text{—}\underset{OH}{\overset{O}{\overset{\|}{\underset{|}{P}}}}\text{—}\underset{OH}{\overset{O}{\overset{\|}{\underset{|}{P}}}}\text{—}OH + H_3PO_3$$

Oxidation of the sodium salt of the $\overset{3}{P}\text{–}O\text{–}\overset{4}{P}\text{–}\overset{4}{P}$ acid by bromine in sodium bicarbonate solution converts it into equimolar proportions of ortho- and pyro-phosphate and the sodium salt of the $\overset{5}{P}\text{–}O\text{–}\overset{4}{P}\text{–}\overset{4}{P}$ acid.

$$Na_4HP_3O_8 + NaHCO_3 + O_2 \rightarrow Na_2HPO_4 + Na_3HP_2O_7 + CO_2$$
$$2Na_4HP_3O_8 + 2NaHCO_3 + O_2 \rightarrow 2Na_5P_3O_9 + 2CO_2 + 2H_2O$$

In N. $HNO_3$ or in 0·5 N. KOH the salt $Na_5P_3O_9$ is hydrolyzed to phosphorous and hypophosphoric acids:

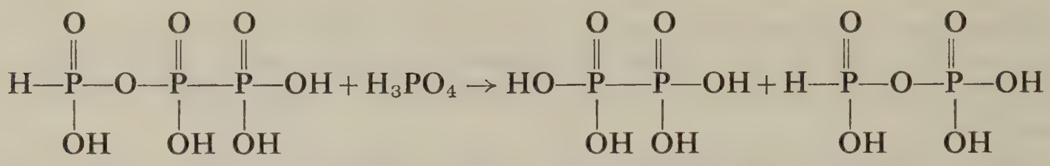
$$H_5P_3O_8 + H_2O \rightarrow H_4P_2O_6 + H_3PO_3$$

In concentrated acid the hypophosphate is further hydrolyzed to phosphite and phosphate:

$$H_5P_3O_8 + 2H_2O \rightarrow 2H_3PO_3 + H_3PO$$

**Refs. p. 662**

The salt $Na_4HP_3O_8$ reacts with orthophosphate to form hypophosphate and isohypophosphate[36]:



$$\mathrm{H{-}\underset{OH}{\overset{O}{P}}{-}O{-}\underset{OH}{\overset{O}{P}}{-}\underset{OH}{\overset{O}{P}}{-}OH + H_3PO_4 \rightarrow HO{-}\underset{OH}{\overset{O}{P}}{-}\underset{OH}{\overset{O}{P}}{-}OH + H{-}\underset{OH}{\overset{O}{P}}{-}O{-}\underset{OH}{\overset{O}{P}}{-}OH}$$

Tetrapotassium hypophosphate gives a 10% yield of $K_5P_3O_9$ on reaction with potassium phosphoramidate in 5 N. HBr (aq.) at 45°C. for 4 days:

$$K_4P_2O_6 + KHPO_3.NH_2 \rightarrow K_5P_3O_9 + NH_3$$

A 4% yield is also obtained by reaction of phosphorus oxychloride with a solution of potassium hypophosphate in the presence of excess potassium bicarbonate. The free acid ($H_5P_3O_9$) and its salts behave in a manner similar to $H_5P_3O_8$ during hydrolysis; in concentrated alkali or in dilute acid, orthophosphate and hypophosphate are formed, and in concentrated acid the hypophosphate is hydrolyzed further to phosphite and orthophosphate.[89]

The main reactions involving hypophosphoric acid are shown in Fig. 5.

## THE ANALYSIS OF HYPOPHOSPHATES

Several methods of analyzing hypophosphates have been reported and these are fully described in Section XXXV (page 1273).

For the sodium salts in the absence of other oxidizable phosphorus compounds, the simplest procedure is oxidation with 0·01 N. or 0·1 N. bromine solution in the presence of sodium bicarbonate. The excess bromine is then determined iodimetrically.[65]

Another method is to heat for 1 hr. with potassium iodate dissolved in 40% sulphuric acid solution. The iodine formed is distilled into potassium iodide solution, which is then titrated with standard arsenite solution.[3]

Hypophosphate can be determined in the presence of reduced acids of phosphorus by dissolving it in 0·5 N. nitric acid and precipitating with silver nitrate solution. The insoluble silver salt is collected, dried at 100°C. and then heated to bring about the decomposition:

$$Ag_4P_2O_6 \rightarrow 2Ag + 2AgPO_3$$

The residue is then weighed. Tetrametaphosphate and linear polyphosphates of chain length greater than tripolyphosphate interfere in this method.[3]

In the presence of hypophosphite, phosphite and phosphate it is an advantage to add a cold, saturated solution of barium nitrate to the hypophosphate solution. The precipitate is collected, washed and dissolved in 10% v/v phosphoric acid solution. Excess of standard silver nitrate solution is then added and after filtration the excess silver in the filtrate is titrated with standard potassium thiocyanate solution.[90-1]

If other reducing agents are absent, hypophosphates can be determined by adding 0·1 N. ceric ammonium nitrate solution and concentrated nitric acid. The solution is boiled until the initial precipitate dissolves, and is then cooled. The excess cerium(IV) is then titrated with standard arsenite solution, in the presence of a trace of osmic acid as a catalyst[92]:

$$P_2O_6^{4-} + 2Ce^{4+} + 2H_2O \rightarrow 2PO_4^{3-} + 2Ce^{3+} + 4H^+$$

Oxidation and hydrolytic reactions can be used to distinguish between hypophosphoric acid and isohypophosphoric, pyrophosphorous and diphosphorous acids: iodine in bicarbonate solution at room temperature oxidizes only the diphosphite.[23] Under the same conditions, bromine slowly oxidizes pyrophosphite[93] and isohypophosphate,[35] but rapidly oxidizes diphosphite[23] and hypophosphate[54] to pyrophosphate. The rates of hydrolysis are different for the four acids. In dilute acid

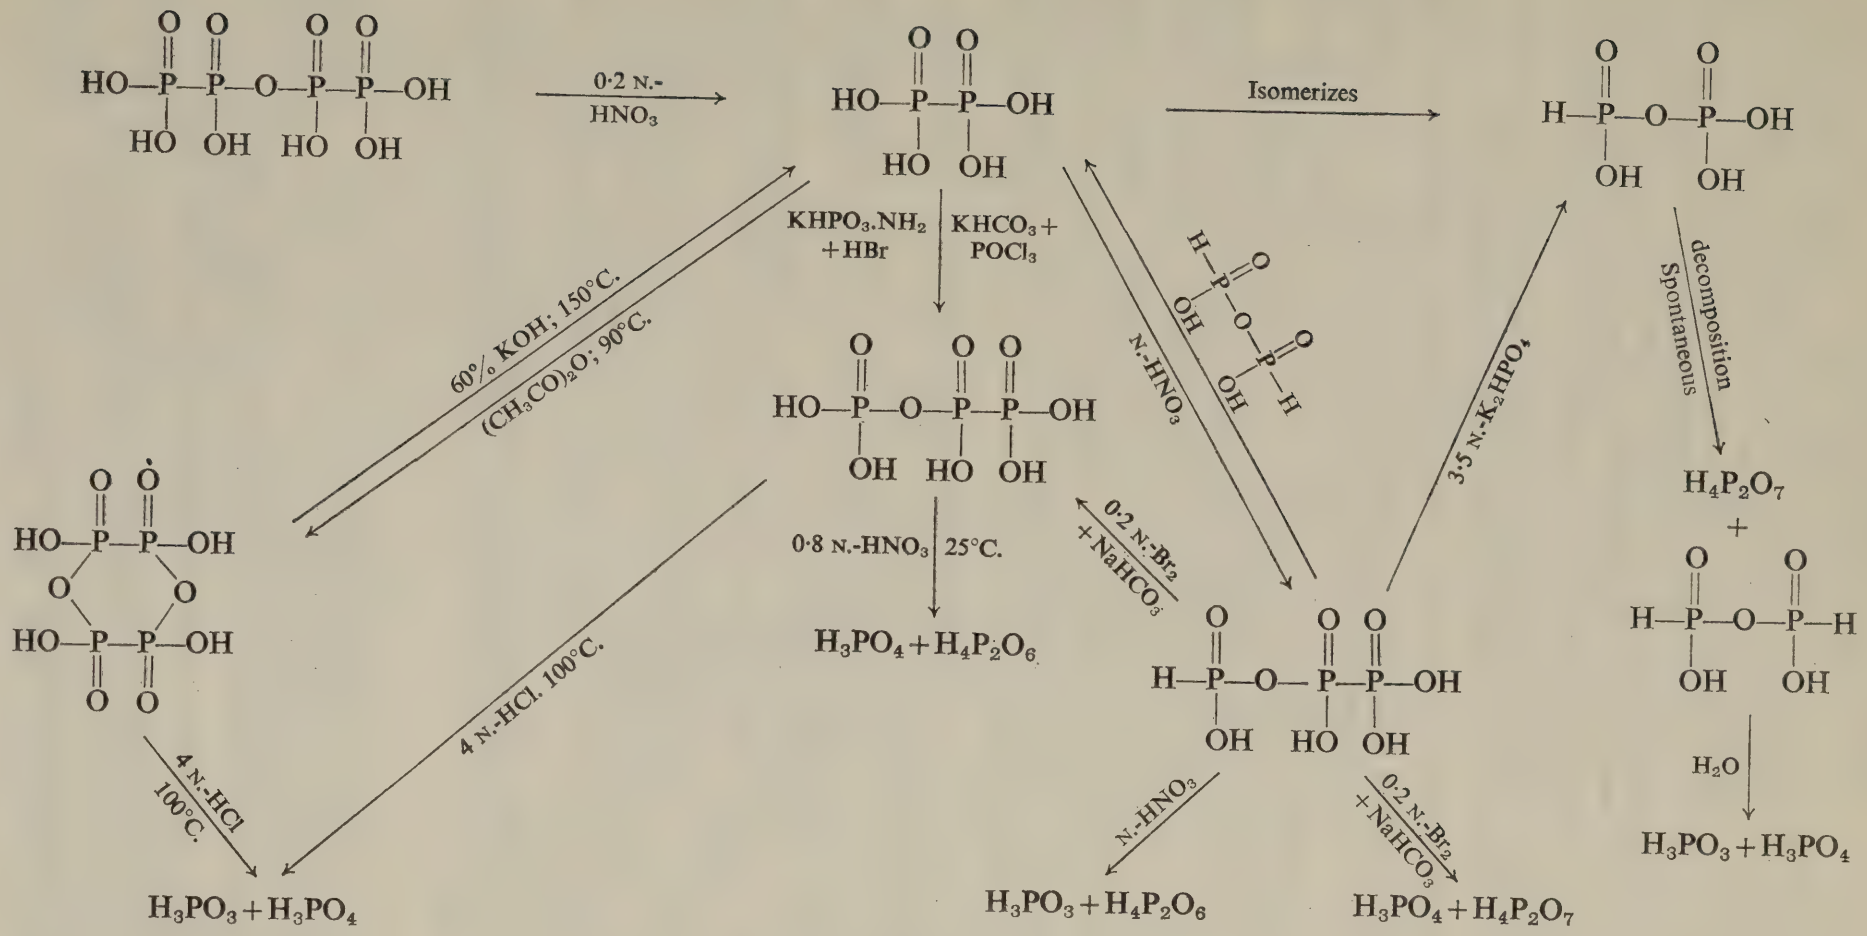


FIG. 5.—Reactions involving hypophosphoric acid

(0·2–0·5 N. HCl) pyrophosphite is hydrolyzed rapidly, with a half life of about 1 min. at 25°C., to form two molecules of phosphite.[36,94] Isohypophosphate forms one molecule each of phosphite and phosphate and the hydrolytic half-life is about 50 min. at 0°C.[89] Diphosphite hydrolyzes to two molecules of phosphite at a rate about 7–10 times slower than pyrophosphite.[22–3] Hypophosphoric acid is much more stable to hydrolysis and has a half-life of about 180 days in N. hydrochloric acid at 25°C.[49,53–4] Hypophosphates are extremely stable under alkaline conditions[24] while isohypophosphate has a half-life of about 440 min. in 0·1 N. sodium hydroxide at room temperature.[36] Diphosphite is not appreciably hydrolyzed in 1 hr. by boiling 2 N. sodium hydroxide[22] whereas pyrophosphite has a half-life of about 2 min. in the 0·1 N. alkali.[36]

Hypophosphates have been distinguished from the more recently discovered lower oxyacids of phosphorus by procedures similar to those described above.

Hypophosphoric acid and the cyclic acid $(\overset{4}{P}\text{–}\overset{4}{P}\text{–}O)_2$ are both completely hydrolyzed by boiling for 1 hr. in 4 N. hydrochloric acid. The $(\overset{4}{P}\text{–}\overset{4}{P}\text{–}O)_2$ acid, however, differs in not being oxidized by bromine in sodium bicarbonate solution. It also forms a barium salt which is insoluble in dilute hydrochloric acid.[88] The $\overset{4}{P}\text{–}\overset{4}{P}\text{–}O\text{–}\overset{4}{P}\text{–}\overset{4}{P}$ acid has similar properties which distinguish it from the hypophosphates.[88]

These three acids can be determined in the presence of one another by stirring with a solution containing sodium acetate and barium chloride. The mixture is then hydrolyzed for 1 hr. at room temperature in 2 N. hydrochloric acid, and the barium salt of $(\overset{4}{P}\text{–}\overset{4}{P}\text{–}O)_2$ is removed by centrifuging. This is now hydrolyzed at 100°C. in 4 N. HCl and oxidized with iodine in sodium bicarbonate solution. Similar treatment of the filtrate gives the sum of the hypophosphate and $\overset{4}{P}\text{–}\overset{4}{P}\text{–}O\text{–}\overset{4}{P}\text{–}\overset{4}{P}$. The hypophosphate content is obtained by oxidizing the original material with bromine and sodium bicarbonate.[36,88]

Oxidation methods for the determination of hypophosphate in the presence of phosphite and hypophosphite have been described.[95]

An electrometric titration procedure using a sulphuric acid solution of uranic sulphate in an atmosphere of carbon dioxide is reported to be a good method of determining hypophosphoric acid.[86,96]

An almost complete separation of ten acids of phosphorus, including hypophosphoric acid, has been achieved by paper chromatography.[97,104] For an acid solvent [$iso\text{-}C_3H_7OH + CCl_3COOH + H_2O + d\,0{\cdot}880\ NH_3(75+3:1+25+0{\cdot}3$ v/v)] the $R_f$ value for the hypophosphate is 0·48 and for a basic solvent [$C_2H_5OH + iso\text{-}C_4H_9OH + H_2O + d\,0{\cdot}880\ NH_3(30+30+39+1$ v/v)] the value is 0·21.[98] Thin layer chromatography has also been used to separate these acids.[105–6] Conditions for the development of colours from the anions by Mo(V)/ (VII) reagent have been established.[107–8]

Traces of copper, zinc, iron and tin in hypophosphates have been detected by electro-deposition on platinum wire electrodes using an applied potential of between 1 and 8 volts.[99]

## SECTION XXIV

# THE PREPARATION OF ORTHOPHOSPHORIC ACID

BY J. E. SUCH

## ORTHOPHOSPHORIC ACID, $H_3PO_4$

### Preparation

SOLUTIONS of chemically pure orthophosphoric acid can be conveniently prepared in the laboratory by the action of dilute nitric acid on white phosphorus, or by the cautious hydrolysis of purified phosphorus oxychloride with distilled water. Both of these methods have been described in detail previously,[1] but, as then, it is scarcely worth following them since extremely pure orthophosphoric acid is readily available commercially.

On the industrial scale, preparation is commonly carried out by either of two methods. The more modern procedure is to burn phosphorus in an excess of air, followed by the hydration of the phosphoric oxide so formed with water or steam, according to the equations:

$$P_4+5O_2 = P_4O_{10}$$
$$P_4O_{10}+6H_2O = 4H_3PO_4$$

In some plants the phosphoric oxide is collected and hydrated separately; in others it is hydrated in the equipment in which the combustion stage also proceeds. Acid of any phosphoric oxide concentration up to 84% $P_2O_5$ (see Section XXVI) may be prepared by this technique, the usual grade being orthophosphoric acid of 75–85% strength (expressed as $H_3PO_4$).

Such commercial orthophosphoric acid is quite pure, containing no more than traces of the lower oxyacids of phosphorus, nor, after simple treatment to remove arsenic, of other impurities. A typical analysis of acid produced by the so-called thermal process is given in Table I.

*Table I.—Typical Analysis of Orthophosphoric Acid Produced by the Thermal Process*

| | |
|---|---|
| $H_3PO_4$ | 85·0% |
| $Fe_2O_3$ | 15 p.p.m. |
| $As_2O_3$ | 1·0 p.p.m. |
| F | <2 p.p.m. |
| $H_2SO_4$ | 18 p.p.m. |
| Pb | 2·0 p.p.m. |
| Cl | 10–20 p.p.m. |
| Ni | <1 p.p.m. |
| Cr | <1 p.p.m. |
| Cu | <1 p.p.m. |

The second, and somewhat older, method of preparing orthophosphoric acid is the treatment of rock phosphate with sulphuric acid. Calcium sulphate (gypsum, $CaSO_4,2H_2O$), silica and other insoluble matter are filtered off to yield an impure solution of orthophosphoric acid which, after further purification to remove fluorine compounds, sulphate and other impurities, can be subsequently concentrated. For some industrial applications, such as the manufacture of phosphatic fertilizers, or technical grade sodium and other metal phosphates, acid of this quality is satisfactory, but the elaborate and often expensive purification procedures which are necessary to achieve the quality required for the manufacture of food and pharmaceutical grade phosphates set a limit to the use of the so-called gypsum or wet-process orthophosphoric acid. A typical analysis of such acid is given in Table II.

*Table II.—Typical Analysis of Orthophosphoric Acid produced by the Gypsum Process*

| | % by wt. | | % by wt. |
|---|---|---|---|
| $P_2O_5$ | 29·9 | $V_2O_5$ | 0·024 |
| CaO | 0·36 | $U_3O_8$ | 0·016 |
| $Fe_2O_3$ | 0·19 | MgO | 0·29 |
| $Al_2O_3$ | 0·17 | $Na_2O$ | 0·19 |
| $Cr_2O_3$ | 0·036 | $SO_3$ | 0·78 |
| $SiO_2$ | 0·70 | F | 1·26 |

A very extensive literature (including many patent specifications) has developed during the past three decades on the technology of the thermal and gypsum processes for the production of orthophosphoric acid; useful bibliographies may be found in reviews[2, 46-7] and technical monographs.[3, 40, 42-3] A fuller account of this technology appears in Section II.

The simultaneous formation of orthophosphoric acid and hydrogen, by the reaction between phosphorus vapour and steam, first described in 1924 by Liljenroth,[4] has since been the subject of many other patents. This process, although lately developed on a pilot plant scale, has not so far developed industrially. The main reaction represented by the equation:

$$P_4+16H_2O = 4H_3PO_4+10H_2$$

has been studied between:

(*a*) phosphorus vapour and steam at high temperatures (800–2000°C.) and at atmospheric pressure, alone or in the presence of catalysts to lower the temperature for effective reaction, and

(*b*) liquid white, or solid red phosphorus and water at relatively low temperature (below 500°C.) as well as at superatmospheric pressure (up to 300 atm.), with and without catalysts.

Under some conditions (1000°C. under atmospheric pressure and in the absence of catalysts), both phosphorous acid and phosphine are formed in addition to orthophosphoric acid and hydrogen.[5-6] On the other hand, high conversions of phosphorus into substantially pure orthophosphoric acid and hydrogen can be obtained at atmospheric pressure by passing mixtures of steam and phosphorus vapour, in mol. ratios of 16:30, over copper or palladium catalysts at 650–800°C.[7-8] The reaction of water at lower temperatures under superatmospheric pressures with white[9-11] and red[12] phosphorus gives products which are generally contaminated with phosphorous acid and phosphine.

The mechanism and thermodynamics of this reaction have been considered more fully in Section V.

The formation of orthophosphoric acid and hydrogen by a similar process from metallic phosphides has also been reported.[13-4] The acid is also formed by the thermal decomposition of ammonium hypophosphite,[48] or the anodic oxidation of white phosphorus.[49]

Other rather more indirect methods have been suggested for the commercial preparation of orthophosphoric acid, such as heating tricalcium orthophosphate with sodium chloride, chlorine or phosgene, followed by aqueous hydrolysis of the phosphorus oxychloride produced in the initial reaction.

Substitutes for sulphuric acid in the usual method of attacking phosphate rock have been reported; for example, hydrochloric acid,[15-6] hydrofluoric acid,[17] and mixtures of sulphurous and hydrochloric acids.[18-9]

Solvent extraction is often recommended as a method of separating and purifying orthophosphoric acid made by these and other processes which do not rely on the formation and filtration of insoluble calcium salts. Many solvents have been suggested for this purpose, including aliphatic alcohols,[20-1, 44] ketones,[22-3] esters,[24, 41] and ethers.[17] Of twenty-four different solvents studied, alcohols were found to be the best for extracting orthophosphoric acid from aqueous solutions, followed by ketones and ethers[25-6]; the theory of the solvent extraction process has also been discussed.[26, 45] The preparation of phosphoric acid by the attack of acids upon phosphate rock, and its purification by solvent extraction are discussed in greater detail in Section II (page 72 *et seq.*).

### Purification

Commercial orthophosphoric acid can be purified by recrystallization from solution as the anhydrous acid[27-8] or as the hemihydrate, $H_3PO_4,\frac{1}{2}H_2O$.[29] Heavy metal or metalloid impurities may be deposited electrolytically using chromium, platinum or tantalum electrodes[30-1] and to assist in the removal of traces of arsenic by this method additions of copper salts are sometimes made.[32-4] Arsenic may also be removed by passing acid containing it over copper foil,[35] or by treating the acid with sodium or hydrogen sulphide and filtering off the precipitated arsenic trisulphide, $As_2S_3$.[40] The precipitation of metallic impurities can also be brought about by the treatment of dilute orthophosphoric acid with several volumes of glacial acetic acid.[36]

## "HEAVY" ORTHOPHOSPHORIC ACID, $D_3PO_4$

"Heavy" orthophosphoric acid (deuterophosphoric acid, $D_3PO_4$), has been prepared in several ways[37-9]:

(*a*) by the addition of phosphoric oxide to heavy water, $D_2O$,
(*b*) by the hydrolysis of phosphorus oxychloride with heavy water, and
(*c*) by the decomposition of barium orthophosphate with heavy sulphuric acid, $D_2SO_4$,

the most convenient method being the first.

## PHYSICAL PROPERTIES

### The System $P_2O_5$–$H_2O$

THE solubility phase diagram for the system $P_2O_5$–$H_2O$, up to and including compositions corresponding to pyrophosphoric acid, shown in Fig. 1 is based on currently available data[1–6] (see also Ref. 234).

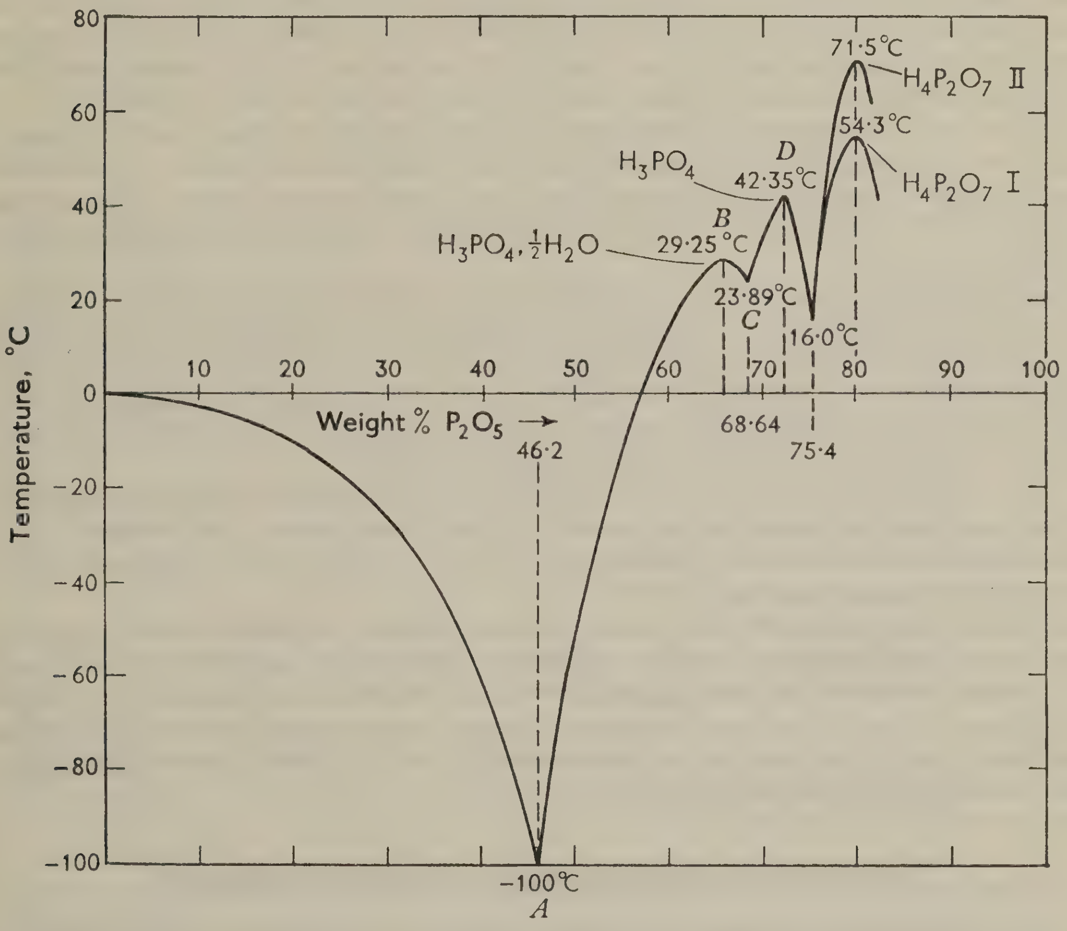

FIG. 1.—Solubility phase diagram of the system $P_2O_5$–$H_2O$

The solid crystalline phases in the orthophosphoric region of the system are the anhydrous acid $H_3PO_4$, m.p. 42·35°C., and the hemihydrate $H_3PO_4,\frac{1}{2}H_2O$, m.p. 29·25°C.

When anhydrous orthophosphoric acid crystals are rapidly melted and the temperature is observed before rearrangement in the liquid phase occurs according to the equilibrium[2,4-6]:

$$2H_3PO_4 \rightleftharpoons H_4P_2O_7 + H_2O$$

freezing-point values approximating to those noted by Ross and Jones,[1] viz. 42·35°C., are obtained. If, however, the anhydrous acid is maintained in the molten condition, the freezing point gradually falls to an equilibrium value of 34·6°C. after about 3 weeks; this temperature corresponds to the presence of about 6 mole-% of pyrophosphoric acid.[4] Thus slow melting of anhydrous crystals in contact with a liquid phase that has had the opportunity to approach equilibrium with other species of phosphoric acid may lead to lower values than 42·35°C.[5,6]

Solid $H_3PO_4$ exists in equilibrium with solutions of different concentrations of $P_2O_5$ at temperatures shown by that section of the curve between the melting point *D* and the eutectic point *C*.

Curve *CBA* shows the temperatures at which the solution is in equilibrium with the hemihydrate as the solid phase. The lowering of the melting point of the hemihydrate is represented by the section of the curve *BC*, *C* being the eutectic point (23·89°C. and 68·64% $P_2O_5$) at which the anhydrous and hemihydrated acids co-exist as solid phases with the solution.

Section *BA* represents the lowering of the melting point of the hemihydrate down to the second eutectic point *A*, at which this hydrate, ice and the solution co-exist. The most recent investigation places this point at −100°C. and 46·2% $P_2O_5$,[3] i.e. at a temperature somewhat lower than that previously reported,[1] but not inconsistent with the experimental data quoted therein. Observations of the freezing points at these low temperatures are difficult owing to the extreme viscosity prevailing.

Evidence for a hydrate $10H_3PO_4,H_2O$ was first obtained by Smith and Menzies,[7] but its existence could not be confirmed by later phase diagram studies[1,8]; however, small changes in the slope of the electrical conductivity–composition curves in this region, at 25°C., are claimed to indicate the presence of a hydrate with the composition quoted above.[8]

Pure orthophosphoric acid supercools readily; in the absence of nuclei, or agitation, acid corresponding in composition to the hemihydrate (91·6% $H_3PO_4$), which normally solidifies at 29·25°C., can be stored without crystallization for long periods at temperatures 10–20°C. below the melting point. Slow rates of crystallization have been reported[1] for supercooled orthophosphoric acids, e.g. 2·6 cm./min. in a horizontal tube at 22°C. for $H_3PO_4,\frac{1}{2}H_2O$, and confirmed.[9]

The transition temperature from the glassy to the liquid state in highly supercooled dilute solutions containing 0·5–10 mole-% $H_3PO_4$ was found to be −114°C. from differential thermal analysis measurements,[10] and −121°C. from a discontinuity in conductivity measurements.[11]

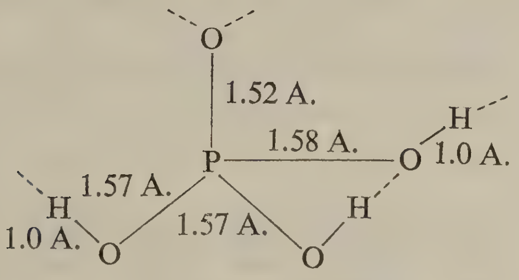
It has been suggested[12] from a study of the physical properties, such as specific heat, molal heat capacity, density, electrical conductivity and dielectric constant of aqueous solutions of orthophosphoric acid, that liquid hydrates are present which have ordered structures, with a preferential arrangement of solvent and solute molecules. For $H_3PO_4$, liquid hydrates with 0·5, 1, 4, 8, 12 and 28 molecules of water per mole of solute have been proposed.

## The Structure of Orthophosphoric Acid and its Hemihydrate

*X*-Ray diffraction studies have established that orthophosphoric acid molecules in the crystalline and liquid states of both the anhydrous and hemihydrated compounds contain $PO_4$ groups in which the oxygen atoms are arranged tetrahedrally around the central phosphorus atom[13-7]; a similar conclusion follows from Raman spectroscopic studies of liquid phosphoric acid and its solutions in water.[18-23] The Raman data, together with the infra-red spectra of $PO_4^{3-}$, $HPO_4^{2-}$, $H_2PO_4^{-}$,

$H_3PO_4$ and their deuterated analogues, have been assigned on the basis of a regular change of symmetry through the series $PO_4^{3-}(T_d)$, $HPO_4^{2-}$ (pseudo-$C_{3v}$), $H_2PO_4^-$ ($C_{2v}$ or lower), and $H_3PO_4$ (lower than pseudo-$C_{3v}$).[335] Urey–Bradley–Simanouti force constants have been calculated for the ions and the free acid, and discussed in relation to P–O bond orders.[336]

Investigations in all these fields have indicated that hydrogen bonding plays an important part in the structures of the crystalline and liquid forms of the acid. For example, three of the oxygen atoms of the $PO_4$ groups in the anhydrous acid are hydrogen-bonded to oxygen atoms in neighbouring $PO_4$ groups (see Fig. 2), whilst in the liquid or solution states hydrogen bonding occurs either to other $PO_4$ groups in the more concentrated acids (86% $H_3PO_4$) or to the water lattice at lower concentrations (54% $H_3PO_4$). Infra-red studies have shown an increased strength of hydrogen bonding in the sequence $HClO_4 < H_2SO_4 < H_3PO_4$, with a corresponding increase in the length of the OH bond, associated with a diminution in the bond force constant.[337]



--- = hydrogen bonds

FIG. 2.—The structure of orthophosphoric acid

The possible existence of ordered structures of liquid hydrates with a range of compositions has already been referred to.[12]

The structure of orthophosphoric acid hemihydrate has not been determined, although incomplete *X*-ray data have been published[14] which suggest that there are four formula weights per unit cell. Although the anhydrous acid and its hemihydrate have the same space group symmetry, it is not possible to deduce structural similarity from available *X*-ray data. However the study of the infra-red spectra of crystalline phosphoric acid and phosphoric acid hemihydrate in a low temperature cell disclosed the existence of a number of crystalline modifications as follows:

Phosphoric acid, cooled in liquid nitrogen or solid carbon dioxide, crystallizes to a glass, which on warming to −54°C. crystallizes to $H_3PO_4$-III. This is converted reversibly at −8° to −6°C., to $H_3PO_4$-I, which is stable at room temperature. A third phase, $H_3PO_4$-II, crystallizes from the melt between +8 and +15°C. if the latter has not been heated much above the melting point. $H_3PO_4$-II is stable if cooled down to −190°C., but when warmed up again is converted to $H_3PO_4$-I at −4° to 0°C.

The hemihydrate similarly forms a glass, which crystallizes at −54° to −49°C. to $H_3PO_4,\frac{1}{2}H_2O$-II. There is an irreversible transformation to $H_3PO_4,\frac{1}{2}H_2O$-I at −32° to −30°C., which is marked by a positive thermal effect, but produces little change in the spectrum.[338]

For a more detailed discussion of the structural chemistry of phosphoric acid see Section XXXIV.

## Density, Partial Molal Volume and Molecular Volume

### DENSITY

A self-consistent composition–density relation at 25°C. over the range 0 to 90% $H_3PO_4$ is represented by the four following equations[24]:

For 0–6% $H_3PO_4$

$$\bar{\rho} = (189{\cdot}5\sqrt{X}+5392{\cdot}0X)\times 10^{-6}$$
$$X = (\sqrt{185{\cdot}46\,\bar{\rho}+0{\cdot}0003088}-0{\cdot}01757)^2$$

For 5–90% $H_3PO_4$

$$\bar{\rho} = (5369{\cdot}1X+17{\cdot}913X^2+0{\cdot}21238X^3-0{\cdot}0005510X^4)\times 10^{-6}$$
$$X = (186{\cdot}3522\bar{\rho}-130{\cdot}8834\bar{\rho}^2+57{\cdot}6796\bar{\rho}^3)$$

where $\bar{\rho}$, the incremental density, is the density of the solution in g./ml., less 0·99707, the density of water at 25°C., and $X$ is the wt.-% of $H_3PO_4$.

The density equations are accurate to less than 1 part in 10,000, the corresponding errors in composition varying, nearly linearly, from just under 0·04% for the most dilute to just under 0·02% for the most concentrated solution.

The equations provide the data for Table I. Although the values quoted differ erratically from those given in International Critical Tables[25] by one or two units in the third decimal place of density, they are the most reliable yet available.

Measurements of the density of aqueous solutions of orthophosphoric acid have also been made at 15°–80°C.[26] Equations fitted to the data (overall deviation in representing the density 0·2 mg./ml.) gave the smoothed densities and density–temperature coefficients in Table II.

Other data[8] at 0°, 25° and 50°C. for orthophosphoric acid ranging in concentration from 0·38 to 98·5% $H_3PO_4$ are in fair agreement with those quoted in Table II. Values have also been recorded at temperatures up to 200°C.[339]

A useful nomograph giving the wt.-% of $H_3PO_4$ and the density of aqueous solutions at temperatures from 15° to 80°C. has been constructed.[28]

The density isotherms at 25°, 45°, 75° and 95°C. of $H_2SO_4$–$H_3PO_4$–$H_2O$ solutions at 33, 52, 63 and 73 wt.-% concentrations of $H_3PO_4+H_2SO_4$ have been determined. They are not linear, but slightly convex towards the composition axis.[340] The temperature dependence of density at equal concentrations is however nearly linear, and is given by the equation

$$\rho_t = \rho_{25}-\alpha(t-25)$$

Table II.—Smoothed Densities and Density-temperature Coefficients of Orthophosphoric Acid Solutions, g./ml.

MOLECULAR VOLUME

Extrapolated values for the density and molecular volume, $MV_0$, of orthophosphoric acid at −273°C. are given as 2·08 g./c.c. and 47·2 respectively.[29] Hence

$$\frac{MV_0}{n} = 11{\cdot}8$$

compared with 11·0 and 11·3 for sulphuric and nitric acids, and close to 10·9, the value of $MV_0$ for oxygen itself; $n$ equals the number of oxygen atoms in the molecule.

## Vapour Pressure

The vapour pressure of water over aqueous solutions of orthophosphoric, pyrophosphoric and other polyphosphoric acids has been studied by various methods over a wide range of composition and temperature. For example, measurements have been made by the static method of solutions containing 4·11–92·7% $P_2O_5$ at temperatures ranging from 25° to 866°C.[30-4]; by the isotonic method, calculated to activities, of solutions containing 1·2–63·7% $P_2O_5$ at 25°C.[35]; and by the dynamic method of solutions containing 62·7–79·6% $P_2O_5$ at 35°–280°C.[36]

The boiling points, at 1 atm., of solutions containing 9·1–92·7% of $P_2O_5$ have been observed[32–3, 37] and some measurements made of the composition of the vapour phase.[32, 38]

*Table V.—Vapour Pressure of Aqueous Orthophosphoric Acid*

Data for acids containing up to 87·99% $H_3PO_4$ (63·9% $P_2O_5$) have been correlated and tabulated,[39] the relevant portions being reproduced in Table V. The vapour pressures in Table V, calculated from equations of the form:

$$\log_{10} p_{\text{mm}} = -\frac{A}{T} - 4{\cdot}9373 \log T + 1{\cdot}639 \times 10^{-5}\, T + 4{\cdot}874 \times 10^{-8}\, T^2 + B$$

represent the data from which they were derived with a probable maximum error of 1%.

For solutions of higher concentration, including pyrophosphoric and polyphosphoric acid compositions, equations[32] based on the values quoted in Table VI may be used to calculate water–vapour pressures over solutions containing 61·6–92·7% $P_2O_5$.

Equations of the form:

$$\log_{10} p_{\text{mm}} = A - B/T$$

fit the data used for the compilation of Table VI with a maximum mean deviation of 3% in the temperature ranges quoted.

Two nomographs relating vapour pressures of orthophosphoric acid and concentrations have been presented,[40–1] of which the second is more useful since it covers a wider range of acid concentrations and is based on more complete data than the first.

The temperature–composition diagram for the complete system $P_2O_5$–$H_2O$ is described more fully in Section XXVI (page 734).

The vapour pressure of mixtures of aqueous orthophosphoric acid with nitric acid has been studied[42]; in contrast to the system $HNO_3$–$H_2SO_4$–$H_2O$, the total vapour pressure of the $HNO_3$–$H_3PO_4$–$H_2O$ system is a simple function of the nitric acid concentration[43] and there is evidence of only a slight tendency to form hydrates.

The vapours over mixtures of 100% nitric and 100% orthophosphoric acid contain no measurable excess of $H_2O$ or $N_2O_5$, from which it has been inferred that orthophosphoric acid cannot be greatly dehydrated in nitric acid solutions. Measurements at 0°C. of the partial pressure of the $HNO_3$ in a range of $H_3PO_4$–$HNO_3$ mixtures suggest that polymerization of $HNO_3$ rather than polyacid formation by elimination of water accounts for the observed results.[44]

## Viscosity

The viscosities of aqueous orthophosphoric acid solutions reported from various earlier sources[45-8] have been smoothed by graphical methods to yield the data[39,49] given in Table VII.

The estimated accuracy of the tabulated values is:

±10% for 0–110% $H_3PO_4$ at 25°C.
±15% for 0–75% $H_3PO_4$ at all temperatures except 25°C.
±10% for 75–118% $H_3PO_4$ at all temperatures.

Other values[8,50] at 0°, 25° and 50°C. for orthophosphoric acids ranging from 0·38 to 98·5% $H_3PO_4$ agree fairly well with those quoted in Table VII.

The most recent data at 25°C.[51] are contained in Table VIII; they are in agreement, where they overlap, with some previous measurements[52] which were not available for the compilation quoted in Table VII, but for solutions more concentrated than 1 molal (8·9% $H_3PO_4$) the viscosities are from 0·7 to 2·0% higher than the values stated therein.

Table VII.—Kinematic Viscosity of Orthophosphoric Acid

| Concentration of acid expressed as | | Viscosity, centistokes at indicated temperature, °C. | | | | | | | | | | | | | | | | | |

*Table VIII.—Dynamic Viscosity of Orthophosphoric Acid at* 25°C., *Centipoises*

| $H_3PO_4$ wt.-% | Viscosity | $H_3PO_4$ wt.-% | Viscosity |
|---|---|---|---|
| 0 | 0·8902 | 45 | 4·094 |
| 5 | 1·015 | 50 | 5·090 |
| 10 | 1·166 | 55 | 6·378 |
| 15 | 1·350 | 60 | 8·105 |
| 20 | 1·576 | 65 | 10·48 |
| 25 | 1·879 | 70 | 13·90 |
| 30 | 2·254 | 75 | 19·03 |
| 35 | 2·728 | 80 | 27·60 |
| 40 | 3·329 | | |

The average deviation of the values shown in Table VIII from observed viscosities is:

±0·15% for 2–21% $H_3PO_4$
±0·31% for 21–49% $H_3PO_4$
±0·77% for 49–83% $H_3PO_4$

The temperature dependence of the viscosity, $\eta$, of orthophosphoric acid has been discussed. The relationship between log $\eta$ and $1/T$ (absolute) is not linear,[53] neither is that between log $\eta/\eta_0$ and $1/T$ (absolute), except possibly for solutions containing less than 68% $H_3PO_4$ in the temperature range 25°–75°C.[50] The viscosity–composition isotherms of the $H_2SO_4$–$H_3PO_4$–$H_2O$ system also deviate from linearity,[340] the deviation becoming less at higher temperatures.[342]

A study of viscosities in the $P_2O_5$–$H_2O$ system at temperatures up to 200°C. showed a discontinuity at 130°–140°C., and a hysteresis effect below 80°, at around 72 wt.-% $P_2O_5$ ($\equiv H_3PO_4$). The viscosity returned to its original value overnight at room temperature. No similar discontinuity was shown by the $P_2O_5$–$SO_3$–$H_2O$ system, and $SO_3$ lowered the viscosity of the $P_2O_5$–$H_2O$ system. The activation energy for viscous flow of phosphoric acid solutions varied with concentration from 3·0 to 8·1 kcal./mole, showing a maximum in the region 100°–170°C. The results suggested that at high $P_2O_5$ concentrations and low temperatures phosphoric acid contains a hydrate and associated or condensed polymer systems.[343]

The relationship between the conductivity and viscosity of orthophosphoric acid solutions has also been studied; a linear correlation is said to exist between the logarithm of the specific resistance and the logarithm of the viscosity,[11] and a minimum has been noted at about 10% $H_3PO_4$ in the curve obtained when corrected conductivity, $(\lambda \times \eta/\eta_{H_2O})$, is expressed as a function of concentration.[50] The simple Falkenhagen formula[54] expressing the viscosity of electrolyte solutions as a function of concentration does not apply to 0·02–1·4 M. aqueous solutions of orthophosphoric acid at 25°C., but a modified formula, which considers the effect of association, is applicable.[52]

## Diffusion Coefficient

The concentration diffusion coefficient, $k$, corrected to 20°C., for aqueous solutions of orthophosphoric acid is reported[55] to be:

| Concentration $H_3PO_4$ | 0·25 N. | 1 N. | 2 N. | 3 N. |
|---|---|---|---|---|
| $k_{20}$ | 0·772 | 0·692 | 0·656 | 0·644 |

A later determination of the diffusion coefficient of aqueous orthophosphoric acid ($D$ in cm.$^2$ sec.$^{-1}$) shows that $D$ decreases from 0·036 to 1 M., remains roughly constant from 1 to 5 M. and then decreases again to 16 M. By extrapolation a value of $7{\cdot}6 \times 10^{-6}$ cm.$^2$ sec.$^{-1}$ is obtained for $D_m^\circ$, the hypothetical limiting diffusion coefficient for undissociated phosphoric acid at 25°.[302]

The thermal diffusion of orthophosphoric acid has also been investigated on the supposition that the velocity of thermal diffusion of the solute is accelerated by the presence of $H^+$ or $OH^-$ ions.[56]

Both the thermal and the concentration diffusion coefficients are smaller than those of strong acids, for example nitric or sulphuric acid, by a factor of about 3, consistent with the smaller degree of dissociation of orthophosphoric acid.

## Surface Tension and Parachor

Surface tension measurements[57, 18] (see Table IX) have been used to calculate the parachor[58] of 100% liquid orthophosphoric acid, and the value obtained denotes the presence of hydrogen bonding; concentrated nitric and sulphuric acids are also thought by the same reasoning to contain similar linkages.

*Table IX.—Surface Tension, $\gamma$, of Orthophosphoric Acid in dynes/cm.*$^2$

| °C. | $H_3PO_4$, wt.-% | | | |
|---|---|---|---|---|
| | 86·00 | 90·33 | 100* | 100·65 |
| 20 | 79·72 | 79·76 | 79·92 | 79·93 |
| 22·5 | 79·48 | 79·57 | 79·81 | 79·84 |
| 25·0 | 79·23 | 79·36 | 79·70 | 79·73 |
| 27·5 | 78·99 | 79·17 | 79·59 | 79·62 |
| 30·0 | 78·74 | 78·96 | 79·48 | 79·50 |

*Interpolated.

The parachor for 100% orthophosphoric acid calculated from these data is only 129·2, compared with the value of 169 obtained by adding together atomic parachors. This is indicative of association, the effect being greater than that shown, for example,

*Table X.—Relative Partial Molal Heat Content of Orthophosphoric Acid in Orthophosphoric Acid Solutions, $(\bar{H}_2 - \bar{H}_2^\circ)$, g.cal./mole* $H_3PO_4$

by sulphuric acid. It should also be remembered that liquid orthophosphoric acid undergoes reorganization (see page 702) with the formation of other species of polyacids.

Two other values of the parachor have also been reported, 144·4 for 2·55 molar orthophosphoric acid and 154·7 for 15·87 molar acid; two intramolecular hydrogen bonds have been postulated from these data, in agreement with *X*-ray crystallographic and Raman spectra studies.[59]

### Heat of Formation of, and Partial Molal Heat Contents and Free Energies in Phosphoric Acid Solutions

The heat of solution of orthophosphoric acid in water, based on early data, has been summarized[60] and tabulated.[39] Slightly different, but possibly more reliable, values are given in Tables X, XI, XII and XIII for the relative partial molal heat content of phosphoric acid in phosphoric acid solutions, $(\bar{H}_2 - \bar{H}_2^\circ)$, the relative partial molal heat content of water in phosphoric acid solutions, $-(\bar{H}_1 - \bar{H}_1^\circ)$, the relative partial molal free energy of phosphoric acid in phosphoric acid solutions, $(\bar{F}_2 - \bar{F}_2^\circ)$, and the relative partial molal free energy of water in phosphoric acid solutions, $-(\bar{F}_1 - \bar{F}_1^\circ)$, at 15°, 25°, 40°, 60°, 70° and 80°C. for phosphoric acid solutions ranging in concentration from 5% to 85% $H_3PO_4$.[61-3]

*Table XIII.—Relative Partial Molal Free Energy of Water in Orthophosphoric Acid Solutions,* $-(\bar{F}_1 - \bar{F}_1^\circ)$, *g.cal./mole* $H_3PO_4$

| 30 | 308·94 | 10000 | 309·41 |
| 40 | 309·00 | 20000 | 309·42 |
| 50 | 309·05 | 50000 | 309·43 |
| 75 | 309·12 | 100000 | 309·43 |
| | | ∞ | 309·44 |

In order to conform with the heats of formation recently reported[301] for $H_3PO_{4(c)}$ and $H_3PO_{4(l)}$, all the results tabulated above should be increased by 1·18 kcal.

The heats and free energies of formation and entropies of orthophosphoric acid in different reference states at 298·16° K. are as follow:

| | $H_3PO_{4(c)}$ | $H_3PO_{4(l)}$ | $H_3PO_{4(\infty H_2O)}$ |
|---|---|---|---|
| $-\Delta F_f^\circ$ kcal./mole | — | 268·73[39] | 274·40[39] |
| $-\Delta H_f^\circ$ kcal./mole | 306·20[62] | 303·10[62] | 309·44[62] |
| | 305·7 ± 0·3[301] | 302·1 ± 0·3[301] | |
| $S^\circ$, g.-cal./mole°C. | 26·41[2] | 38·3[39] | 37·6[39] |

The heats of neutralization of phosphoric acid to the three stages of ionization (p. 700) are 14·9, 12·3 and 7·5 kcal./mole respectively.[344]

### Specific Heat and Heat of Fusion of Crystalline Orthophosphoric Acid and its Hemihydrate

Although slightly differing heats of fusion based on freezing-point determinations have been reported,[39, 64] the most probable values[2, 301] are as follow:

$$H_3PO_{4(c)} = H_3PO_{4(l)}, \qquad \Delta H^\circ = 3200 \pm 400 \text{ g.-cal./mole}^{301}$$
$$H_3PO_4,\tfrac{1}{2}H_2O_{(c)} = H_3PO_4,\tfrac{1}{2}H_2O_{(l)}, \qquad \Delta H^\circ = 8762 \text{ g.-cal./mole}^{2}$$

The heat capacities, $C_p$, heat content, $(H - H_0^\circ)$, and entropy of the two crystalline forms are contained in Table XV.

*Table XV.—Heat Capacity, Heat Content and Entropy of* $H_3PO_{4(c)}$ *and* $H_3PO_4,\frac{1}{2}H_2O_{(c)}$

### Specific Heat of Aqueous Orthophosphoric Acid Solutions; Partial Molal Heat Capacity

Measurements[65] earlier than those tabulated below were limited to specific heats at 21°C. and average specific heats between this temperature and the boiling points of the acids investigated. Smoothed values from a more detailed and self-consistent set of data[61] are given in Table XVI.

A nomograph presenting these data has been devised.[66]

It has been pointed out that the rapid change in specific heat above 60°C.[61] may be accounted for by changes in the properties of water and the degree of hydration of the orthophosphoric ions present; sulphuric and acetic acids show similar behaviour.

*Table XVI.—Specific Heat $C_p$ of Orthophosphoric Acid Solutions, g.-cal./°C./g.*

| $H_3PO_4$ wt.-% | 15°C. | 25°C. | 40°C. | 60°C. | 70°C. | 80°C. |

*Extrapolated values

Partial molal heat capacities derived from these data[61] and given in Table XVII, when plotted against concentration, also show abrupt changes in slope at 0·1, 2·2, 4, 8 and 15 $m$ $H_3PO_4$, the break at 2·2 molality being the most pronounced. These, and similar changes with composition in the density, dielectric constant, conductivity, pH and activity at 25°C. possibly correspond to changes in the number or relative concentrations of species in solution.

*Table XVII.—Partial Molal Heat Capacities, $\bar{C}_{p_2}$, g.-cal./°C./mole, of* $H_3PO_4$ *in Orthophosphoric Acid Solution*

| $H_3PO_4$ wt.-% | °C. | | | | | |

| 100 | 37·63 | 38·11 | 38·39 | 39·28 | 39·33 | 39·33 |

Data for the relative partial molal heat capacity of water in orthophosphoric acid solution, $-(\bar{C}_{p_1} - \bar{C}_{p_1})$, are also available[61]; other partial molal data have been given above (page 674).

## Activity and Degree of Ionization of Orthophosphoric Acid

The activity of orthophosphoric acid at 25°C. has been calculated from vapour pressure measurements of aqueous solutions up to 10 *m*.[35] from e.m.f. measurements using the system[67]: Pb(two-phase amalgam)/$PbHPO_4(s)$, $H_3PO_4(m)/H_2$

$$E^{\circ}_{25} = 0{\cdot}2507 \text{ volt}$$

over the same range of molality, and from the system[68]:

$$Hg/Hg_2HPO_4(s),H_3PO_4(m)/H_2$$
$$E^{\circ}_{25} = -0{\cdot}6359 \text{ volt}$$

over the range 0–4 *m*. The results are compared in Table XVIII.

*Table XVIII.—The Activity, $a_u$ of Orthophosphoric Acid at 25°C.*

| $H_3PO_4$ molality $m$ | $a_u$ | | |
|---|---|---|---|
| | From vapour pressures[34] | From e.m.f. | |
| | | Lead phosphate electrode[67] | Mercurous phosphate electrode[68] |
| 0·02 | 0·01031 | 0·01045 | 0·01154 |
| 0·03 | 0·01738 | 0·01758 | 0·01771 |
| 0·05 | 0·03291 | 0·03331 | 0·0320 |
| 0·08 | 0·05851 | 0·05913 | 0·05521 |
| 0·10 | 0·07688 | 0·07779 | 0·06973 |
| 0·20 | 0·1605 | 0·1708 | 0·1530 |
| 0·30 | 0·2493 | 0·2675 | 0·2386 |
| 0·40 | 0·3417 | 0·3666 | 0·3336 |
| 0·60 | 0·5360 | 0·5809 | 0·5199 |
| 0·80 | 0·7425 | 0·8132 | 0·7211 |
| 1·00 | 0·9615 | 1·06 | 0·9108 |
| 2·00 | 2·275 | 2·585 | 1·965 |
| 4·00 | 6·461 | 7·60 | 4·223 |
| 8·00 | 27·96 | 33·37 | — |
| 10·00 | 49·97 | 58·64 | — |

At concentrations of orthophosphoric acid from 0·02–0·1 *m*., the activities calculated from the vapour pressure measurements are in good agreement with those obtained from the e.m.f. of the lead phosphate electrode; divergence at higher concentrations is attributed to the increased solubility of lead phosphate in the more concentrated acid.

The values reported by Larson[68] do not depend on the applicability of the Debye–Hückel limiting law at concentrations in the range 0–0·1 *m*., as do those of Elmore *et al.*[35] and Mason and Blum[67]; nor, in the absence of data, have any corrections been made for the solubility of mercurous phosphate.

The activity coefficient of the undissociated part of the orthophosphoric acid, ($\gamma_u \equiv 1$), does not vary over the range 0·02–0·1 *m*.

The activity of water in solutions of orthophosphoric acid, as calculated from the vapour pressure of the solutions,[35] is shown in Table XIX. These values are generally in good agreement with previous data.[30, 34]

The degree of ionization of orthophosphoric acid has been calculated[35] from conductance data[69] and ionization constants[70] by the method of Banks,[71] giving the values in Table XX, which were used to calculate some of the activities listed in Table XIX.

## The Acidity Function of Orthophosphoric Acid

The acidity function, $H_0$, which measures the ability of a medium to transfer a proton to a neutral molecule, is defined by Hammett[72] as:

$$-H_0 = \log a_{\mathrm{H}^+} + \log \frac{f_{\mathrm{B}}}{f_{\mathrm{BH}^+}},$$

where $a_{\mathrm{H}^+}$ is the hydrogen ion activity and $f_{\mathrm{B}}$ and $f_{\mathrm{BH}^+}$ are the activity coefficients of the neutral molecule and conjugate acid respectively; in dilute solution the acidity function is substantially the same as the pH.

*Table XIX.—Activity of Water ($a_1$) in Orthophosphoric Acid Solutions, at 25°C.*

| $H_3PO_4$ molality $m$ | Activity of water ($a_1$) | Reference standard |

| 0·06 | 0·3473 |
| 0·07 | 0·3301 |
| 0·08 | 0·3162 |
| 0·09 | 0·3040 |
| 0·10 | 0·2938 |

The first measurements on orthophosphoric acid,[73] using the method of Hammett and Deyrup,[72] gave values for $H_0$ varying from $+1{\cdot}08$ to $-3{\cdot}34$ for acid solutions ranging from 5 to 80% $H_3PO_4$, at 19 ± 2·0°C. These data were extended, by similar methods, to cover solutions containing 62–86% of $P_2O_5$, that is, to include pyrophosphoric and other polyphosphoric acids.[74-5]

The last data[74-5] are in good agreement below 62% $P_2O_5$ (86% $H_3PO_4$), but contrary to Gel'bshtein *et al.*[74] the results of Downing and Pearson do not show a maximum in the plot of $H_0$ versus % $P_2O_5$ at 80% $P_2O_5$, corresponding approximately with the formula $H_4P_2O_7$ for pyrophosphoric acid. As other parameters such as density, viscosity, refractive index and composition show regular change over the concentration range in question, it is now believed that the reported maximum for $H_0$ can be ascribed to decomposition of the particular indicator used to measure this quantity, and not to an abrupt change in the nature of the acid, especially since later work by the same authors did not show any maximum value for $H_0$.[345] According to Downing and Pearson the value of $H_0$, at 25°C., changes steadily from $-4{\cdot}1$ for 89·6% $H_3PO_4$ (65% $P_2O_5$) to $-7{\cdot}1$ for 118% $H_3PO_4$ (85·7% $P_2O_5$). Gel'bshtein *et al.* now confirm this monotonic variation over a wider range of concentration, from $+0{\cdot}92$ for 3·6% $H_3PO_4$ (5% $P_2O_5$), through $-4{\cdot}03$ at 65% $P_2O_5$ to $-6{\cdot}84$ at 85% $P_2O_5$.[345]

The acidity function can also be correlated with the activities of water and phosphoric acid in aqueous solutions by the linear relationship[76]:

$$H_0 = -0{\cdot}80+0{\cdot}98 \log \frac{(a_{HX})}{a_{H_2O}}$$

which fits the data for $H_0$[73] and activities.[35] Hydrochloric and perchloric acids behave similarly, but sulphuric acid shows a curvilinear relationship. On any basis of comparison the acidities of the conventional strong acids are considerably higher than that of orthophosphoric acid.

The acidity function of orthophosphoric acid in acetic acid has also been studied.[77-8]

## Refractive Index of Orthophosphoric Acid

Systematic studies of the refractive index of orthophosphoric acids have not been reported; values quoted in Table XXI[79] cover the more dilute range of concentrations and the linear equation:

$$\%\ P_2O_5 = 522{\cdot}09\ n_D^{25} - 685{\cdot}07$$

has been proposed[75] for solutions containing 60–85% of $P_2O_5$. Over a wider concentration range the refractive index, $n$, of phosphoric acid solutions at 25°C. for the Hg (green) line at 5460·7 A. is said to be given by the equation:

$$n = 1{\cdot}333977+0{\cdot}001999w^{1/2}+0{\cdot}07155w+0{\cdot}0868841w^{3/2} -0{\cdot}2375104w^2+0{\cdot}3625678w^{5/2}-0{\cdot}1669960w^3$$

where $w$ is the concentration, weight fraction, of $H_3PO_4$ from 0 to 0·90.[346]

*Table XXI.—Refractive Index, $n_D^{17{\cdot}5}$, of Orthophosphoric Acid Solutions*

| % $H_3PO_4$ | % $P_2O_5$ | $n_D^{17{\cdot}5}$ |
|---|---|---|
| 0 | 0 | 1·33320 |
| 5 | 3·62 | 1·33775 |
| 10 | 7·24 | 1·34203 |
| 20 | 14·49 | 1·35032 |
| 30 | 21·73 | 1·35846 |

The two sets[75,79] of data do not fit on extrapolation, nor are earlier values[80] in agreement with those quoted in Table XXI, partly owing to the determinations having been made at different temperatures.

Differential refractometry has been employed to study the degree of dissociation of dilute solutions of orthophosphoric acid[81] and a value of $n_D^{20}=1{\cdot}4503$ has been reported for anhydrous orthophosphoric acid crystals.[4]

## Magnetic Susceptibility and Dielectric Constant of Orthophosphoric Acid

The molar magnetic susceptibility, $-\chi_m$, of orthophosphoric acid has been measured[82-3] and is of the order of $45\times10^{-6}$.

The variation with concentration of the dielectric constant of dilute aqueous solutions of phosphoric acid has been investigated. A point of inflection in the curve plotting dielectric constant against concentration can be attributed to hydration of the ions; some average values[84] for solutions at 20·2° to 21·5°C. are contained in Table XXII.

*Table XXII.—Dielectric Constant of Orthophosphoric Acid Solutions*

| $H_3PO_4$ wt.-% | Dielectric constant $\epsilon$ |
|---|---|
| 0 | 80·0 |
| 0·10 | 77·5 |
| 0·15 | 74·9 |
| 0·20 | 68·4 |
| 0·25 | 73·7 |
| 0·30 | 79·0 |
| 0·40 | 80·6 |
| 0·50 | 80·4 |

Values at higher concentrations have also been recorded. The dielectric constant of 100% $H_3PO_4$ at 25°C. and 4·89–19·32 Mc/sec. is $61 \pm 12$, the high value confirming association by hydrogen bonding[347] (see p. 571). The static dielectric constant, $\epsilon_0$, at 3, 10 and 17 Gc/sec. decreases from 78 for water to a minimum of 19 for 65 *m* $H_3PO_4$,[348] confirming previous observations at lower frequencies.[347]

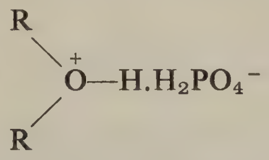
## Solubility of Orthophosphoric Acid in Organic Solvents

Orthophosphoric acid is soluble in a large number of organic solvents.

Thermal analysis of the system diethyl ether–orthophosphoric acid in the concentration range 0–17·5% ether showed[85] the existence of two compounds:

| | | |
|---|---|---|
| | $(C_2H_5)_2O,6H_3PO_4$ | m.p. 28·2°C. |
| and | $(C_2H_5)_2O,4H_3PO_4$ | m.p. 30·0°C. |

An equimolecular compound, $(C_2H_5)_2O,H_3PO_4$, reported from calorimetric measurements,[86] is believed to have an oxonium type structure:



but the compound has not been isolated in the solid state.

The partition coefficient at 23°C. for $H_3PO_4$ between water and diethyl ether[87] is shown in Table XXIII.

*Table XXIII.—Partition Coefficient of* $H_3PO_4$ *between Water and Diethyl Ether at* 23°C.

| g. $H_3PO_4$ in | | Partition coefficient |
|---|---|---|
| 100 g. $H_2O$ | 100 g. $(C_2H_5)_2O$ | |
| 34·8 | 0·01 | 0·00064 |
| 82·0 | 0·26 | 0·0032 |
| 105·0 | 0·95 | 0·009 |
| 136·5 | 1·78 | 0·136 |

The solubility of diethyl ether in orthophosphoric acid is small.[88]

The application in industrial practice of the solubility of orthophosphoric acid in organic compounds to solvent extraction processes for the separation and purification of the acid has been mentioned (Section XXIV, page 667), and has resulted in a search for the most effective solvents. Of eighteen investigated the best were found to be *iso*amyl alcohol and fusel oil[89]; in a more recent investigation[90] the most effective solvents out of the twenty-four mentioned were tertiary amyl alcohol, butanol, *cyclo*hexanol, 2-hydroxyethyl-*n*-hexyl ether, *cyclo*pentanone and tri-*n*-butyl phosphate. The distribution coefficients, $K = C_0/C_w$, where $C_0$ is the equilibrium concentration of total solute in the organic phase, in g. moles/l. and $C_w$ that of the total solute in the aqueous phase in the same units for all the solvents, are given in Table XXIV.

*Table XXIV.—Distribution Coefficients, K, at* 25°C., *for* $H_3PO_4$ *between Water and Various Solvents*

| Solvent | *K* |
|---|---|
| *tert*-amyl alcohol | 0·1648 |
| *n*-butanol | 0·1462 |
| *cyclo*hexanol | 0·0908 |
| 2-hydroxyethyl-*n*-hexyl ether | 0·1294 |
| octylene glycol | 0·0674 |
| *cyclo*pentanone | 0·2371 |
| *iso*amyl alcohol | 0·0471 |
| *n*-amyl alcohol | 0·0478 |
| 2-hydroxyethyl phenyl ether | 0·0437 |
| *n*-hexyl alcohol | 0·0312 |
| benzyl alcohol | 0·0264 |
| tri-*n*-butyl phosphate | 0·1149 |
| 2-ethyl-l-butanol | 0·0149 |
| *o*-chlorophenol | 0·0050 |
| *n*-butyl ether | 0·00003 |
| triperfluorobutylamine | 0·0000 |
| acetophenone | 0·0005 |
| ethyleneglycol dibutyl ether | 0·0000 |
| thiophen | 0·0000 |
| methyl *iso*butyl ketone | 0·0003 |
| chloroform | 0·00007 |
| carbon tetrachloride | 0·00007 |
| *n*-hexyl ether | 0·0034 |
| 1-pentamethiol | 0·0004 |

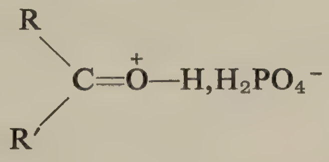
The theory of the extraction by such solvents of orthophosphoric acid alone, or in admixture with hydrochloric acid, and the effects on the distribution coefficient of such factors as the chemical and physical character of the solvent, acid concentration, acidity, and activity coefficients have been discussed on the basis of data obtained in such studies.[90, 304–6] A similar study of the effect of electrolytes on the distribution of orthophosphoric acid between water and *iso*amyl alcohol showed, as expected, that the proportion of acid dissolving in the organic phase increased with increasing salt concentration. The effectiveness of a series of chlorides in altering the distribution coefficient was related to the charge and radius of the cations:

$$Mg^{++} > Li^{+} > Ca^{++} > Sr^{++} > Na^{+} > NH_4^{+} > K^{+}$$ [307]

Orthophosphoric acid hemihydrate dissolves readily in benzyl cyanide to the extent of 0·5 g. $H_3PO_4,\frac{1}{2}H_2O$ per ml., and if dioxan is then added, the addition compound dioxan, $2H_3PO_4$, m.p. 82°–85°C., crystallizes out.[91] The anhydrous acid is soluble to the extent of 26% in ethyl acetate, in which solution *trans*-esterification is thought, from Raman spectroscopic evidence,[22] to occur to a slight extent.

The solubilities of phenol and of citric, malic, oxalic, succinic and *iso*valeric acids in orthophosphoric acid of various concentrations have been measured[92] and there are indications that compound formation, similar to that mentioned for diethyl ether, takes place.

Freezing studies[93] on a wide range of organic substances, including acids, esters, aldehydes, ketones, phenols and acid anhydrides, with orthophosphoric acid as one component, showed that several addition compounds could be isolated from the system as crystalline compounds, their general formula being of the type:



The compounds which formed such oxonium salts were acetic and pyruvic acids, benzaldehyde, anisaldehyde, acetophenone, benzophenone and coumarin. Sulphuric acid forms such compounds more readily than orthophosphoric acid, by virtue of its higher acidity function (q.v.).

The interaction between phosphoric acid and polar organic solvents has also been studied by proton magnetic resonance. The solvents were of two types:

I (including $Me_2SO$, $Me_2CO$, $(MeO)_3PO$ and $Et_2O$); polar solvents which form complexes, and also dissociate and eventually ionize the acid, the solvent donor properties decreasing in the order shown above.

II (including MeOH, EtOH (and $H_2O$)); polar solvents which are themselves associated, and besides exhibiting the above behaviour, also dissociate themselves and exchange protons with phosphoric acid.[349]

The infra-red spectra of non-aqueous solutions of phosphoric and deuterophosphoric acid have been recorded.[350]

The ternary system orthophosphoric acid–phenol–water[94] is of interest because it exhibits closed layering isotherms in the temperature range 68°–100°C., which are the upper binary critical temperature for the system phenol–water and the lower binary critical temperature for the system orthophosphoric acid–phenol, respectively; closed isotherms are typical when such conditions occur. The compound $H_3PO_4,\frac{1}{2}H_2O$ was noted in the relevant binary system.

Fewer data are available for the solubility of orthophosphoric acid in inorganic solvents other than water. It is, however, known to be sparingly soluble in anhydrous liquid hydrogen chloride, and does not act as a solvo-acid in this medium.[308]

The solubility of oxygen and paraffin hydrocarbons in phosphoric acid solutions has been measured in connection with research on fuel cells.[351-3] The solubility of oxygen at 25° and 30°C., as determined by a gas-liquid chromatographic method,[352] falls off rapidly and continuously with increasing acid concentration.[351] A correlation has been presented to enable the solubility of oxygen and hydrocarbons in 85–105% phosphoric acid to be predicted with reasonable accuracy.[353]

## Electrical and Thermal Conductivity of Orthophosphoric Acid

### SPECIFIC AND EQUIVALENT CONDUCTIVITY

Table XXV[39] contains information derived from sources prior to 1927, together with more recent data[95] obtained at 25°C.

Measurements have also been reported[50] for slightly higher concentrations of acid than those of Noyes *et al.*,[96] but not over as wide a range of temperature. At 25°C. they are only in agreement with the values given in Table XXV at concentrations below 30% and above 80% $H_3PO_4$; inside this range they are about 10–15% lower.

At 50°C. they are also much lower than numerous values quoted at the same temperature[8]; the data at 0° and 25°C. are in excellent agreement with those given in Table XXV. Values at 50°C. are therefore given from reference 8 in Table XXVI.

*Table XXV.—Electrical Conductivity of Aqueous Orthophosphoric Acid*

Maxima in the specific conductance–concentration curves in the region of 40–50% $H_3PO_4$, tending to higher concentrations with increasing temperature,[95, 50, 8] agree with previous reports[96] and suggest the presence of hydrated ions. However, conductivity isotherms corrected for variation of viscosity and molar volume are claimed to show no such maximum.[309]

According to most authors, the temperature coefficient of specific conductivity changes from positive to negative as the temperature increases and the temperature of maximum conductivity varies with the acid concentration[8] as shown in Fig. 3.

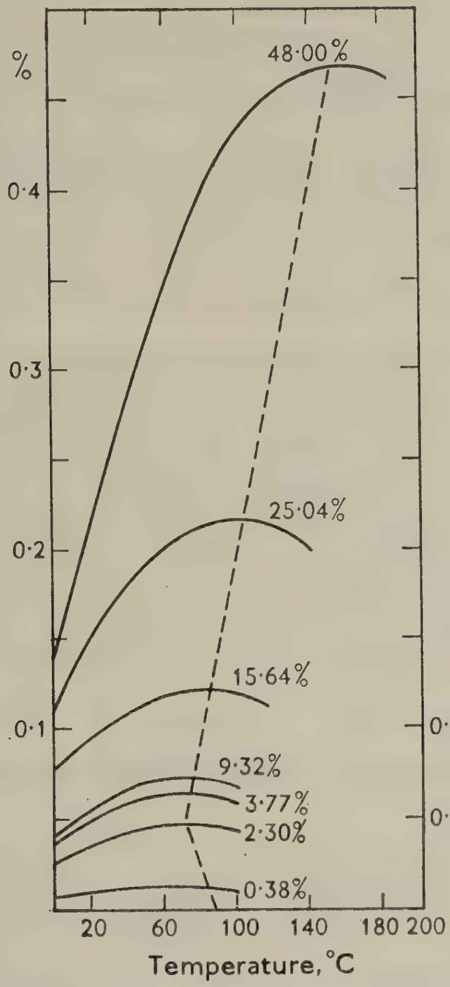

FIG. 3.—Variation of specific conductivity of orthophosphoric acid with temperature

More recent studies of the conductivity of a series of acids of more than 90% $H_3PO_4$ content show that in this case also conductivity increases with temperature over the range 20° to 200°C. At any particular temperature the conductivity falls with increasing $P_2O_5$ concentration.[310, 354] Values for the equivalent conductivity of more dilute (0·01–1·5 N.) phosphoric acid have been recorded as high as 300°C.[355]

A single set of observations on 0·13 M. (1·08% $H_3PO_4$) orthophosphoric acid, at temperatures up to 200°C. and pressures up to 15·30 atm. also shows a maximum in specific conductivity at about 70°C.[97]

The surprisingly low limiting equivalent conductance of the dihydrogen phosphate ion ($\lambda^{\circ}_{H_2PO_4^-}$), reported as $33 \pm 1{\cdot}0$ ohm$^{-1}$ cm.$^2$ on the basis of calculations from the e.m.f. of suitable concentration cells using the lead amalgam–lead hydrogen phosphate electrode,[98] was in agreement with values derived from the conductances of $KH_2PO_4$ and $Na_2HPO_4$.[95] The validity of the interpretation of these data was, however, questioned,[98] and recalculation gave an even lower value ($\lambda^{\circ}_{H_2PO_4^-} = 16$ ohm$^{-1}$ cm.$^2$) which was apparently confirmed by some fresh measurements of e.m.f.

and transference numbers, using concentration cells with a mercury–dimercury hydrogen phosphate electrode system. However, a further determination of the transference number of $H_3PO_4$ by the moving boundary method gave quite different results, which cast doubt upon the accuracy of the e.m.f. method in regions of low concentration. These new data led to a value of $\lambda^\circ_A = 40{\cdot}2$ ohm$^{-1}$ cm.$^{-2}$ for the limiting conductance of the [$H_2PO_4^-$] ion.[356] Nevertheless they suggested that the cationic transference number $t_H$ increases with increasing concentration, an observation which was not supported by other workers.[98, 357, 359] A later study[357] by a similar method showed that these data could all be reconciled by assuming the occurrence of hydrogen bonded triple ions, $H_2PO_4^-.H^+.H_2PO_4^-$ with a formation constant of 3 l./mole. Recalculation of the data of[356], allowing for triple ion formation and for hydrolysis in the following $KH_2PO_4$ solution, gave a value of $\lambda^\circ_A = 35{\cdot}6$ ohm$^{-1}$ cm.$^2$. This was in better agreement with subsequent values of 31·9,[368], 32·3[357] and 32·8 ([357] recalc. from the data of[95]) ohm$^{-1}$ cm.$^2$ In order to account for the difference in the values of $\lambda^\circ_{H_2PO_4^-}$ derived from conductance and e.m.f. data, the presence, even in dilute solutions, of the species $H_4PO_4^+$ had been suggested[98, 303] according to the equilibrium:

$$H^+ + H_3PO_4 \rightleftharpoons H_4PO_4^+$$

and if this were so calculation would lead to the value of 250 ohm$^{-1}$ cm.$^2$ for $\lambda^\circ_{H_4PO_4^+}$. Some support for this view has been derived from a study of the exchange of oxygen between phosphoric acid and water as a function of concentration and temperature (155°–170°C.) The exchange velocity fell to a minimum value at an acid concentration of 2–2·5 M. The results suggest the presence of $H_4PO_4^+$ in concentrated solutions, while in dilute solutions $H_2PO_4^-$ is probably the active exchange agent.[358] However, in view of the close correlation between results from the conductance and moving boundary methods, it is more likely that the discrepancy shown by the e.m.f. method is due to the fact that the method of calculation magnifies any errors in the e.m.f. data, particularly at low concentrations.[356-7]

### TRANSFERENCE NUMBER

The transference numbers ($t_H$) for orthophosphoric acid, at 25°C.,[98] are contained in Table XXVII.

*Table XXVII.—Transference Numbers for Orthophosphoric Acid Solutions at* 25°C.

| Molarity | 0·02 | 0·10 | 0·50 | 2·00 | 4·00 |
|---|---|---|---|---|---|
| $t_H$ | 0·952 | 0·933 | 0·914 | 0·897 | 0·889 |

Transference numbers of the phosphate ($H_2PO_4^-$) anion have been determined at 25°C by a radioactive ($^{32}P$) modification of the Hittorf method. The range of concentration covered (0·027–0·43 mol. fraction) was much greater than in previous work (e.g. Ref. 98). The isotherm shows a maximum value of 0·065 g. mole F$^{-1}$ at an acid mol. fraction of 0·15.[359]

### CONDUCTIVITY IN MELTS

The mechanism of electrical conduction in melts of anhydrous[4] and hemihydrated[5] orthophosphoric acid has been studied and provides some evidence in support of the $H_4PO_4^+$ anion mentioned previously and also of the presence of pyrophosphoric acid in liquid anhydrous orthophosphoric acid. The abnormally high electrical conductivity of the latter (similar in this respect to sulphuric acid[99]) is believed to be due to the $H_2PO_4^-$ ion conducting current by a proton-switch mechanism[4, 22, 343, 359] (see also Ref. 360). The ionic equilibrium may be represented as follows:

$$(a) \qquad 2H_3PO_4 \rightleftharpoons H_4PO_4^+ + H_2PO_4^-$$

However, the electrical conductivity of fused orthophosphoric acid falls slowly with time to an equilibrium value corresponding to the formation of pyrophosphoric acid, thus:

$$(b) \qquad 2H_3PO_4 \rightleftharpoons H_3O^+ + H_3P_2O_7^-$$

for the existence of which, in such a melt, there is abundant evidence from chromatographic analysis,[100-1] cryoscopic and e.m.f. measurements[361] and isotope exchange studies.[102] The observed 15% decrease in conductivity corresponds to 7·5 mole-% of pyrophosphoric acid.

If pure crystalline orthophosphoric acid, m.p. 42·35°C., is kept molten for several weeks, its freezing point falls to 34·6°C., owing to the setting up of the equilibrium represented by equation (*b*); cryoscopic calculations from this freezing-point depression lead to 5·8 mole-% of pyrophosphoric acid,[4] in fair agreement with the values deduced from conductivity decrease, chromatography (6·5 mole-%) and isotopic exchange studies.[102]

Measurements of the conductivity of orthophosphoric and trideuterophosphoric acids made quickly after melting and given in Table XXVIII,[4] are thought to be preferable to earlier values, on account of the slow change referred to above.

*Table XXVIII.—Specific Conductance (K) of Orthophosphoric and Trideuterophosphoric Acid, ohm$^{-1}$ cm.$^{-1}$ × 10$^2$*

| Temperature °C. | 25 | 30 | 40 | 50 | 60 |
|---|---|---|---|---|---|
| $H_3PO_4$ | 4·675 | 5·589 | 7·680 | 10·13 | 12·70 |
| $D_3PO_4$ | 2·818 | 3·378 | 4·632 | 5·94 | 7·261 |

Thus deuteration lowers the specific conductivity of orthophosphoric acid by about 60%. Later data covering a wider range of concentrations (62–86% $P_2O_5$)[362] are in reasonable agreement with the values of Greenwood and Thompson[4] but differ slightly from the values of previous authors.[310, 363]

According to the recent measurements of Greenwood and Thompson,[4] although there is a change in the slope of the 40°C. isotherm of the composition–conductivity diagram (see Fig. 4), there is no minimum and neither is there an inflection in the region of composition corresponding to the hemihydrate $2H_3PO_4,H_2O$. The change of slope occurs at 25 mole-% of $P_2O_5$, that is to say at a composition corresponding to $H_3PO_4$. Addition of water to an acid of this composition increases and addition of phosphoric oxide decreases the conductivity. It is suggested[4] that, being a more powerful proton-acceptor than $H_3PO_4$, water removed protons from $H_4PO_4^+$ and thus raises the concentration of the current-carrying $H_2PO_4^-$ ion, as follows:

$$(c) \qquad 2H_4PO_4^+ + 2H_2O \rightarrow 2H_3O^+ + 2H_3PO_4$$

$$(d) \qquad 2H_3PO_4 \rightleftharpoons H_4PO_4^+ + H_2PO_4^-$$

the overall effect being:

$$(e) \qquad H_4PO_4^+ + 2H_2O \rightarrow 2H_3O^+ + H_2PO_4^-$$

By analogy with the sulphuric acid system,[103] the hydroxonium ion is unlikely to have abnormal mobility and the increase in conductivity may therefore be ascribed to the increased concentration of the $H_2PO_4^-$ ion. On the other hand, addition of phosphoric oxide, which reduces conductivity, involves the more complex solvolysis of the $P_4O_{10}$ molecule (q.v.), but the overall reaction can probably be written:

$$(f) \qquad P_4O_{10} + 8H_3PO_4 \rightarrow 6H_4P_2O_7$$

with some dissociation of the pyrophosphoric acid by the equilibrium:

$$(g) \qquad H_4P_2O_7 + H_3PO_4 \rightleftharpoons H_4PO_4^+ + H_3P_2O_7^-$$

As conductivity decreases sharply, and neither of these ions is thought to have appreciable abnormal mobility, the fall is due to the decrease in $H_2PO_4^-$ ion concentration by the removal of orthophosphoric acid (equations (*f*) and (*g*)). The lack of mobility of $H_3P_2O_7^-$ probably resembles that of the $HS_2O_7^-$ ion in sulphuric acid.[104] $H_4PO_4^+$ lacks a dipole moment, and hence any proton-switches in which it was involved would be randomly effected and not in the preferred direction of the applied field.

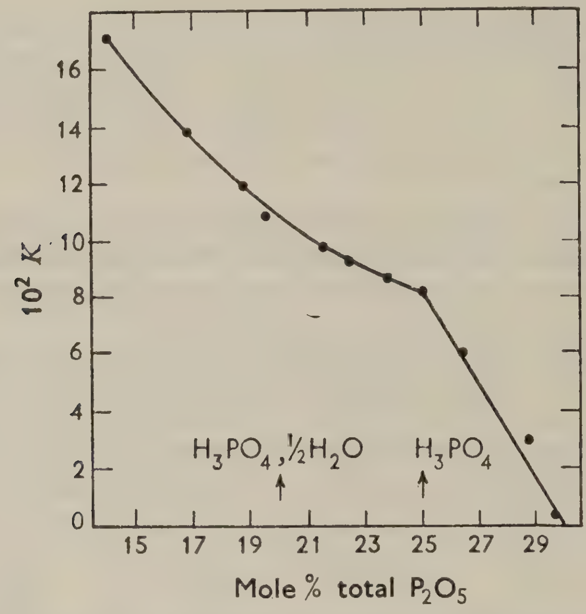

FIG. 4—Conductivity–composition isotherm for $H_2O$–$P_2O_5$ at 40°C.

The extent of the protolysis described by equation (*a*) has been estimated[4] and is compared with that for sulphuric acid and water:

$$K_{(\text{apparent})}[H_4PO_4^+][H_2PO_4^-] = 1{\cdot}7 \times 10^{-2} \text{ mole}^2 \text{ kg.}^{-2} \text{ at } 25°\text{C.}$$
$$(H_2SO_4) = 2{\cdot}9 \times 10^{-4} \text{ mole}^2 \text{ kg.}^{-2} \text{ at } 25°\text{C.}$$
$$(H_2O) = 1{\cdot}01 \times 10^{-14} \text{ mole}^2 \text{ kg.}^{-2} \text{ at } 25°\text{C.}$$

The initial concentration of ions in molten orthophosphoric acid is therefore about eight times that in sulphuric acid and stronger by a factor of $10^6$ compared with water.

Although no discontinuity was observed in the conductivity–mole % $P_2O_5$ curve, shown in Fig. 4, at the composition $2H_3PO_4,H_2O$ the hemihydrate certainly exists as a solid phase; its high electrical conductivity in the molten state is almost double that of the freshly molten anhydrous acid, and has also been shown by transport measurements to be due to the presence of the anomalously conducting species, $H_2PO_4^-$, which provides a proton-switch mechanism. Unlike the anhydrous acid, however, the conductivity of fresh melts of the hemihydrate does not vary with time.[5]

*Table XXIX.—Specific Conductance (K) of Molten Orthophosphoric Acid Hemihydrate, ohm$^{-1}$ cm.$^{-1}$ × $10^2$*

| °C. | 25 | 30 | 40 | 50 | 60 | 70 |
|---|---|---|---|---|---|---|
| $2H_3PO_4,H_2O$ (melt) | 7·008 | 8·230 | 10·99 | 14·66 | 17·50 | 21·21 |

The conductivity of the solid hemihydrate is much less than that of a liquid with the same composition, Table XXX.

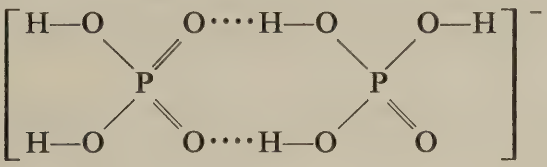
*Table XXX.—Specific Conductance (K) of Crystalline Orthophosphoric Acid Hemihydrate, ohm$^{-1}$ cm.$^{-1}$ × 10$^3$*

| °C. | 19 | 21 | 23 | 25 | 26 |
|---|---|---|---|---|---|
| $2H_3PO_4,H_2O$ (cryst.) | 0·97 | 1·22 | 1·63 | 2·36 | 3·12 |

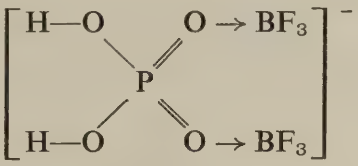
It has been suggested[5] that, when molten hemihydrate ionizes, the anomalously conducting ion $H_2PO_4^-$ solvates with the liberated phosphoric acid thus:

$$(h) \qquad 2H_3PO_4 + H_2O \rightarrow 2H_3PO_4,H_2O \rightleftharpoons H_3O^+ + H_3PO_4,H_2PO_4^-$$

and that the stability of the solvated ion arises from hydrogen-bonding, for example,

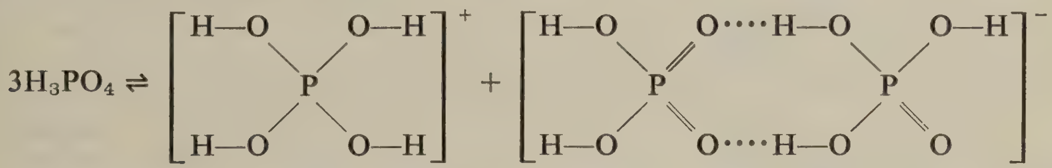


It is of interest, in this connection, to note that in the absence of hydrogen bridges in the postulated structure for the boron trifluoride ion-complex of orthophosphoric acid:



the proton-switch conduction mechanism is suppressed.[105] It is also possible that the $H_2PO_4^-$ ion is solvated in melts of anhydrous orthophosphoric acid, for example,

(*i*)



On the basis of equation (*h*), the autoprotolysis constant of phosphoric acid hemihydrate at 25°C. has been calculated, and is slightly larger than that of the parent acid:

$$K_{(\text{apparent})}(2H_3PO_4,H_2O) \simeq 4{\cdot}4 \times 10^{-2} \text{ mole}^2 \text{ kg.}^{-2}$$

### CONDUCTIVITY OF AQUEOUS $H_3PO_4$–HCl AND $H_3PO_4$–$N_2O_4$

The abnormally low electrical conductivities reported by Pessel[106] for mixtures of orthophosphoric acid and hydrochloric acid were later[107] attributed to the unrecognized presence of sodium salts in the original preparations; mixtures of pure orthophosphoric acid, prepared from phosphoric oxide, with hydrochloric acid or sulphuric acid had conductivities of the orders expected. However the conductimetric and cryoscopic behaviour of the $H_3PO_4$–$H_2SO_4$ and similar systems has been explained by assuming association[343, 369]:

$$2H_3PO_4 + H_2SO_4 \rightarrow [P(OH)_4{}^+]_2SO_4{}^{--}$$

while infra-red[328] and conductivity-transference number[365] studies suggested the existence of the species $2H_2SO_4,H_3PO_4$ in a mixture containing 0·31 mole fraction of $H_3PO_4$.

The effect on the electrical conductivity of replacing water in hydrochloric acid by orthophosphoric acid has been systematically studied. For solutions of hydrochloric acid less than 1N. the conductivity increases with added orthophosphoric acid, but for solutions of higher normality the reverse is true. These changes have been discussed in terms of ion concentration and viscosity.[108]

Solutions of dinitrogen tetroxide, $N_2O_4$, in orthophosphoric acid also exhibit a maximum in their conductivity–concentration curves,[109] at 0·06 mole-% of $N_2O_4$, which is thought to be connected with a change in colour from colourless to yellow. Similar effects have been noted for nitryl fluoride, $NO_2F$.[110] Solutions containing more than 1 mole-% $NO_2F$ are coloured and at 60 mole-% a solid separates. The conductivity–concentration curve passes through a small initial maximum at the lower and through a second blunt maximum at the higher concentration; all these phenomena are indicative of complex formation.

### THERMAL CONDUCTIVITY

Few data are available on the thermal conductivity of phosphoric acid, but a nomograph covering the range 5–50% has been constructed[311] (Fig. 5).

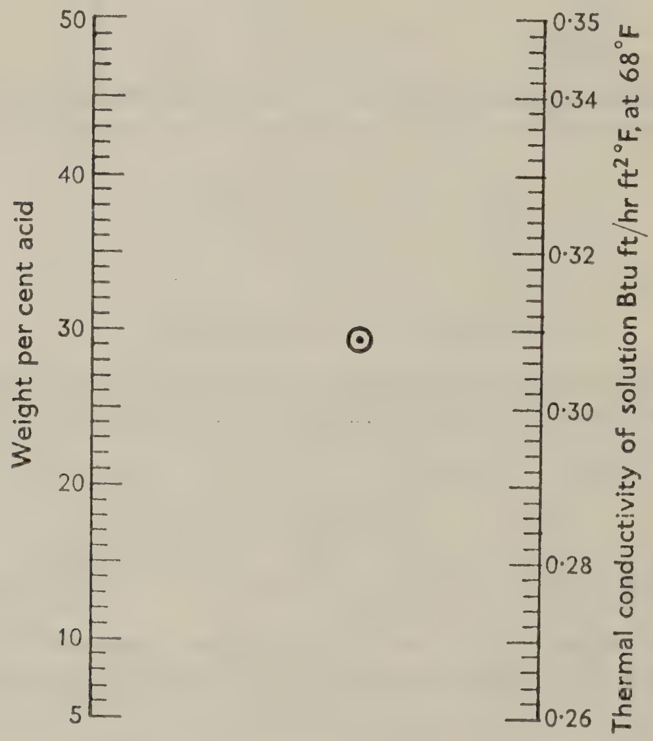


FIG. 5.—Thermal conductivity of orthophosphoric acid

Data have been recorded for more concentrated acid, as shown below:

*Thermal Conductivity of Phosphoric Acid*[366]

| Concentration Wt.-% $H_3PO_4$ | $t$ °C. | $10^4$ kcal./cm. sec. °C. | $10^7$ d$K$/d$t$ cal./cm. sec. °C.$^2$ |

## Dissociation Constants; Heat, Free Energy and Entropy of Ionization; Heat Capacity and Standard Entropies of Orthophosphoric Acid

Many measurements have been made of the dissociation constants of orthophosphoric acid, which ionizes in three stages:

$$\begin{gathered} H_3PO_4 \rightleftharpoons H^+ + H_2PO_4^- \\ H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-} \\ HPO_4^{2-} \rightleftharpoons H^+ + PO_4^{3-} \end{gathered}$$

Equations which represent recent and accurately determined values for the first[111] and second[112] dissociation constants are respectively:

$$-\log_{10} K_1 = 799{\cdot}31/T - 4{\cdot}5535 + 0{\cdot}013486T,$$

where $T$ is the absolute temperature (0°C. = 273·16° K.), for the temperature range 0–60°C., and

$$-\log_{10} K_2 = 2073{\cdot}0/T - 5{\cdot}9884 + 0{\cdot}020912T$$

over the temperature range 0–50°C. A similar equation for $K_2$, but with slightly different constants,[113] gives results which do not differ significantly from those given by the above equations up to 40°C., above which the values are somewhat higher. As the derived thermodynamic constants $\Delta H°$ and $\Delta C_p°$ are sensitive to variation in the temperature coefficient, these differ somewhat from the values derived from reference 112, but are given in parentheses, for comparison, in Table XXXI; the values for $\Delta F°$ and $\Delta S°$ are not affected.

At 25°C. the equations quoted above lead to the values:

$$\begin{aligned} K_1 &= 0{\cdot}711 \times 10^{-2} \\ K_2 &= 6{\cdot}31 \times 10^{-8} \end{aligned}$$

Simpler but less accurate equations for $K_1$, $K_2$ and $K_3$, have been given, based on thermodynamic data in the literature.[367]

The second dissociation constant, $K_2$, has been reported[114] as $6{\cdot}1 \times 10^{-8}$, $5{\cdot}82 \times 10^{-8}$, $5{\cdot}75 \times 10^{-8}$ and $5{\cdot}69 \times 10^{-8}$ at 60°, 70°, 80° and 90°C. respectively; in the region where the experimental observations overlap those of reference 112 they are in agreement.

Acceptable values for $K_3$, at 25°C., are $4{\cdot}73 \times 10^{-13}$ [115] or $4{\cdot}22 \times 10^{-13}$ [116]; previously reported values, lying between $10^{-13}$ and $10^{-12}$, are much less accurately established.

Extensive bibliographies of other values for the three dissociation constants have been compiled.[79, 312] Comparison of the dissociation constants of orthophosphoric acid with those of linear polyphosphoric acids having 2, 3, 6 and ~60 phosphorus atoms in the chain shows that the terminal hydrogens become more acidic and the last two dissociation constants approach a value of $10^{-8}$ as the chain length increases.[313]

The thermodynamic constants for orthophosphoric acid in water, at 25°C., derived from ionization data obtained during the dissociation constant determinations, are given in Table XXXI (see also [373]).

The relationship between the dissociation constants of orthophosphoric acid supports theories advanced for the calculation of such constants from equations involving the molecular structure and formal charges of oxyacid ions. The differences between the free energies of ionization, $\Delta F°$, of $H_3PO_4$, $H_2PO_4^-$ and $HPO_4^{2-}$, approximately 7 kcal., are characteristic of the general reactions[119, 120]:

$$\begin{gathered} X(OH)_2 \rightarrow HOXO^- + H^+ \\ HOXO^- \rightarrow {}^-OXO^- + H^+ \end{gathered}$$

This difference in energy corresponds, approximately, with the factor of $10^{-5}$ for the ratio of successive dissociation constants,

$$K_1 : K_2 : K_3 = 1 : 10^{-5} : 10^{-10}$$

proposed by Pauling.[121]

Another empirical equation for calculating dissociation constants, based on a more general formula, which includes terms for the formal charge on the central atom of the inorganic oxyacid and the number of non-hydroxyl oxygen atoms attached to it,[122] is:

$$\mathrm{p}K = 2{\cdot}1 + 4{\cdot}9(n-1).$$

For orthophosphoric acid (where $n = 1$, 2 or 3, corresponding to $K_1$, $K_2$ and $K_3$ respectively), this equation leads to values for $\mathrm{p}K_{1,2,3}$ of 2·1, 7·0 and 11.9, in fair agreement with those quoted in Table XXXI and also, it is claimed, for other oxyacids with similar structures.

*Table XXXI.—Thermodynamic Constants for Orthophosphoric Acid in Water, at* 25°C.

| | $H_3PO_4 \rightleftharpoons H^+ + H_2PO_4^-$ | $H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-}$ | $HPO_4^{2-} \rightleftharpoons H^+ + PO_4^{3-}$ |

|---|---|
| $H_3PO_4$(aq.) | 37·6 [118] |
| $H_2PO_4^-$ | 21·6 [118] |
| $HPO_4^{2-}$ | −8·0 [111-2] |
| $PO_4^{3-}$ | −51·0 [111-2] |

Predictions of dissociation constants can also be made, with some accuracy, from average p$K$ values derived from differential potentiometric titration curves.[123]

The dissociation of orthophosphoric acid possibly occurs by a mechanism similar to that proposed for nitric and sulphuric acids; that is by virtue of hydrogen bridges linking acid and water molecules. From a consideration of the rates of solution of zirconium and titanium in orthophosphoric acid solutions (5–85% $H_3PO_4$), it has been stated[124] that complete dissociation only occurs when there are more than 12 molecules ($m$) of water per molecule of $H_3PO_4$; that when $m < 4$ and $> 1$, the acid is partially ionized and that when $m \leqq 1$ the acid is undissociated, a conclusion at variance with evidence from conductivity measurements (q.v.). Solvation has also been invoked to account for discontinuities observed when other properties of aqueous orthophosphoric acid solutions, such as conductivity and viscosity, are correlated with concentration (q.v.). An alternative explanation,[371] which is supported by other observations,[357] is that species more acidic than $H_3PO_4$, such as the dimer $H_6P_2O_8$, are present. On the assumption that this ionizes to yield the triple ion $H_5P_2O_8^-$, equations can be derived which satisfactorily express the degree of dissociation of phosphoric acids in the concentration range 0·1–10 *m.* as a function of concentration, pH, and the concentrations of the various probable ionized and neutral species present in the solution.

To explain the rise in dissociation constant with increasing orthophosphoric acid concentration, the presence of $H_7(PO_6)$ molecules, with three totally dissociated hydrogen atoms has been suggested,[125–6] but this idea has not been investigated further by other workers.

The entropies, $S°$, of oxygenated ions of the form $XO_n^{-z}$ can be systematized on the basis of their size and charge by the relationship[127]:

$$S° = 43{\cdot}5 - 46{\cdot}5\,(z - 0{\cdot}28n),$$

where $z$ = the charge and $n$ = the number of oxygen atoms around the central nucleus, disregarding those present as hydroxyl groups. The entropies quoted in Table XXXI for $H_2PO_4^-$, $HPO_4^{2-}$ and $PO_4^{3-}$ are in good agreement with values calculated according to this equation, which also applies to other oxyanions such as $HSO_4^-$, $SO_4^{2-}$, $HSO_3^-$ and $SO_3^{2-}$.

It has been shown that a standard state can be chosen at any temperature, such that the partial molal entropies of any class of ions are linearly related to the corresponding entropies at 25°. Preliminary constants have been given which enable the calculation of entropy values up to 200°C. for $HPO_4^{2-}$ and $H_2PO_4^-$, using the equation:

$$\bar{S}^\circ_{t2} = a(t_2) + b(t_2)\bar{S}^\circ_{(t_1)}{}^{372}$$

From these values and the entropies at 25°C. it is possible to calculate corresponding values of the partial molal heat capacities for phosphate ions, using the equation:

$$[\bar{C}^\circ_{p2}]^{t2}_{25} = \frac{a_{(t2)} - \bar{S}^\circ_{25}[1{\cdot}000 - b_{(t2)}]}{\ln T_2/298{\cdot}2}$$

Heat capacities calculated in this way[373] are given below:

*Ionic partial molal heat capacities (g.-cal. mole$^{-1}$ deg.$^{-1}$)*

| *ion* | $\bar{C}^\circ_{p25}$ | $[\bar{C}^\circ_p]^{60}_{25}$ | $[\bar{C}^\circ_p]^{100}_{25}$ | $[\bar{C}^\circ_p]^{150}_{25}$ | $[\bar{C}^\circ_p]^{200}_{25}$ |
|---|---|---|---|---|---|
| $PO_4^{3-}$ | −226 | −200 | −216 | −205 | −227 |
| $HPO_4^{2-}$ | −132 | −118 | −129 | −138 | −146 |
| $H_2PO_4^-$ | −55 | −31 | −23 | −39 | −41 |

The effect of electrolytes on the dissociation constants of orthophosphoric acid has been investigated by a number of authors,[128–33, 312, 314] and equations are given for their evaluation in various alkali and alkaline-earth halide and sulphate solutions, in sea water and in urine. Generally speaking p$K_n$ decreases with increase in ionic strength and the effect of cations is in the increasing order $K^+$, $Na^+$, $Mg^{2+}$ and of anions $PO_4^{3-}$, $SO_4^{2-}$ and $Cl^-$.

The effect of pressure on the first dissociation constant, $K_1$, of orthophosphoric acid has been measured[134] at 25°C., the results being summarized in Table XXXII.

*Table XXXII.—$K_1$ (× 100) at 25°C. for Orthophosphoric Acid*

| Pressure, atm. | 1 | 500 | 1000 | 1500 | 2000 |
|---|---|---|---|---|---|
| $H_3PO_4$, molarity | | | | | |
| 0·00576 | 0·71 | 0·98 | 1·33 | 1·69 | 2·10 |
| 0·01 | 0·67 | 0·90 | 1·20 | 1·55 | 2·01 |
| 0·1 | 0·88 | 1·21 | 1·64 | 2·12 | 2·55 |

From this investigation, the change in partial molal volume of orthophosphoric acid on ionization was found to be −15·5 c.c./mole at 1 atm. and −10·7 c.c./mole at 2000 atm., whilst the change in compressibility on ionization was $-2{\cdot}4\times10^{-3}$ atm.$^{-1}$, c.c., mole$^{-1}$. A similar determination of the dissociation constants $K_1$ and $K_2$ at 22°C. and pressures up to 1000 kg./cm.$^2$ shows that the volume change on ionization at 1 atm. is 14·6–15·2 c.c./mole ($K_1$) and 22·0–28·1 c.c./mole ($K_2$) respectively.[315] Later data by the same author are in agreement with these values.[374]

Orthophosphoric acid is a slightly stronger acid in $D_2O$ than it is in water, according to calculations of the first and second dissociation constants from e.m.f. measurements, at 20°C., with the cell[135]:

$$D_2,Pt/H_3PO_4 \text{ in } D_2O/KCl(sat.), \text{ calomel.}$$

The corresponding p$K$ values are recorded in Table XXXIII, together with more recent values obtained by other methods.[316–7, 375]

*Table XXXIII.—Dissociation Constants of Orthophosphoric Acid in Water and* $D_2O$

| p$K_n$ | in $H_2O$ | in $D_2O$ | Temperature °C. | Reference |
|---|---|---|---|---|
| p$K_1$ | 1·983 | 2·188 | 20 | 135 |
| | 2·128 | 2·362 | 25 | 316 |
| | 2·145 | 2·350 | 25 | 375 |
| p$K_2$ | 7·207 | 7·666 | 20 | 135 |
| | 7·190 | 7·750 | 25 | 316,317 |

The effect of substituting a deuteron for a proton in the acid itself was to decrease the acid strength in water. It has been shown, using glass electrodes standardized for water solutions, that the pL (the generalized equivalent of pH, where L includes all isotopically different hydrogen ions) in a solvent of D atom fraction $n$ is given by[375]:

$$pL = (\text{meter reading}) + 0{\cdot}3314n + 0{\cdot}0766n^2$$

The first dissociation constant of phosphoric acid in hydrogen peroxide–water mixtures decreases non-linearly with $H_2O_2$ mole fraction. In this, it resembles acids such as acetic acid, rather than picric acid, where the variation is linear. The difference has been explained by solvation of the undissociated $H_3PO_4$ molecules which occurs to a much smaller extent in the internally hydrogen-bonded picric acid.[376] The dissociation of phosphoric acid in certain organic solvents has been studied[377–8] with the results given below:

| p$K$ | Water | 44·2% aq. acetone | solvent 50·9% aq. dioxan | 48·7% aq. dimethyl formamide | Acetic acid |
|---|---|---|---|---|---|
| p$K_1$ | 2·75 | 3·20 | 3·85 | 4·08 | 4·4 |
| p$K_2$ | 7·15 | 8·15 | 8·62 | 4·92 | — |
| p$K_3$ | 10·83 | 10·98 | 10·95 | 11·11 | — |
| Reference | 377 | 377 | 377 | 377 | 378 |

### Hydrogen-ion Concentration and Titration Curve

Because the dissociation constants of ionization of orthophosphoric acid are of quite different orders of magnitude, the hydrogen-ion concentration or pH titration curve is of considerable interest and three separate stages can be recognized when the acid is neutralized with an alkali, for example sodium hydroxide solution, corresponding to the formation of $NaH_2PO_4$, $Na_2HPO_4$ and $Na_3PO_4$ respectively. The graph in Fig. 6 shows the variation in pH when sodium hydroxide (0·0919 N.) is added to 100 c.c. of orthophosphoric acid solution (0·01277 M.) at 20°C.[136]

The first inflection, corresponding to the first stage in the neutralization, occurs at about pH 4·5, the second at about pH 9·0, but ionization at the third stage is too weak to give a distinguishable inflection and the course of the curve corresponds to the addition of excess sodium hydroxide. The titration curve for orthophosphoric acid can therefore be considered as consisting of the curves of three separate monobasic acids of widely differing strengths (see also Section XXVI, page 736).

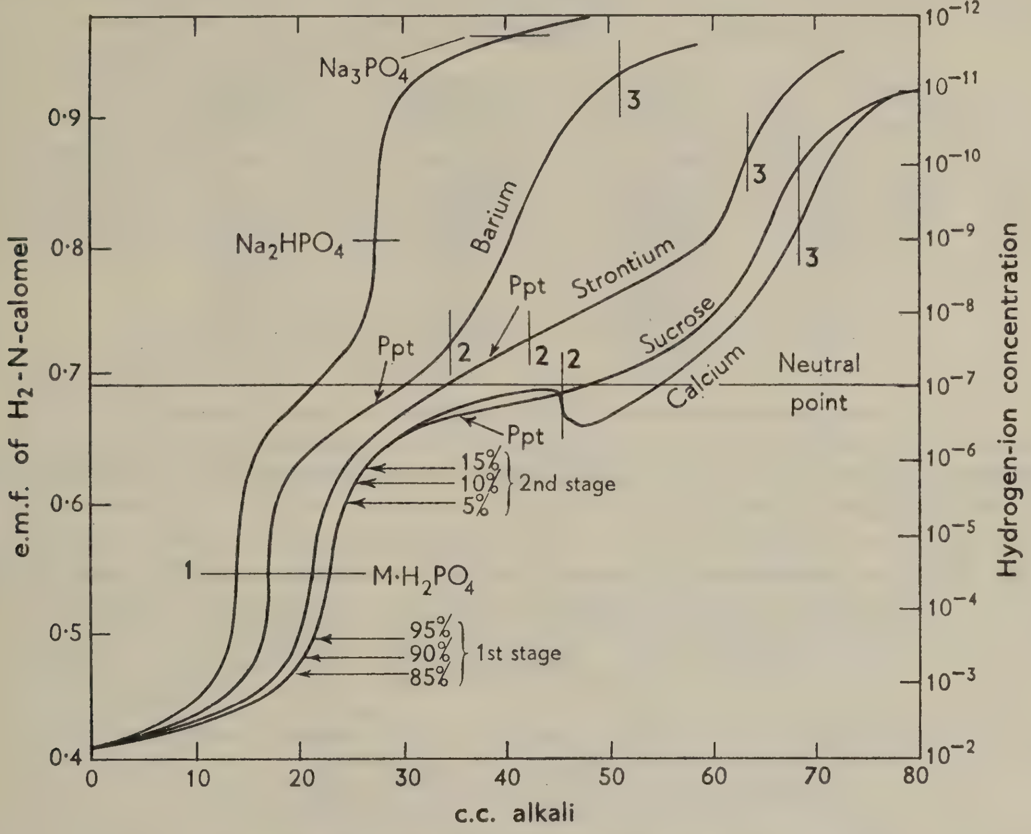

FIG. 6.—Titration curve of phosphoric acid

The choice of suitable indicators enables the inflection points to be observed visually, as well as by electrometric pH measurements, and affords a useful method for the differential titrimetric analysis of the soluble alkali metal phosphates (see Section XXXV, page 1257). If a phosphoric acid solution to be titrated against sodium hydroxide is first saturated with sodium chloride or sodium nitrate, it is claimed that sharper end points can be obtained, when azo-violet or thymolphthalein is used as indicator.[318] If the electrometric titrations are performed in very dilute solution, for example 0·001 to 0·0001 M., only the first stoicheiometric point in the neutralization can be recognized by an inflection in the curve.[137]

The neutralization of orthophosphoric acid by alkaline-earth hydroxides has also been studied; the pH-titration curves show breaks at the first stage of the neutralization, but thereafter insoluble phosphates are formed and other inflections are masked.[138] The volume changes, $\Delta V$, resulting from the mixing of aqueous solutions of phosphoric acid and alkalis supported the three-step dissociation mechanism for phosphoric acid. The maximum positive values of $\Delta V$ were at the $MH_2PO_4$ neutralization point, and the maximum negative values at the $M_3PO_4$ neutralization point.[379]

### Orthodeuterophosphoric Acid $D_3PO_4$; Physical Properties

The first preparation of orthodeuterophosphoric acid (53% $D_3PO_4$) dilute solution was concentrated to 83% $D_3PO_4$ by heating *in vacuo* at 54°C. in order to avoid pyrophosphoric acid formation,[22] but no measurements of physical properties were reported. A product, more nearly anhydrous, had $d_{20}^{4}=1{\cdot}890$, m.p. 38·4°C., and $n_D^{20}=1{\cdot}4430$.[139] The most reliable data, however, are given in Table XXXIV for orthodeuterophosphoric acid prepared by the addition of phosphoric oxide, purified by repeated sublimation *in vacuo*, to $D_2O$.[4]

*Table XXXIV.—Density,* $d_4^t$*; Viscosity,* $\eta$*; and Conductivity,* $K$*, of* $D_3PO_4$ *at 25° to 65°C.*

| 65 | 1·8767 | 46·86 | 7·94 |

As seen in Table XXXV, $D_3PO_4$ has a higher m.p., $d_4^t$ and $\eta$, but a lower $K$ and $n_D^{20}$ than orthophosphoric acid.[4]

*Table XXXV.—Comparison of Some Physical Properties of* $H_3PO_4$ *and* $D_3PO_4$

| Property | $D_3PO_4$ | $H_3PO_4$ |
|---|---|---|
| m.p. °C. | 46·0 | 42·35 |
| $d_4^{25}$ | 1·9083 | 1·8683 |
| $\eta$ centipoises | 231·8 | 177·5 |
| $K$ ohm$^{-1}$ cm.$^{-1}$ | $2{\cdot}818\times10^{-2}$ | $4{\cdot}675\times10^{-2}$ |
| $n_D^{20}$ | 1·4430 | 1·4503 |

Unlike sulphuric acid, in which the activation energies of conduction and viscous flow are virtually unchanged by deuteration, there is a large influence when orthophosphoric acid is deuterated, especially on viscosity. Insufficient information is available to deduce reasons for the difference.[4]

## CHEMICAL PROPERTIES

### Action of Heat on Orthophosphoric Acid

When a dilute aqueous solution of orthophosphoric acid is heated water evaporates, the solution becomes more concentrated with respect to orthophosphoric acid and the boiling point increases slowly up to the composition corresponding to about 65% $P_2O_5$ (87·7% $H_3PO_4$). Thereafter the boiling point rises rapidly and the presence, in solution, of pyrophosphoric acid formed by the reaction:

$$2H_3PO_4 \rightleftharpoons H_4P_2O_7 + H_2O$$

has been observed by paper and ion-exchange chromatographic analysis[100-1, 140] even though the $P_2O_5$ content has risen to only 68·8%, compared with 72·4% required for the anhydrous acid.

Liquid orthophosphoric acid itself has been shown by chromatographic analysis to contain about 12·7% of its $P_2O_5$ content in the form of pyrophosphoric acid and a corresponding proportion of 'free' water, possibly strongly solvated by the orthophosphoric acid, in accord with the equilibrium represented above; this conclusion is supported by conductivity measurements[4] and isotope exchange studies.[102]

On further heating, water continues to evaporate and condensation occurs according to the general equation:

$$nH_3PO_4 \rightleftharpoons H_{n+2}P_nO_{3n+1}+(n-1)H_2O$$

with the formation of mixtures of polyphosphoric acids, the proportions of the various constituents being related to the phosphoric oxide content of the mixture (see also Section XXVI, page 728).

The vapours above boiling orthophosphoric acid, b.p. 255°C., contain approximately 0·02 wt.-% $P_2O_5$; this proportion increases as the acid becomes more concentrated upon heating, until the azeotropic composition of 92·4% $P_2O_5$ is reached at about 864°C. at 760 mm. Hg, when liquid and vapour have the same composition.[32]

It has also been claimed that even at temperatures as low as 130°C. the partial pressure of $H_3PO_4$ in the vapour amounts to several thousandths of a mm. of Hg.[38]

## Anodic Behaviour of Metals in Orthophosphoric Acid

### COPPER

When a copper surface is anodically etched in concentrated aqueous solutions (> 10 N.) of orthophosphoric acid, it becomes as bright as if it had been polished, provided voltage and current density are regulated.[141] The mechanism of the process has been extensively studied on account of its industrial application.[145–51]

Over the range of voltage and current density in which electro-polishing occurs, the viscous layer formed on the surface of the anode contains phosphate ions which act as acceptors for the $Cu^{++}$ ions liberated by the current.[145] The reaction products concentrate in the hollows on the surface of the copper and passivate it, whereas the raised portions continue to be attacked, resulting in a general levelling and brightening of the surface.

The compounds responsible for the passivating effect are not definitely established, but the following have been suggested: $x\text{Cu}(H_2PO_4)_2,yH_3PO_4$,[152] $CuHPO_4$ and $Cu_2(PO_4)_3$,[142] or hydrated complexes of the type $CuH_2PO_4(OH)$. These are said to be in equilibrium with the acid in the solution on the one hand, and the surface oxide film on the metal surface on the other,[143–4] the formation of the complex being coincident with the appearance of the polished surface. In the critical polishing range the rate determining stage, that is the passage of phosphate radicals from solution to the anode, is diffusion controlled.[145–6,150–1]

Anodic polarization curves of copper in orthophosphoric acid[142,146,148–9] show several distinct stages in observed potentials: (*a*) when the product of the current density and the square root of the time in sec. is constant, (*b*) when the potential rises owing to the anode being electrolytically oxidized to $Cu_2O$, (*c*) another rise in potential when evolution of gaseous oxygen takes place on the anode surface and (*d*) a final levelling off in potential as the oxygen is evolved, the rate of evolution depending on whether the metal has been annealed or worked.[153] It is possible to differentiate between the stages of accumulation of reaction products and oxide film formation on the anode, by differential electrostatic capacity measurements on copper anodes immersed in 15 molar phosphoric acid.[148] Surface films, of the order of 100 A. thick, on copper electrolytically polished in orthophosphoric acid, have been reported to contain traces of unidentified phosphorus compounds in addition to oxides of copper.[154]

If single crystals of copper, sawn parallel to the (100), (110) and (111) faces, are polished anodically in orthophosphoric acid, *d* 1·53, the potentials of the three faces, when measured against the saturated calomel electrode after 3 min. immersion, are 0·342, 0·354 and 0·337 volts respectively; after much longer immersion in the polishing bath no difference is observed, all potentials being equal at 0·352 volts, showing that anodic polishing results in preferential formation of (110) faces.[155]

LEAD

As with copper, the anodic behaviour of lead in orthophosphoric acid can be considered in different stages. The electrolysis of 2·99, 22·80 and 40·5 N. $H_3PO_4$ with lead electrodes proceeds in steps. Firstly, when $Pb^{2+}$ ions pass into solution, forming a film of lead phosphate, accompanied by increase in potential and passivation of the anode; secondly, between 0·85 and 1·2 volts, when PbO and $PbO_2$ formation increases the degree of passivation, with fall in current density; and finally, electrolysis of $H_3PO_4$ at a potential of about 2·0 volts, accompanied by oxygen evolution.[156]

ZINC

In the anodic phosphatization of pure zinc in orthophosphoric acid solutions, as the current density increases, so does the concentration of $Zn^{++}$ ions in the neighbourhood of the anode, whilst that of the $H_2PO_4^-$ ions decreases. Further increase in current density results in a rise in the anode potential to the values required for reactions leading to the formation of $Zn_3(PO_4)_2$, $Zn(OH)_2$ and ZnO.[157]

MAGNESIUM

A theoretical study of the pH–potential diagrams for the system $Mg–H_3PO_4–H_2O$, confirmed by observation, indicates that magnesium is effectively passivated at pH less than 2 in solutions containing $10^{-6}$ g. ions of phosphate per litre.[158]

TITANIUM

Titanium is readily passivated electrochemically in orthophosphoric acid solutions.[159]

STEEL AND ALLOY STEELS

Carbon steels and alloy steels acquire a polish when used as anodes in electrolytic cells containing orthophosphoric acid[160–2]; generally speaking, the anodic attack proceeds in stages,[160–2] and additives, such as chromium trioxide, $CrO_3$, and sulphuric acid are often used to increase the polishing life of the electrolyte.[161]

## Action on Metals and Corrosion

Orthophosphoric acid is not nearly as corrosive as other common mineral acids, but the rate of attack on metals and alloys depends on the purity and concentration of the acid, the temperature and environment. Corrosion by orthophosphoric acid is often accompanied by the formation of protective or semi-protective films, so that large variations in the rate of attack on the same metal may be observed under different conditions. Aeration also increases the rate of corrosion of most metals and alloys.

The extensive literature concerned with corrosion by orthophosphoric acid is to be found mainly in technical journals and useful collections of data for a wide range of metals and alloys are available.[163–76, 319]

ALUMINIUM

Orthophosphoric acid solutions are inherently corrosive to aluminium and its alloys[177–9]; penetration rates are as follow (Table XXXVI).

*Table XXXVI.—Corrosion Rates for Aluminium in Orthophosphoric Acid*

| % $H_3PO_4$ | Temperature °C. | Penetration rate inches per year |
|---|---|---|
| 42 | 15 | 0·292 [179] |
| 76 | 15 | 0·730 [179] |
| 85 | 95 | 0·63 [164] |

However the addition of small quantities of phosphoric acid reduces the corrosion of aluminium-clad fuel elements in pressurized water reactors, although heavy deposits are formed.[320]

### ANTIMONY

At 15°C. antimony suffers moderate attack by orthophosphoric acid solutions (up to 76% $H_3PO_4$), the corrosion rate being of the order of 0·01 in./year.[179]

### BISMUTH

Bismuth is unattacked under the conditions described for antimony[179] because of the formation of a protective layer of bismuth phosphate.

### CADMIUM

Cadmium is moderately attacked by orthophosphoric acid at 15°C., the rate being equivalent to a penetration of approximately 0·02 in./year for 76% $H_3PO_4$.[178] The rate of solution of cadmium in more dilute acids increases with time over a period of a few hours[180]; for example, in 0·1N. $H_3PO_4$ the loss expressed in mg./cm.$^2$ increases from 0·35 to 1·4 at 20°C., from 0·49 to 2·2 at 40°C. and from 0·54 to 3·0 at 60°C. Other similar data for 0·5N., N. and 2N. $H_3PO_4$ are available in the same reference, the rate of solution increasing with rise in both acid strength and temperature.

### COPPER (AND ALLOYS)

Copper and its alloys resist attack by orthophosphoric acid moderately well as long as the content of dissolved oxygen, or of oxidizing impurities, such as ferric compounds, is fairly low.[164, 172, 179, 182] In quiescent, unaerated 76% orthophosphoric acid at 20°C. copper corrodes at a rate equivalent to a penetration of 0·008 in./year[178]; under aerated and stirred conditions at higher temperatures, the rate of corrosion by all grades of orthophosphoric acid may rise to many times this value.

Data on copper alloyed with zinc, tin, nickel, aluminium and silicon are available.[172, 183–6, 321]

Copper shows relatively good corrosion resistance to solutions of orthophosphoric acid at 1000 lb./sq. in. pressure and at 285°C.,[187] whilst in the absence of oxygen it is not appreciably corroded by dilute orthophosphoric acid in steam heated above its critical temperature to 4550 lb./sq. in. and 440°C.,[188] i.e., conditions under which copper–silver alloys are rapidly attacked.

### GOLD

Gold and its alloys with platinum, silver[189] and silver with palladium[190] are practically unattacked by orthophosphoric acid over a wide range of temperature and concentration of acid. Electro-plating of iron and steel is possible with the metal and many of its alloys.

### LEAD

As a consequence of the formation of thin films of insoluble lead phosphate in pure and of lead sulphate in crude orthophosphoric acid solutions, the resistance shown by lead to corrosion by the former is very satisfactory and to the latter exceptionally good.[165, 178]

The corrosion rates in Table XXXVII have been reported for the pure acid,[175] the rates of attack by impure acid, for example that produced by the gypsum process, being much less.

Other data are available for different environments and acid concentrations.[165, 191] Antimonial lead, containing about 7% of antimony, does not show the same resistance as pure lead.[165, 179]

MAGNESIUM

Magnesium is attacked extremely rapidly by both pure and impure orthophosphoric acids.[178]

MOLYBDENUM

Molybdenum is very little affected by boiling phosphoric acid at concentrations in the range 1–85% $H_3PO_4$.[322]

NICKEL

Nickel shows moderate resistance to attack by pure dilute orthophosphoric acid in the cold,[164,178] but hot concentrated solutions are much more corrosive; for example, at 95°C. penetrations of about 0·7 in./year for 85% $H_3PO_4$ have been recorded.[164,174]

*Table XXXVII.—Corrosion Rates for Lead in Orthophosphoric Acid*

| % $H_3PO_4$ | Temperature °C. | Penetration rate inches per year |
|---|---|---|
| 72 | 20 | 0·0043 |
| 10 | 81 | 0·0014 |
| 25 | 81 | 0·043 |
| 50 | 81 | 0·065 |

The high nickel alloys, especially those containing molybdenum or chromium, exhibit a high degree of corrosion resistance to orthophosphoric acid of all concentrations. At room temperature the rate of attack is less than 0·002 in./year for any type of alloy and for all concentrations of acid; at higher temperatures nickel alloys containing molybdenum are somewhat more resistant than others.[163,174,192]

Useful summaries of corrosion data are available. [163–4,174]

NIOBIUM

Niobium has a high degree of resistance to attack by unaerated, unstirred 85% $H_3PO_4$ at temperatures in the region of 25°C., the penetration recorded over a 36-day test being only 0·00002 in./year.[181] Niobium also shows good resistance to 3–10% $H_3PO_4$ at temperatures up to 300°C., but the protective film which forms under these conditions does not prevent hydrogen embrittlement of the metal.[323]

PLATINUM

Platinum and its alloys with gold are virtually unattacked by orthophosphoric acid (cf. polyphosphoric acids) at concentrations up to 100% $H_3PO_4$, and up to their boiling points; their use for electroplating iron and steel to improve corrosion resistance has been suggested.[189,323]

SILVER

Silver is not attacked by either pure or impure orthophosphoric acid in the cold,[178,189,193] nor is it seriously attacked at temperatures up to 200°C., except when aerated.[182,189,194] Under extreme conditions of temperature, up to 300°C., alloys with copper or nickel are more resistant than silver itself,[182] for which a penetration rate of only 0·007 in./year in 85% $H_3PO_4$ at 249°C. and at 1000 lb./sq. in. pressure has been reported.[187] At even higher temperature and pressure, 440°C. and 4550 lb./sq. in., pure silver and a fine-grained alloy of silver containing 1% of nickel are scarcely attacked, but alloys with higher nickel contents fail through attack on the nickel phase.[188] A silver–silicon alloy, containing 1–2% of silicon, is reported to be corrosion resistant to orthophosphoric acid up to 400°C.[195]

### IRON AND STEEL

Pure iron is readily attacked by dilute or concentrated orthophosphoric acid,[178] the rate of attack being reduced somewhat by the inhibiting effect of the organic impurities present in some concentrated impure acids.[164] Generally speaking, however, crude orthophosphoric acids are more corrosive towards iron and its alloys, on account of the presence of fluoride, chloride or sulphate ions.

The corrosion of ferrous alloys by orthophosphoric acid has received much study on account of the extensive use of such alloys as materials of construction for processes in which the acid is made on an industrial scale. Detailed data on the corrosion rates of a wide range of steels and other ferrous alloys are to be found in the more general review papers referred to earlier.[163–6, 171, 173, 176, 323] The extent of corrosion varies greatly depending on the type of alloy, the purity and concentration of the orthophosphoric acid, the temperature and the conditions of exposure to attack.

However, the typical behaviour of several classes of alloys can be summarized. Cast iron is, in general, subject to severe corrosive attack by pure and crude orthophosphoric acid solutions.[163] Moderate resistance is shown by stainless steels containing up to about 18% of chromium,[164, 179, 196] but above this percentage excellent resistance has been reported and especially so when 10–15% of nickel and 2–4% of molybdenum are also present in the alloys.[163–4, 171, 179, 186, 192, 196–204] A 25% Cr, 5% Ni stainless steel is unstable in phosphoric acid because of periodic depassivation in some specimens, which is promoted by chloride ion.[380] The high alloy stainless steels, containing about 20% of chromium and 30% of nickel, together with a little molybdenum and copper, are practically unattacked, even under the most severe conditions and in the presence of impure acid.[163, 171, 192, 196, 205, 206, 380–1] Steels stabilized by titanium or niobium, and with low carbon contents, are claimed to be more resistant to the type of corrosion attributable to weld-decay at gas or electric-welded joints when immersed in orthophosphoric acid solutions.[163, 171, 196, 202] The high silicon irons, namely those containing about 14% of silicon and 1% of carbon, show good resistance to pure orthophosphoric acid up to about 100°C., but not towards acids with fluorine compounds as impurities.[163, 176, 202, 204, 324]

Although iron is usually dissolved by orthophosphoric acid, under certain conditions in dilute acid solutions a protective coating of phosphate can be formed on the metal surface, thus effectively preventing further attack.[207] A similar phenomenon has been demonstrated in stainless steels.[382] The initial reaction can be represented by the equation:

$$\mathrm{Fe + 2H_3PO_4 = Fe(H_2PO_4)_2 + H_2}$$

As the concentration of iron in solution increases, the following equilibria can occur[208–9]:

$$\begin{aligned}&\mathrm{Fe(H_2PO_4)_2 \rightleftharpoons FeHPO_4 + H_3PO_4}\\&\mathrm{3FeHPO_4 \rightleftharpoons Fe_3(PO_4)_2 + H_3PO_4}\\&\mathrm{3Fe(H_2PO_4)_2 \rightleftharpoons Fe_3(PO_4)_2 + 4H_3PO_4}\\&\mathrm{2FeHPO_4 + Fe \rightleftharpoons Fe_3(PO_4)_2 + H_2}\end{aligned}$$

with the ultimate formation of relatively insoluble secondary and tertiary phosphates of iron, which deposit as a thin layer on the metal surface. Other metals, such as manganese and zinc, behave in a similar manner and this principle has been utilized in the so-called 'phosphatization' processes used commercially for producing paint-adherent protective coatings on several metals. Both the theoretical and practical aspects of these processes have been discussed and reviewed.[208, 210–1]

### TANTALUM

Tantalum is inert to all concentrations of pure orthophosphoric acid up to 175°C. In the presence of more than 10 p.p.m. of fluorides, however, embrittlement and pitting occur; sulphates also accelerate corrosion.[163–4, 166, 170, 181, 187, 323]

Chlorides, however, do not accelerate the corrosion of commercially pure tantalum.[383] An alloy of Ta (40%), Nb (46%), Ti (10%) and Ni (4%), resisted the attack of phosphoric acid at 200°C.[384]

### TIN

Tin is readily attacked by pure and crude orthophosphoric acids, the reported corrosion rates[163, 178] being given in Table XXXVIII.

*Table XXXVIII.—Corrosion Rates for Tin in Orthophosphoric Acid*

| | Concentration $H_3PO_4$ % | Temperature °C. | Penetration inches per year |
|---|---|---|---|
| Pure $H_3PO_4$ | 76<br>85 | 15<br>93 | 0·01<br>0·88 |
| Crude $H_3PO_4$ | 76<br>62 | 15<br>98 | 0·24<br>1·14 |

### TITANIUM

Titanium is fairly resistant to attack by pure 10% orthophosphoric acid at 80°C. and by 85% acid at 25°C.,[212] a penetration rate of 0·007 in./year being recorded for the latter.[181] In the higher acid concentration ranges and at higher temperatures, titanium is subject to increased attack and is not satisfactorily resistant, at 60°C., to solutions containing more than 3% $H_3PO_4$. At 35°C. the rate of penetration increases from 0·002 to 0·028 in./year as the concentration rises from 30 to 80% $H_3PO_4$.[213, 322] Arc-melted titanium is said to be more resistant to orthophosphoric acid solutions than powder-metallurgy titanium, and alloys with 14% of zirconium have increased resistance to this medium.[214] Niobium (up to 50%) also increases the resistance of titanium to attack by phosphoric acid,[385] but aluminium–titanium alloys are less resistant.[386] Measurements at 40°, 50° and 60°C. show that the rate of solution of titanium in 6–28 N. orthophosphoric acid can be regarded as approximately proportional to its concentration and that the activation energy of the reaction is 15·67 kcal./mole.[215, 325]

### TUNGSTEN

Tungsten is little attacked by boiling phosphoric acid solutions in the range 1–85% $H_3PO_4$.[322]

### ZINC

Zinc is very readily attacked by solutions of both pure and crude orthophosphoric acid at all concentrations and all temperatures.[164, 178]

### ZIRCONIUM

The corrosion resistance of zirconium to orthophosphoric acid of all concentrations is very high at temperatures up to 60°C.[181, 216–7] At 100°C. the corrosion resistance falls off rapidly with increasing acid concentration, as Table XXXIX shows.[212, 322]

*Table XXXIX.—Corrosion Rates for Zirconium in Orthophosphoric Acid at* 100°C.

| Concentration, % $H_3PO_4$ | 60 | 70 | 80 | 85 |
|---|---|---|---|---|
| Penetration in inches per year | 0·004 | 0·008 | 0·024 | 0·044 |

Alloys of zirconium and niobium show satisfactory resistance to phosphoric acid (up to 40%) at 100°C. for 100 hr.[326]

### INHIBITORS FOR REDUCING THE ATTACK ON METALS BY ORTHOPHOSPHORIC ACID

The extent to which metals are attacked by orthophosphoric acid may be reduced by small amounts of inhibitors dissolved in it. Of the inorganic substances suggested for this purpose, pentavalent arsenic[164, 218] is very effective in preventing attack on steel, whilst chromates are reported as inhibiting the attack on aluminium and light metal alloys.[219, 220] The addition of 0·05–2·5 g./l. of copper to the acid is said to reduce the corrosion of austenitic steels containing chromium and nickel.[221] Many organic inhibitors have been reported, most of which are nitrogeneous compounds such as amines,[222–4] nitriles[224] or thioureas[225]; aldehydes (in conjunction with ionizable halides),[226] pine oil and glue[164] have also been mentioned. As the presence of sulphuric, fluosilicic and hydrofluoric acids tends to increase the corrosive effect of orthophosphoric acid,[164] the addition of more inhibitor is required with crude acid than with pure acid to obtain the same effect.

The corrosion of copper or brass by phosphoric acid is inhibited by furfuraldehyde[387] or mercaptobenzthiazole.[388]

## Radioactive and Isotopic Exchange Reactions with Orthophosphoric Acid

Radioactive phosphorus, $^{32}P$, in orthophosphoric acid does not exchange in aqueous solution with other phosphorus compounds, such as phosphorous acid,[227] hypophosphorous acid,[228] pyrophosphate, hypophosphate or other condensed phosphates,[229–31] phosphoric acid esters,[232] nor with biological phosphates.[233]

Radioactive phosphorus can therefore be employed as a tracer in analytical procedures, and when it does appear in a phosphorus compound, other than the original, it may be assumed that the second must have been produced from the first.

Isotopic exchange of $^{18}O$ between orthophosphoric acid and water in which it is dissolved does, however, take place.[102, 234–5] The rate of exchange, reported to be lower than that observed between water and phosphorous or hypophosphorous acid,[234] has been extensively studied. The rate of exchange of $^{18}O$ between orthophosphoric acid and water was measured at various temperatures as a function of the acid concentration, taking into account the fact that some pyrophosphoric acid is present in nominal compositions just below 100% $H_3PO_4$,[102] with the results shown in Table XL. The equation representing the exchange is:

$$H_2O^* + H_3PO_4 \rightleftharpoons H_2O + H_3PO_4^* \quad (1)$$

*Table XL.—Exchange Rates of* $^{18}O$ *between Water and Orthophosphoric Acid, g. atoms/l. sec.* × $10^4$

| $H_3PO_4$ $f$ | °C. | | | | | | | Energy of activation kcal./mole |
|---|---|---|---|---|---|---|---|---|
| | 25 | 40 | 60 | 80 | 90 | 100 | 110 | |
| 8·8 | — | — | — | — | 0·141 | 0·341 | 0·78 | 26·5 |
| 12·2 | — | — | 0·0286 | 0·221 | 0·511 | 1·14 | 2·62 | 24·0 |
| 15·1 | — | 0·0137 | 0·106 | 0·672 | 1·59 | 3·45 | 8·65 | 23·1 |
| 17·8 | 0·0148 | 0·070 | 0·462 | 2·05 | 4·53 | 9·47 | — | 19·7 |

$f$=formality of solution, which is molarity corrected for presence of pyrophosphoric acid, where necessary.

An alternative path for exchange, in the more concentrated acids, is the equilibrium:

$$2H_3PO_4 \rightleftharpoons H_4P_2O_7 + H_2O \quad (2)$$

and the rate of change of reaction shown in (2) was found to be almost identical with the isotope exchange rates (see Table XLI).

*Table XLI.—Comparison between* $H_4P_2O_7$ *Hydrolysis Rate and* $H_3PO_4$–$H_2O$ *Isotopic Exchange Rate*

| °C. | $H_3PO_4$ *f* | $H_4P_2O_7$ hydrolysis rate mole/l. sec. | $H_3PO_4$–$H_2O$ isotope exchange rate g. atoms/l. sec. |
|---|---|---|---|
| 25 | 18·0 | $1{\cdot}5 \times 10^{-6}$ | $1{\cdot}9 \times 10^{-6}$ |
| 60 | 7·8 | $5 \times 10^{-5}$ | $4{\cdot}6 \times 10^{-6}$ |

It is claimed[102] that the observed exchange rates can be represented satisfactorily by an equation of the form:

$$\text{(3)} \qquad \text{rate} = k_1a_1a_w + k_2a_1^2 + k_3a_1^3/a_w$$

where $a_1$ and $a_w$ are the activities of the orthophosphoric acid and water, and $k_1$, $k_2$ and $k_3$ have the values $3{\cdot}8 \times 10^{-5}$, $2{\cdot}4 \times 10^{-7}$ and $4{\cdot}5 \times 10^{-12}$ g. atom/l. sec. respectively. The first term is important at low concentrations of $H_3PO_4$, the second at higher concentrations and the third only at the highest concentrations.

The mechanism of the isotopic exchange is believed to involve direct replacement of oxygen in $H_3PO_4$ (first term in equation (3)) and the reversible formation and hydrolysis of $H_4P_2O_7$ and possibly $H_5P_3O_{10}$ (second and third terms). The interaction of undissociated $H_3PO_4$ with its conjugate acid $H_4PO_4^+$ may be involved in these reactions.[327]

Isotopic dilution analysis[102] confirmed the presence of pyrophosphoric acid in very concentrated orthophosphoric acid solutions, the results agreeing with those obtained by chromatographic analysis[100-1] and conductivity measurements.[4]

In contrast to this, it appears that the mechanism of $^{18}O$ exchange at higher pH is analogous to the hydrolysis of monoalkyl phosphates, involving a first order attack of $H_2{}^{18}O$ on the monoanion $H_2PO_4^-$. Above pH 0 nucleophilic catalysis by anions of strong acids ($Cl^-$, $ClO_4^-$) was absent, but at higher phosphoric acid concentrations the perchlorate anion strongly catalyzes the exchange, perhaps by a salt effect[327] or through the formation of the species $P(OH)_4^+$.[358]

## The Reactions of Orthophosphoric Acid

### REACTION WITH HALOGEN ACIDS AND HALIDES

Orthophosphoric acid reacts with hydrogen fluoride according to the equilibrium:

$$H_3PO_4 + HF \rightleftharpoons H_2PO_3F + H_2O$$

the reaction proceeding further towards the right in the presence of strong acids, such as perchloric, nitric, sulphuric or benzenesulphonic acid, which remove free water from the system.[236] On the other hand monofluorophosphoric acid is completely hydrolyzed, according to the reverse reaction, when boiled in aqueous solution.[237]

Dry gaseous hydrogen chloride is absorbed by pure orthophosphoric acid to the extent of 8% by weight; such solutions, with respect to pH and conductivity, behave as if the compound $H_4PO_4Cl$ were present. This compound, soluble in $H_3PO_4$, slowly decomposes with the evolution of HCl if the orthophosphoric acid is allowed to crystallize out at room temperature.[238]

The isobaric absorption of hydrogen chloride, at 28·7–747·7 mm. pressure, and of hydrogen bromide, at 73·0–670·5 mm. pressure, by orthophosphoric acid (81·5–99·5% $H_3PO_4$) at temperatures between 50° and 160°C., has been studied and the heats of absorption measured. For HCl this varies from −2700 to −6 g.-cal./mole between 50° and 160°C. and from −2600 to −1100 g.-cal./mole between 70° and 160°C. for HBr. The diminution in heat of absorption with temperature is attributed to interaction between halogen acid and orthophosphoric acid,[239] for example:

$$3HCl + H_3PO_4 \rightleftharpoons POCl_3 + 3H_2O$$

Highly soluble calcium chloride, bromide and iodide form a series of double salts with orthophosphoric acid, under the specific conditions shown in Table XLII.[240]

*Table XLII.—Double Salts formed between Orthophosphoric Acid and Calcium Halides*

| Formula | Name | % Calcium halide | Temperature °C. |
|---|---|---|---|
| $CaCl_2,Ca_3(PO_4)_2$ | chlorospodiosite | 52–54<br>or 52–61 | 150<br>175 |
| $CaCl_2,3Ca_3(PO_4)_2$ | chloroapatite | 44–52 | 175 |
| $CaCl_2,Ca(H_2PO_4)_2,2H_2O$ | monocalcium chlorophosphate | not < 41–52 | 25–125 |
| $CaBr_2,Ca(H_2PO_4)_2,8H_2O$ | monocalcium bromophosphate | 53–58<br>or 55–56 | 0<br>25 |
| $CaBr_2,Ca(H_2PO_4)_2,2H_2O$ | monocalcium bromophosphate | 60–66 | 25–175 |
| $CaI_2,Ca(H_2PO_4)_2,8H_2O$ | monocalcium iodophosphate | — | at room temperature |

The formation of $CaCl_2,Ca(H_2PO_4)_2,2H_2O$ at 25°C. was previously reported in a physico-chemical study of the system $CaO–P_2O_5–HCl–H_2O$,[241] and its preparation as an intermediate in the production of calcium hydrogen phosphate, $CaHPO_4$, has been described.[242]

The reaction between magnesium chloride and orthophosphoric acid in 12·5, 25 and 50% excess over the stoicheiometric proportions required to form $Mg(H_2PO_4)_2$, has been studied at 49°, 75° and 95°C.; a higher temperature favours the removal of chloride ions as hydrogen chloride, for example:

$$2H_3PO_4 + MgCl_2 = Mg(H_2PO_4)_2 + 2HCl$$

and the mean activation energy of the process is reported to be 14·34 kcal./mole. With a 50% excess of orthophosphoric acid at 95°C., conversion is complete in 215 min.[243] Similar reactions occur with other alkali and alkaline-earth salts, the product obtained depending on the excess of acid used and the final temperature to which the reaction mixture is submitted.

### REACTION WITH OXYACIDS

Orthophosphoric acid and perchloric acid form a compound $H_3PO_4,HClO_4$, m.p. 46°–47°C., the electrolysis of which in methyl nitrite indicates that $H_3PO_4$ forms a positive ion, i.e. has basic properties, relative to the stronger acid $HClO_4$, in this solvent. The reaction:

$$PO(OH)_3 + HClO_4 = \overset{+}{P}(OH)_4ClO_4^-$$

may be compared with[244]:

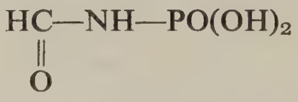
$$NH_3 + HClO_4 = NH_4^+ClO_4^-$$

The heat of solution of the complex in methyl nitrite is 13·9 kcal./mole. The *X*-ray diffraction pattern shows no resemblance to other perchlorates and the name tetrahydroxophosphor(V) perchlorate has been proposed.[245]

In a similar way infra-red,[328], N.M.R.[329] and other[330,343,365,369] evidence has been adduced for the existence of protonated species such as $\overset{+}{P}(OH)_4$ in the system $H_2SO_4$–$H_3PO_4$–$H_2O$. Other authors have interpreted electrical conductivity, viscosity, density, and refractive index isotherms as showing that no such interaction occurs.[331] Further study of the system is obviously desirable.

### REACTION WITH HYDROGEN CYANIDE

When 100% orthophosphoric acid and hydrogen cyanide are kept in a sealed tube for several weeks at room temperature, a viscous liquid separates which eventually crystallizes as a white amorphous solid. The composition corresponds to the formation of $H_3PO_4$,HCN which, from the mechanism of its breakdown on heating to form carbon monoxide and monoammonium dihydrogen phosphate, is believed[246] to have the structure:



$$\underset{\overset{\|}{O}}{HC}—NH—PO(OH)_2$$

### REACTIONS WITH GRAPHITE

Whilst under most conditions of concentration and temperature graphite and carbon are not attacked by orthophosphoric acid, the former, in the presence of an oxidizing agent such as chromic acid, begins to react at 80°–100°C. to form a brown material the *X*-ray powder diagram of which resembles that of the blue graphite–sulphuric acid compound which contains 24 carbon atoms to 1 molecule ion $HSO_4^-$. It is believed that in such compounds the hexagonal planes of the graphite are spread by the insertion of acid layers between them.[247] The rapid rate of wet oxidation of highly graphitized samples of carbon by orthophosphoric acid and bichromate possibly involves graphite–phosphate formation and decomposition.[248] Similar indications of 'salt' formation are obtained during the anodic oxidation of well-ordered specimens of pyrolytic graphite.[364]

### COMPLEXING OF METAL IONS BY ORTHOPHOSPHORIC ACID

The complexing of metal ions by orthophosphoric acid is well known and has been used in analytical chemistry for many years.[249–51] For example, the decolorizing action of orthophosphoric acid on the ferric ion is said to be due to the formation of the stable, soluble, colourless $FeHPO_4^+$ ion.[252–3] Other evidence[254] cited for the existence of soluble ferric ion–orthophosphoric acid complexes includes (*a*) the lowering of the oxidation potential of the ferrous-ferric system in the presence of orthophosphoric acid,[255] (*b*) the enhanced conductivity of mixtures of ferric salts and orthophosphoric acid above that expected from the sum of the constituent conductivities,[256] (*c*) the fact that the presence of orthophosphoric acid causes the reversible iodometric oxidation of the ferrous ion to proceed to completion,[257] and (*d*) the interference shown by orthophosphates to the colour developed by ferric and thiocyanate ions. It has also been reported that there is evidence for anionic orthophosphate–ferrate complexes from the movement of iron to the anode in transference measurements.

Various formulations for the complexes have been proposed, for example:

$[Fe(PO_4)_2]^{3-}$ and $[Fe(PO_4)_3]^{6-}$ [259]
$[FeHPO_4]^{+}$ [252–3]
$[FeH_2PO_4]^{2+}$ [260]
$[Fe(PO_4)Cl_3]^{3-}$ in the presence of chloride ions[256,261]

but it has also been stated that the complex(es) cannot be represented stoicheiometrically.[257] Ion-exchange studies[254] have shown the existence in solution of a complex containing three orthophosphate groups per iron atom, whilst breaks in the conductimetric titration curves of ferric chloride and orthophosphoric acid[262] indicate both $Fe(HPO_4)^+$ and $Fe(HPO_4)_2^-$ ions. Spectrophotometric studies have been used to study the stability of some of the complexes,[253, 263] crystalline salts of several of the phosphato-ferric acids have been isolated[255, 259, 264–5] and the phase diagram of the system $Fe–H_3PO_4–H_2O$ has been described.[255]

Aluminium, like iron, forms quite stable complexes with orthophosphoric acid,[255, 260] for some of which dissociation constants have been reported.[266]

Complexes between orthophosphoric acid and the following metals have also been mentioned: copper,[267] cobalt,[268] silver,[269] thorium,[270] plutonium,[271] uranium,[272] iridium[332] and even calcium.[273]

Some studies have also been made of the soluble complexes formed between the alkali and alkaline-earth metals and orthophosphoric acid; measurements of the dissociation constants for the 1 : 1 complexes, $MHPO_4$, show that they are not so stable as, for example, the iron and aluminium complexes referred to above.[274–5] The subject is fully discussed by Van Wazer and Callis.[258]

The formation of an extremely viscous fluid when 1·0–1·5 moles of alumina are dissolved in 1·0 mole or orthophosphoric acid is interesting. On drying, the solution forms an amorphous solid which can be dispersed again in water to give a solution with the original viscous properties.[276] It has been suggested that the colloidal nature of such solutions is due to the formation of polymeric aggregates, in which $PO_4$ tetrahedra are held together by aluminium ions. The degree of aggregation and stability of these polymers, like those of the heteropolyacids of phosphorus, are pH-dependent, being greater in a highly acid medium.[277] Excess of phosphoric acid reacts with corundum, even at 100°–120°C., giving aluminophosphates similar to those formed from hydrated alumina. Hydrated aluminophosphates, $Al_2O_3,3P_2O_5$, and the quartz, tridymite, and cristobalite forms of $AlPO_4$, together with *X*-ray diffraction lines belonging to an unidentified compound, can be detected at various higher temperatures. A glassy phase is formed at 1400°C.[389]

On the evidence of solubility and vapour pressure measurements,[278–80] soluble borophosphoric acids have been reported, but the nature of such complexes and their salts is as yet little understood; they probably contain a B–O–P network, similar to that believed to exist in boron phosphate, $BPO_4$.

Solubility evidence has also been invoked to support the belief that arsenophosphoric acids exist in solution, although the corresponding compounds cannot be isolated.[281]

### REACTION WITH SILICA

Silica, in any of its forms, when heated with orthophosphoric acid, dissolves to an extent dependent on its state of sub-division and on the temperature and concentration of the acid. The amorphous hydrated precipitate which first separates from solution dehydrates on further heating and eventually becomes crystalline.

A hydrated compound, $2P_2O_5,SiO_2,4H_2O$, has been described; it is formed by the action on silica of orthophosphoric acid previously heated to 250°–300°C.,[282] or by raising to 200°C. and thereafter maintaining at 125°C. for about 300 hr. a mixture of silica gel and orthophosphoric acid.[283] It has been suggested [283] that the compound can be regarded as a heteropoly-acid of the type $H_8[Si(PO_4)_4]$, but direct proof of octabasicity is lacking since it decomposes in warm water, alkali and acid, with the separation of silica. The clear solution obtained in cold water contains colloidal silica and, from electrical conductivity measurements, the compound is thought to be completely dissociated in dilute solutions.

Several references have been made to an anhydrous compound with the composition $P_2O_5,SiO_2$[282, 284–5] which separates when phosphoric acid and silica are heated together in sealed tubes or for prolonged periods at high temperatures. From a study of its behaviour in molten silver nitrate, when silver pyrophosphate is formed, it has been claimed[285] that $P_2O_5,SiO_2$ should be considered as neutral silicon pyrophosphate, $SiP_2O_7$, a conclusion supported by *X*-ray structural evidence.[286] The occurrence of the pyrophosphate structure is not surprising, since at the temperature of preparation the phosphoric acid would consist of a mixture of polyphosphate species.

When colloidal solutions of silica are evaporated with various proportions of phosphoric acid and the products dried at 110°C., gelatinous solids are formed; prolonged drying at 200°C. does not alter their composition, but the compounds become anhydrous. Evidence from composition, behaviour with molten or powdered silver nitrate and *X*-ray powder diffraction analysis using internal standards,[285] indicates that the compounds shown in Table XLIII can be formed.

*Table XLIII.—Compounds formed from Colloidal Silica and Phosphoric Acid*

| Molar ratio $P_2O_5/SiO_2$ | Compound | Preparation and properties |
|---|---|---|
| 1·0 | $P_2O_5,SiO_2,H_2O$<br>$Si(HPO_4)_2$<br>Silicon acid orthophosphate | From solutions containing $P_2O_5/SiO_2 \geqq 1$<br>Formed only when drying temperature is held below 180°C.; converts to $SiP_2O_7$ on further heating |
| 1·0 | $P_2O_5,SiO_2$ $SiP_2O_7$<br>Neutral silicon pyrophosphate | From solutions containing $P_2O_5/SiO_2 \geqq 1$<br>Exists in two, or possibly three allotropic forms, according to method of preparation |
| 0·66 | $2P_2O_5,3SiO_2$<br>$Si_3(PO_4)_4$<br>Neutral silicon orthophosphate | From solutions containing $P_2O_3/SiO_2 < 1$<br>No change in *X*-ray pattern by heating to 900°C. |

Attempts to isolate compounds with molar ratio $P_2O_5/SiO_2 = 2$ did not succeed.[285]

If phosphoric acid is heated in Pyrex glass containers at 300°C., the white mass which eventually forms is said to be neutral silicon orthophosphate.[285] Borosilicate glass is, however, unaffected by boiling 30–40% phosphoric acid.[333] Attack on high alkali glasses results primarily from the formation and solution of acid phosphates,[390] but in many cases a film of phosphate is formed which renders them more resistant to attack than low alkali glasses. Quartz is more resistant than either.[391]

The solubility of amorphous silica in orthophosphoric acid has been studied at 50° and 90°C.[287] At 90°C. a solid phase of variable composition, $n SiO_2, m P_2O_5, q H_2O$, is observed. The solubility of silica decreases as the concentration of the acid rises and increases with rising temperature. Equilibrium compositions in the ternary system, after 6 to 12 days at 90°C., are given in Table XLIV.

*Table XLIV.—Compositions in the Ternary System* $P_2O_5$–$SiO_2$–$H_2O$ *at* 90°C.

| Liquid phase | | Solid phase | |
|---|---|---|---|
| % $P_2O_5$ | % $SiO_2$ | % $P_2O_5$ | % $SiO_2$ |
| 4·68 | 0·029 | 3·89 | 27·30 |
| 6·98 | 0·027 | 7·60 | 32·13 |
| 13·51 | 0·019 | 9·20 | 31·53 |
| 17·74 | 0·013 | 12·89 | 29·90 |
| 26·42 | 0·006 | 20·61 | 30·84 |
| 27·52 | 0·007 | 21·90 | 26·37 |
| 42·10 | — | 33·95 | 26·41 |
| 42·14 | — | 36·47 | 25·40 |

The ternary solid phases decompose to give crystalline silicophosphates when heated to 325°–350°C. The existence of the two compounds $P_2O_5,SiO_2$ and $2P_2O_5,3SiO_2$ has been deduced from thermal, chemical, optical and *X*-ray studies of the phases separating from melts in the $P_2O_5$–$SiO_2$ system in the range 50–100 mole-% of $SiO_2$, at high temperatures and atmospheric pressure[288]; however it has also been claimed[289] that the only two crystalline phases to appear in sealed tubes at such temperatures are $P_2O_5,SiO_2$ and $P_2O_5,2SiO_2$, previous reports of $2P_2O_5,3SiO_2$ being attributed to loss of $P_2O_5$ from $P_2O_5,SiO_2$ when working in an open system at high temperature. Two modifications of $P_2O_5,SiO_2$ are reported[289]:

(*a*) a low temperature (< 700°C.) form, of which the *X*-ray powder diffraction pattern resembles closely that of the neutral silicon pyrophosphate prepared from colloidal silica solution at low temperature[285];

(*b*) a high temperature (> 1030°C.) form, with an *X*-ray powder diffraction pattern which, although similar to that of the high temperature variety,[286] differs from that of the sample prepared at high temperature from colloidal silica.[285]

It appears, therefore, that there may be at least three different crystalline modifications of $SiP_2O_7$. This is supported by an infra-red study of the system which also disclosed three isomers. Products formed at 300–350° had a loose structure and were slowly decomposed by water. Those formed at 400°–700° were dense, stable to water or $HF/H_2SO_4$, and had a lower ion exchange capacity towards Na(I) or $(UO_2)$(II) ions.[392]

The kinetics of the solution of germanium dioxide in 6–8 M. $H_3PO_4$ are most interesting. The reaction velocity increases to a maximum over 1–2 days and then declines to a very low value. The second stage is associated with the formation of $GeO_2,P_2O_5,2H_2O$, which probably has the structure $H_2[Ge(PO_4)_2],nH_2O$.[393]

### REACTION WITH BORON TRIFLUORIDE

As it does with all inorganic oxyacids, boron trifluoride forms co-ordination compounds with orthophosphoric acid, solutions of which, saturated with boron trifluoride, are widely used as catalysts in alkylation, polymerization and other organic reactions.[290]

In 1947 it was reported[291-3] that definite co-ordination compounds are formed, for example $H_3PO_4,BF_3$ and $H_4P_2O_7,2BF_3$, which are comparatively stable liquids on storage and not decomposed at 100°C. Because the compounds are difficult to purify by fractional crystallization or distillation, their physical constants are not known with any accuracy. The adducts decompose when distilled, and the orthophosphoric acid complex solidifies to a glassy mass at $-100$°C.

However, when stoicheiometrically accurate (1 in $10^4$) proportions of boron trifluoride are absorbed in orthophosphoric or deuterophosphoric acid, the 1 : 1 complexes formed have the properties shown in Table XLV.[4]

*Table XLV.—Densities, Viscosities and Electrical Conductivities of* $BF_3,H_3PO_4$ *and* $BF_3,D_3PO_4$

| | Density, $d_4^{t°}$ g./cm.$^3$ | | Viscosity, $\eta$ centipoises | | Specific conductivity, $K$ ohm$^{-1}$ cm.$^{-1}$ | |
|---|---|---|---|---|---|---|
| °C. | $BF_3,H_3PO_4$ | $BF_3,D_3PO_4$ | $BF_3,H_3PO_4$ | $BF_3,D_3PO_4$ | $BF_3,H_3PO_4$ | $BF_3,D_3PO_4$ |
| 25 | 1·8831 | 1·9058 | 46·16 | 48·51 | $8{\cdot}23 \times 10^{-3}$ | $8{\cdot}20 \times 10^{-3}$ |
| 30 | 1·8777 | 1·8990 | 39·27 | 41·66 | $9{\cdot}29 \times 10^{-3}$ | $9{\cdot}25 \times 10^{-3}$ |
| 35 | 1·8734 | 1·8933 | 34·26 | 35·85 | $10{\cdot}41 \times 10^{-3}$ | $10{\cdot}37 \times 10^{-3}$ |
| 40 | 1·8681 | 1·8870 | 30·35 | 31·11 | $11{\cdot}85 \times 10^{-3}$ | $11{\cdot}50 \times 10^{-3}$ |

Previously reported values for density and electrical conductivity of the boron trifluoride–orthophosphoric acid complex[294-6] differ from those quoted in Table XLV, and probably refer to solutions more concentrated with respect to boron trifluoride than corresponds to the mole ratio of unity. At 40°C. it was observed that one mole of orthophosphoric acid could absorb 1·084 moles of boron trifluoride.[4]

The 1 : 1 complexes of boron trifluoride and orthophosphoric or deuterophosphoric acid are very much more mobile than their parent acids and in this respect are unique among the boron trifluoride adducts. Their electrical conductivities are also much lower than those of the acids, which themselves have abnormally large conductivity. This may be attributed[4] to boron trifluoride molecules occupying sites formerly available for hydrogen bonding, which confers high viscosity and is a pre-requisite for electrical conduction by proton-jumps (see page 692). Conduction in the complexes thus proceeds by normal ionic migration. A comparison of the viscosity and conductivity of the $BF_3$ complexes of orthophosphoric and deuterophosphoric acid is given in Table XLVI.[4]

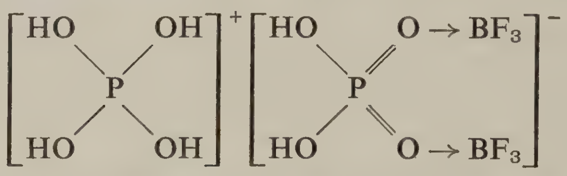
*Table XLVI.—Comparison of Viscosity and Conductivity of the* $BF_3$ *Complexes of Orthophosphoric Acid and Deuterophosphoric Acids at* 25°C.

| | $H_3PO_4$ | $BF_3,H_3PO_4$ | $D_3PO_4$ | $BF_3,D_3PO_4$ |
|---|---|---|---|---|
| Viscosity $\eta_{25}$ cps. | 177·5 | 46·16 | 231·8 | 48·51 |
| Specific conductivity $K$,ohm$^{-1}$ cm.$^{-1}$ | $4{\cdot}675 \times 10^{-2}$ | $0{\cdot}823 \times 10^{-2}$ | $2{\cdot}818 \times 10^{-2}$ | $0{\cdot}820 \times 10^{-2}$ |

Although boron trifluoride–orthophosphoric acid has been represented[297] as:

$$[H^+]_3[PO_4BF_3]^{3-}$$

on the basis of stoicheiometry, cryoscopic molecular weight determinations[294] and electrical conduction characteristics, the following structure appears more likely[4]:



Calculations show that this molten complex is ionized to the extent of about 60–70%.

A compound with half the amount of boron trifluoride, $BF_3,2H_3PO_4$, has been envisaged and some evidence exists to support this idea from a slight irregularity in the 40°C. conductivity–composition isotherm at the mole ratio 0·5.[4]

## USES OF ORTHOPHOSPHORIC ACID

By far the greatest consumption of pure orthophosphoric acid is in the preparation of various salts for use in the food, detergent and dentifrice industries, and of the less pure acid in the production of phosphatic fertilizers and detergent phosphates.

Because pure orthophosphoric acid is devoid of odour and, when greatly diluted, not injurious to health, it is often used as a constituent of tonic medicines and soft drinks. Being non-toxic it is employed for the manufacture of certain foodstuffs, such as gelatin, for removing milk-stone from dairy equipment and in the preparation of activated carbon for sugar-refining. It is also an acceptable source of supplemental phosphorus for beef cattle.

The acid is also used to control hydrogen ion concentration in the production of antibiotic drugs and often as a food for micro-organisms themselves; another application in the field of medicine is the manufacture of dental cements.

In conjunction with certain of its salts it is the basis of many preparations for metal finishing processes designed to provide protective phosphate coatings on iron, steel and other metals and the acid can also be used in pickling to remove mill-scale and rust. Orthophosphoric acid is also a constituent of solutions employed for chemically polishing brass and aluminium ware, and in the electropolishing of many metals and alloys.

In the textile industry it provides a convenient means of adjusting the acidity of the dye-bath, having no corrosive action on machinery.

Miscellaneous uses are as a coagulant in the processing of rubber latex, the production of non-corrosive soldering fluxes of the aniline phosphate type and in the preparation of dehydration, polymerization and alkylation catalysts for the oil-refining industry. The acid has also been used, in admixture with other materials, to improve the compressive strengths of clay soils.

The uses of orthophosphoric acid have been fully described, with extensive bibliographies.[298–300]

### SECTION XXVI

# LINEAR POLYPHOSPHORIC ACIDS

BY J. E. SUCH

THE conception of a series of polyphosphoric acids derived from orthophosphoric acid by the abstraction of water, advanced as long ago as 1845 by Fleitmann and Henneberg,[1] suggested the following compounds:

| | | |
|---|---|---|
| orthophosphoric acid | $H_3PO_4$ | |
| di- or pyrophosphoric acid | $H_4P_2O_7$ | ($2H_3PO_4$ less $H_2O$) |
| triphosphoric acid | $H_5P_3O_{10}$ | ($3H_3PO_4$ less $2H_2O$) |
| tetraphosphoric acid | $H_6P_4O_{13}$ | ($4H_3PO_4$ less $3H_2O$) |
| | etc. | etc., |

the general equation for the series being

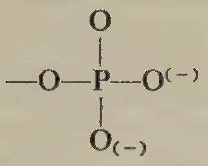
$$nH_3PO_4 = H_{n+2}P_nO_{3n+1} + (n-1)H_2O$$

When $n$ is a very large number the formula for the acid approaches $(HPO_3)_n$, which, analytically, would be indistinguishable from the last group of the three acids, originally classified by Graham as orthophosphoric, pyrophosphoric and metaphosphoric acids.

Although the salts of some of these acids, other than ortho- and pyrophosphoric acids, have been described by early workers,[2] the question of the existence of polyphosphates of acids intermediate between pyrophosphoric and so-called metaphosphoric acid remained in some doubt for nearly a century. Owing to inadequate analytical procedures and lack of knowledge of the structural arrangements of the compounds under study, it often proved difficult to decide whether many were individual bodies or just mixtures of the two end-members of the polyphosphoric acid series.

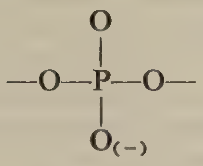
However, the application of *X*-ray, infra-red and nuclear magnetic resonance techniques has, of late years, clarified the structural problems, and the use of physico-chemical methods of analysis, such as paper and ion-exchange chromatography, permits the identification and fairly accurate determination of the various species of phosphates, either in the pure state or in mixtures. Also, since the polyphosphoric acids and their salts behave as poly-electrolytes, many of the physical methods of investigation used in the field of high polymer chemistry have, during the last two decades, been applied to them, with important results. These include the determination of molecular size by ultra-centrifugation[3-8] and diffusion,[9] end-group titration,[10] intrinsic viscosity in salt solutions,[11] cryoscopy,[12] light-scattering[13] and limiting viscosity in water[11,13,114]; the investigation of molecular shape by nuclear magnetic resonance peaks,[15-6] by flow bi-refringence[17] and anisotropy in electrical conductivity measurements[18-9] and of the size distribution of the species present in mixtures, by solubility fractionation,[20] paper-chromatography[21-2] and anion-exchange.[23-7]

The conclusions to be drawn from these diverse fields of investigation have been reviewed,[28,146,160] and support the idea that phosphates can be regarded as phosphorus compounds with anions in which each phosphorus atom is surrounded by four oxygen atoms, tetrahedrally arranged. This is the unit for more complex structures in which, by sharing oxygen atoms between adjacent tetrahedra, chain, ring and branched polymers may be formed. Thus, it has been suggested[29] that there are three main structural units from which polyphosphates can be assembled, end groups, middle groups and branching points, which may be represented as follows:



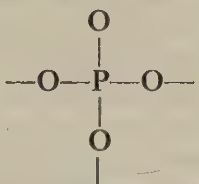
$-O-\overset{\overset{O}{|}}{\underset{\underset{O_{(-)}}{|}}{P}}-O^{(-)}$

end group



$-O-\overset{\overset{O}{|}}{\underset{\underset{O_{(-)}}{|}}{P}}-O-$

middle group



$-O-\overset{\overset{O}{|}}{\underset{\underset{\underset{|}{O}}{|}}{P}}-O-$

branching point

In the end $PO_4$ group, one oxygen is shared and there are two negative charges (or ester linkages); in the middle $PO_4$ group, two oxygen atoms are shared with adjacent groups and there is one negative charge (or ester linkage); finally, there is the branching point, in which three oxygen atoms are shared by neighbouring $PO_4$ groups.

By assembling two end-groups, the pyrophosphate molecule is formed, and by the addition of middle groups the series of linear polyphosphate ions can be envisaged. Combination of middle groups gives ring molecule ions and branching points can be introduced to form branched chains, or to attach rings to chains (see page 754).

The constitution of the linear polyphosphoric acids of general formula $H_{n+2}P_nO_{3n+1}$ can be depicted as shown in Table I.[30]

*Table I.—The Linear Polyphosphoric Acids of General Formula* $H_{n+2}P_nO_{3n+1}$

| Formula | % $P_2O_5$ | Constitution of acid $H_{n+2}P_nO_{3n+1}$ | Rational name | Number of dissociated hydrogen atoms | |
|---|---|---|---|---|---|
| | | | | Strong | Weak |
| $H_3PO_4$ | 72·39 |  $HO-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-OH$ | mono- (ortho) | 1 | 2 |
| $H_4P_2O_7$ | 79·72 |  $OH-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-OH$ | di- (pyro) | 2 | 2 |
| $H_5P_3O_{10}$ | 82·52 |  $OH-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-OH$ | tri- (tripoly) | 3 | 2 |
| $H_6P_4O_{13}$ | 83·98 |  $HO-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-OH$ | tetra- | 4 | 2 |
| $H_{n+2}P_nO_{3n+1}$ | — |  $HO-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\cdots-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}-OH$ | polyphosphoric acid | $n$ | 2 |

Although it had been suggested that phosphoric acids having a phosphoric oxide content greater than that of $H_3PO_4$ contained various polyphosphoric acids,[31-2] most early workers assumed them to be simple mixtures of orthophosphoric, pyrophosphoric and metaphosphoric acids. However, subsequent studies of the composition of such acids,[33-5] and more particularly those in which paper,[36-7] thin layer[161-2] and ion-exchange[38-40, 163] chromatography have been employed, support the conclusion that the so-called strong (or condensed) phosphoric acids are equilibrium mixtures of the various linear polyphosphoric acids, the structures of which are given in Table I, at least for compositions up to about 86% of phosphoric oxide.

It has also been established that the equilibrium composition, expressed in terms of the linear polymers, is a function of the phosphoric oxide concentration and is not dependent on the method of preparation. Equilibrium conditions, attained fairly quickly at the temperatures commonly used in the preparative methods,[41] are frozen by chilling to room temperature, at which any further rearrangements are too slow to be significant for practical purposes.

Mixtures having more than 86% of phosphoric oxide contain some cyclic polyphosphoric acids, in addition to the linear polymers,[40] but a conclusion drawn from early paper-chromatographic analyses[36] that the lower members of the polyphosphoric acid series (up to nonaphosphoric acid) tended towards zero at 88·7% $P_2O_5$, a composition equivalent to $(HPO_3)_n$, could not be substantiated from the results of later ion-exchange studies.[40] These indicated the presence, not only of linear and cyclic polyphosphoric acids in such a composition, but also of more complex ring-containing structures as well.

The compositions of phosphoric acids, in terms of the constituent polyphosphoric acids, given in Table II and in Fig. 1, are based on data contained in reference 40.

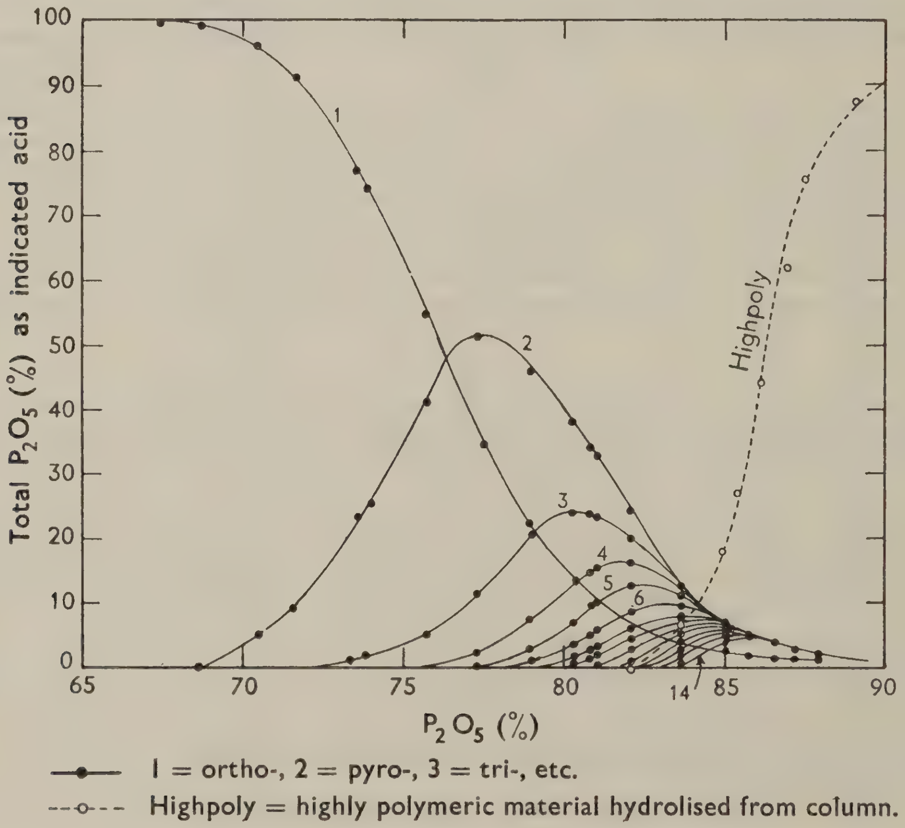


FIG. 1.—The composition of phosphoric acids

Using a flexible chain to represent the polyphosphoric acids existing in equilibrium in liquid phosphoric acids, Parks and Van Wazer[42] have calculated, from theoretical considerations, the distribution of the various species of polyphosphoric acids in liquids with varying phosphoric oxide contents. Their results are in close agreement

*Table II.—Composition of Phosphoric Acids (% Total $P_2O_5$ as Constituent Polyphosphoric Acids)*

| * | Total $P_2O_5$ % | $\frac{[P_2O_5]}{[H_2O]}$ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | High-poly | Tri-meta- | Tetra-meta |

High-poly = material retained by resin.

with the analytical evidence so far available, except for mixtures containing more complex structures than the purely linear polyphosphoric acids upon which the theoretical calculations were based. In subsequent statistical treatments it was claimed that the amount of free orthophosphoric acid in polyphosphoric acid could be explained by regarding this acid as the fundamental unit from which the polyphosphoric acids are constructed.[152,164] A modification of these calculations, using a few empirical parameters, permitted the calculation of chain-length distributions for polyphosphoric acids which fit available data even more closely.[165] It has been observed, however, that in polyphosphoric acid obtained by dehydrating gypsum process phosphoric acid (see page 77), the distribution of polyphosphate species is displaced towards higher molecular weights, compared with pure polyphosphoric acid of the same $P_2O_5$ content.[166-7]

The rotational isomeric state theory of linear macromolecules[168] has been used to analyze the unperturbed dimensions of the polyphosphate chain. The results are explicable on the assumption that electrostatic or steric interactions cause little hindrance to rotation about one bond of the chain while all its neighbours are *trans*, but greatly impede simultaneous large rotations about pairs of adjoining bonds.[169]

### Preparation of Linear Polyphosphoric Acids

The linear polyphosphoric acids can be most readily prepared by evaporating orthophosphoric acid,[36-8,166,170] or by the addition of phosphoric oxide, (H) form, to it.[36,40,171]

The evaporation can be performed in pyrex containers up to about 180°C.,[37] in graphite crucibles up to about 350°C., at which point some reduction to elemental phosphorus begins to take place, or up to 750°C. preferably in Hastelloy, gold or platinum.[36-7,43] Evaporation in gold or platinum gives acids with stable purple or brown colours, possibly a colloidal effect.[44] Heat for the dehydration[166] or distillation[171] of phosphoric acid can be provided by burning a suitable fuel in a flame which is submerged in the acid.

When phosphoric oxide is used with orthophosphoric acid to prepare the linear polyphosphoric acids, it is often necessary to heat the mixtures as the oxide is slow to dissolve in the viscous medium. One method of doing this is to seal orthophosphoric acid and phosphoric oxide in pyrex containers and heat in a furnace, at about 350°C., for 10–20 min. and then chill rapidly to room temperature.[36]

If monoammonium phosphate is heated for 3 hours at 340°C. it loses all its ammonia and some water, giving pyrophosphoric acid. At 440°C. higher polyphosphoric acids are formed and at 600°C. branched ultraphosphoric acids result.[153]

Polyphosphoric acids are also formed in reactions between orthophosphoric acid and phosphorus oxychloride[37,45,46] of the type:

$$(n-1)\mathrm{POCl_3}+(2n+1)\mathrm{H_3PO_4} = 3\mathrm{H}_{n+2}\mathrm{P}_n\mathrm{O}_{3n+1}+3(n-1)\mathrm{HCl}$$

and it has also been claimed[47] that electrolysis of acids containing at least 72·4% $P_2O_5$, using high current density, produces polyphosphoric acids ($n=3{\cdot}5$ average) without significant formation of reduced phosphorus compounds. The reaction of phosphoric oxide with hydrogen peroxide yields permonophosphoric acid and the lower polyphosphoric acids. No tetrametaphosphoric acid is detected, since the lower cyclic phosphoric acids are rapidly decomposed by water in presence of excess hydrogen peroxide.[172] Tetraphosphorus hendecaoxide, $P_4O_{11}$, is said to yield a mixture of perdiphosphoric and pyrophosphoric acids on treatment with water.[173] The lower polyphosphoric acids and their esters have also been detected in the so-called 'Langheld ester', obtained by the reaction of phosphoric oxide with diethyl ether.[174]

### Physical Properties of Linear Polyphosphoric Acids

The linear polyphosphoric acids are very hygroscopic and range, at room temperature, from viscous liquids through gums to glassy solids when containing more than 86% $P_2O_5$.[37] The only known crystalline compositions in the phosphoric oxide–water system, apart from orthophosphoric acid hemi-hydrate, $4H_2O,P_2O_5$, and orthophosphoric acid itself, $3H_2O,P_2O_5$, are the two forms of pyrophosphoric acid (q.v.). A crystalline tetraphosphoric acid, $3H_2O,2P_2O_5$, has been reported,[48–9] but it is more than likely that this was actually one of the two crystalline forms of pyrophosphoric acid, produced either by surface hydrolysis or slow crystallization from the liquid acid[37]; there is also some doubt about the identity of a crystalline metaphosphoric acid, $H_2O,P_2O_5$, described in the literature.[50–1]

### DENSITY

The densities of acids with phosphoric oxide contents in the range 72·43–88·74% $P_2O_5$, which are given in Table III, have been extracted from data published by the Tennessee Valley Authority.[52]

*Table III.—Density of Linear Polyphosphoric Acids*

| Concentration wt.-% $P_2O_5$ | Density, g./c.c. at indicated temperature, °C. | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | 25 | 30 | 40 | 50 | 75 | 100 | 125 | 150 |
| 72·43 | 1·863 | 1·859 | 1·852 | 1·845 | 1·826 | 1·808 | 1·789 | 1·771 |
| 74 | 1·889 | 1·885 | 1·878 | 1·871 | 1·852 | 1·834 | 1·816 | 1·798 |
| 76 | 1·921 | 1·918 | 1·911 | 1·903 | 1·886 | 1·868 | 1·850 | 1·832 |
| 78 | 1·954 | 1·950 | 1·943 | 1·936 | 1·919 | 1·901 | 1·884 | 1·866 |
| 79·76 | 1·983 | 1·979 | 1·972 | 1·965 | 1·948 | 1·931 | 1·914 | 1·896 |
| 80 | 1·987 | 1·983 | 1·976 | 1·969 | 1·952 | 1·935 | 1·918 | 1·900 |
| 82 | 2·019 | 2·016 | 2·009 | 2·002 | 1·985 | 1·968 | 1·951 | 1·934 |

| 86 | 2·084 | 2·081 | 2·075 | 2·068 | 2·052 | 2·035 | 2·019 | 2·003 |
| 88·74 | 2·129 | 2·126 | 2·120 | 2·113 | 2·097 | 2·081 | 2·065 | 2·049 |

*Table IV.—Kinematic Viscosity in Centistokes of Polyphosphoric Acids, 72·43–85·41% $P_2O_5$*

| °C. | % $P_2O_5$ | | | | |
|---|---|---|---|---|---|
| | 72·43 | 76·01 | 79·63 | 83·25 | 85·41 |
| 20 | 140 | 600 | — | — | — |
| 25 | 100 | 440 | 2200 | — | — |
| 30 | 81 | 330 | 1600 | — | — |
| 40 | 53 | 173 | 810 | — | — |
| 50 | 36 | 110 | 410 | — | — |
| 60 | 25 | 70 | 270 | 1500 | — |
| 70 | 19 | 50 | 170 | 1000 | — |
| 80 | 14 | 33 | 100 | 600 | 2000 |
| 90 | 11 | 25 | 67 | 380 | 1200 |
| 100 | 9·2 | 19 | 50 | 250 | 830 |
| 110 | 7·7 | 15 | 38 | 190 | 550 |
| 120 | 6·2 | 12 | 29 | 120 | 400 |
| 130 | 5·2 | 9·6 | 22 | 99 | 320 |
| 140 | 4·5 | 8·0 | 18 | 68 | 210 |
| 150 | 4·1 | 7·1 | 15 | 54 | 170 |
| 160 | 3·5 | 6·0 | 13 | 41 | 130 |
| 170 | 3·2 | 5·2 | 10 | 34 | 107 |
| 180 | 2·9 | 4·5 | 8·8 | 28 | 87 |

To a first approximation, the densities of the polyphosphoric acids are proportional to their phosphoric oxide contents and the following equation, although not in exact conformity with the data in Table III, is relevant:

$$d_{25^\circ\text{C.}} = 0{\cdot}0167 \times (\%\ P_2O_5) + 0{\cdot}66 \quad \text{for} \quad 50 < \%\ P_2O_5 < 95$$

and the temperature correction:

$$d_{t^\circ\text{C.}} = d_{25^\circ\text{C.}} - 0{\cdot}0009(t^\circ\text{C.} - 25)$$

may be applied.[51]

VISCOSITY

The kinematic viscosity, in centistokes, of certain polyphosphoric acids at the indicated temperatures is shown in Table IV, the accuracy claimed being of the order of 10%.[52]

Other, possibly more accurate, data obtained by the Hoeppler rolling-ball viscometer for a narrower range of compositions, and at temperatures for which values were not given in Table IV, are shown in Table V.[53]

*Table V.—Dynamic Viscosity in Centipoises of Polyphosphoric Acids,* 81·47–84·39% $P_2O_5$

| 1·24 | 86·4 | 75–200 | 0·221 | 8·494 |

ELECTRICAL CONDUCTIVITY

The specific electrical conductivity of phosphoric acid (62·15–85·58% $P_2O_5$) has been measured at 25–60°C.[175] The results, given in Table VII, differ slightly from previous results recorded in this region, and discussed elsewhere (page 693).

### REFRACTIVE INDEX

The refractive index, at 25°C., of polyphosphoric acids, in the narrow range of composition 81·57–84·47% $P_2O_5$, varies linearly with concentration; it was found to be constant on storage under dry conditions and also after repeated heating and cooling cycles,[53] see Table VIII.

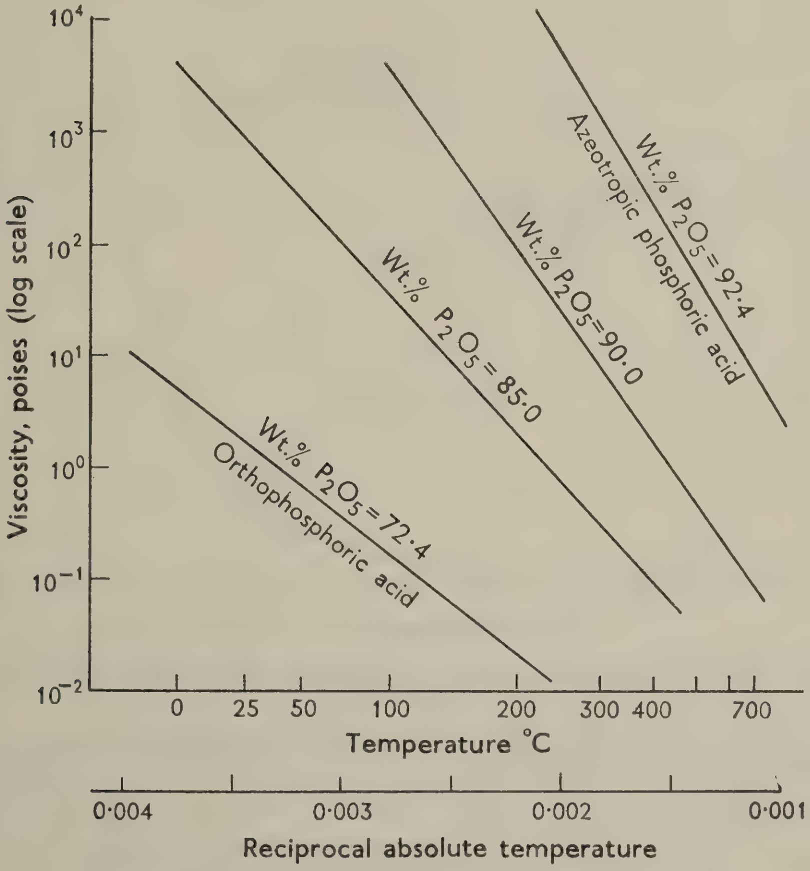

FIG. 2.—Variation of viscosity of polyphosphoric acids with temperature

### VAPOUR PRESSURE AND VAPORIZATION OF POLYPHOSPHORIC ACIDS

Vapour pressure equations and boiling points[43] have been given, for polyphosphoric acids containing 72·4–92·7% $P_2O_5$, in Table VI, Section XXV (see page 676).

These data have been used to deduce the following equation,[51] which is said to fit the data in the range 50–100 mm. to 760 mm. of Hg over the composition range 20–92% within experimental error:

$$\log_{10} p_{\text{mm}} = 8{\cdot}7788 - (5{\cdot}9080 \times \text{b.p.}/T)$$

where $p_{\text{mm}}$ is the vapour pressure in mm. Hg of the given acid at the temperature $T$ (°K.) and b.p. is the boiling point in °K. as measured at 760 mm.

*Table VIII.—Refractive Index of Polyphosphoric Acids at* 25°C.

| % $P_2O_5$ | $n_D^{25}$ |
|---|---|
| 81·57 | 1·4700 |
| 82·46 | 1·4711 |
| 83·57 | 1·4725 |
| 84·47 | 1·4735 |

The boiling points of various compositions in the $P_2O_5$–$H_2O$ system are shown in Fig. 3. The boiling point increases only slowly up to compositions containing 60–70% $P_2O_5$; thereafter the rise is rapid. The presence of an azeotrope has been demonstrated[43, 55]; when orthophosphoric acid is heated, both water and phosphoric oxide eventually volatilize until an azeotropic mixture is obtained, which varies in composition from 91·1 to 92·1% $P_2O_5$ as the pressure in the system at its boiling point increases from 104 to 753 mm., the corresponding boiling points being 694° and 869°C. respectively. The azeotropic composition can be obtained from samples both richer and poorer in phosphoric oxide. At 760 mm. the boiling point and composition of the azeotrope are about 864°C. and 92·4% $P_2O_5$.

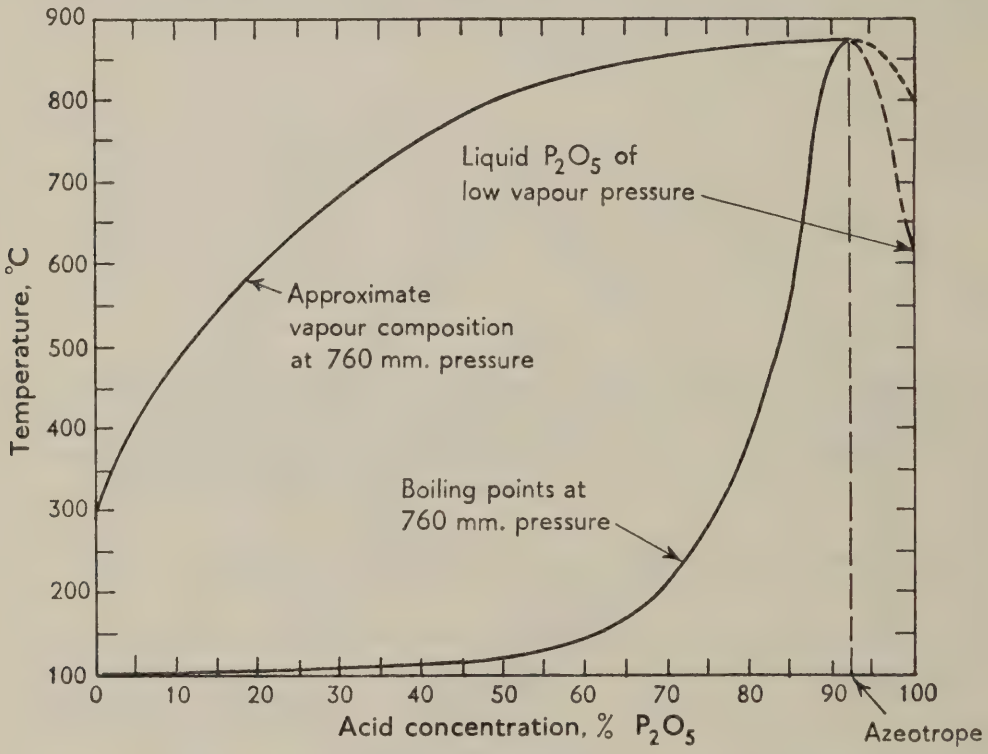

FIG. 3.—Boiling points and vapour compositions in the system $P_2O_5$–$H_2O$

The composition of the vapour above boiling phosphoric acid becomes progressively richer in phosphoric oxide up to the azeotrope, when both vapour and liquid have the same composition.[43] This change is shown graphically in Fig. 3.

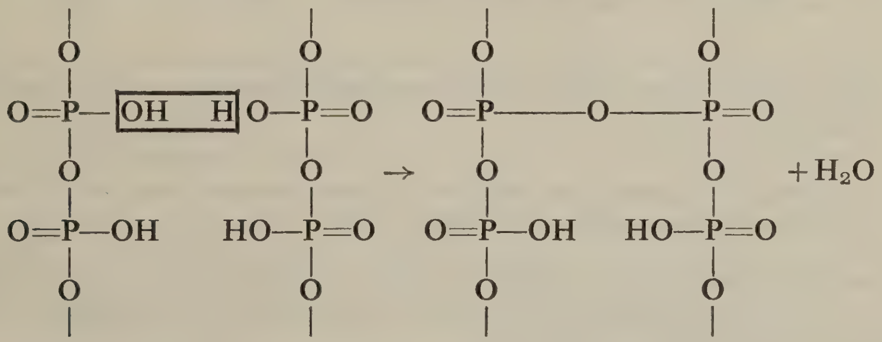
The nature of the molecular species in the vapour phase has been discussed.[51,55] Early vapour density measurements had suggested that the vapour over samples containing 91% of phosphoric oxide contained the dimeric form of so-called metaphosphoric acid, $(HPO_3)_2$; the most recent[43] vapour density determinations at 1020°C., however, indicate that the vapour consists of a mixture of water and phosphoric oxide vapour ($P_4O_{10}$) and, possibly, low molecular weight 'ultraphosphate' compounds of the type $H_2O,3P_2O_5$ (see Table IX).

*Table IX.—Apparent Molecular Weights in the* $H_2O–P_2O_5$ *System at* 1020°C.[51]

| % $P_2O_5$ in liquid | Acid composition | Mol. wt. observed | Mol. wt. calculated assuming vapour to be | |
|---|---|---|---|---|
| | | | $P_4O_{10}+H_2O$ | $H_2O,3P_2O_5+H_2O$ |
| 61·5 | 85% $H_3PO_4$ | 44·8 | 42·4 | 43·7 |
| 72·4 | 100% $H_3PO_4$ | 56·0 | 56·0 | 58·8 |
| 88·0 | Near 'meta phosphoric acid', $(HPO_3)_x$ | 109·6 | 102·4 | 107·8 |
| 92·0 | Azeotropic acid | 132·2 | 130·0 | 153·0 |

In an attempt to identify the constituents present, the vapours from phosphoric acid melts held at 450°C. (which varied in composition with heating time) were condensed by quenching in liquid air. The products were analyzed chromatographically; it was not possible to identify tetrametaphosphoric acid, which might have been expected to be present as the first identifiable hydrolysis product of phosphoric oxide, but only high molecular weight polyphosphoric acids.[37,56] It appears that there is insufficient evidence, to date, to be specific on this problem.

Acids containing more than about 92% $P_2O_5$, sometimes called ultraphosphoric acids, have not been very thoroughly studied, but it has been suggested[37] that cross-linking of long chain polyphosphoric acids can take place as follows:



leading to the formation of three-dimensional networks with the required high phosphoric oxide content, analogous in structure to some of the forms of phosphoric oxide itself (see pages 390, 391). The presence of up to 20% trimetaphosphate among the products of hydrolysis of ultraphosphates has been claimed as evidence that cyclic structures, joined in linear or two dimensional arrangements, are present in these networks.[176]

## Chemical Properties of Linear Polyphosphoric Acids

The linear polyphosphoric acids are strongly hygroscopic at room temperature and, when exposed to moist air, rapidly become less viscous and undergo hydrolysis to less complex forms; storage under strictly anhydrous conditions is therefore necessary to preserve their original composition.

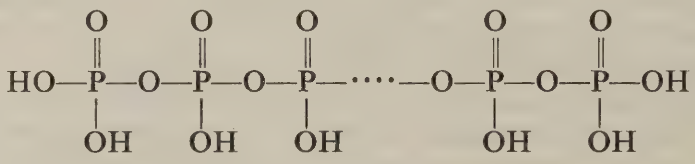
When linear polyphosphoric acids are dissolved in water, unless precautions are taken to cool the mixture, the rise in temperature on dilution causes rapid hydrolytic degradation to mixtures of less complex acids. If the conditions of dilution are accompanied by a large increase in temperature, the polyphosphoric acids present are converted almost completely to the orthophosphate state. For example, if an acid containing 84% $P_2O_5$, corresponding to tetraphosphoric acid, $H_6P_4O_{13}$, is diluted with water to approximately 54% $P_2O_5$, corresponding to 75% $H_3PO_4$, without cooling, the temperature of the solution rises to 120–140°C. and the hydrolysis to orthophosphoric acid is completed in less than 2 min.[34]

Hydrolytic degradation on dilution is reduced to a minimum if the acids are slowly added to sufficient ice-cold normal sodium or potassium hydroxide to keep the solution alkaline at all times.[37]

When stored under dry conditions, only those linear polyphosphoric acids of which the compositions correspond approximately to pyrophosphoric acid (79·72% $P_2O_5$) crystallize on long standing.[35–6, 57–60] As the solid phase usually has a different composition from the liquid phase in terms of the constituent polyphosphoric acids, such methods of investigation require careful interpretation; in addition, supercooling of the highly viscous liquids renders accurate observations of the freezing points difficult (see also under Orthophosphoric and Pyrophosphoric Acids).

NEUTRALIZATION—pH TITRATION CURVES

It has been noted[37, 61–2] that linear polyphosphoric acids contain two different kinds of hydroxyl groups which can be distinguished by their ionization constants and consequently by their behaviour on neutralization. If the linear polyphosphoric acids are presented schematically by the formulation



$$\mathrm{HO{-}\underset{\underset{OH}{|}}{\overset{\overset{O}{\|}}{P}}{-}O{-}\underset{\underset{OH}{|}}{\overset{\overset{O}{\|}}{P}}{-}O{-}\underset{\underset{OH}{|}}{\overset{\overset{O}{\|}}{P}}{-}\cdots\cdots{-}O{-}\underset{\underset{OH}{|}}{\overset{\overset{O}{\|}}{P}}{-}O{-}\underset{\underset{OH}{|}}{\overset{\overset{O}{\|}}{P}}{-}OH}$$

the two types of hydroxyl groups are as follows:

(*a*) Strongly dissociated hydroxyl groups, of which there is one attached to each phosphorus atom in the chain; these may be determined by titrating with an alkali to a pH of about 4·5.

(*b*) Weakly dissociated hydroxyl groups, of which there are two, one in each of the end $PO_4$ groups in the chain; these may be determined by titration between pH about 4·5 and pH about 9·0.

If (*a*) and (*b*) represent the numbers of strong and weak acid groups, respectively, then the average chain length, $n$, of a mixture of polyphosphoric acids, in which $n$ is equal to or greater than 2, is given by:

$$n = \frac{2a}{b}$$

Since mono- (ortho) and di- (pyro) phosphoric acids both have the same ratio of strong to weakly acid groups, namely unity, corrections to the above equation must be made when calculating the average chain length of mixtures of polyphosphoric acids containing free orthophosphoric acid. If $c$ represents the number of orthophosphate phosphorus atoms present in the mixture (which can be determined by suitable alternative analytical procedures, such as colorimetry) then the corrected equation for average chain length becomes:

$$n = \frac{2(a-c)}{b-c}$$

Differential titration methods have been described for the determination of the average chain length of the linear polyphosphoric acids, which employ the principles outlined above and which can also be corrected to take into account the presence of not only orthophosphoric but cyclic and branched polyphosphoric acids as well.[10,37,63–5]

Electrometric titration curves obtained for freshly prepared solutions of various linear and cyclic polyphosphoric acids[61–2] are depicted in Fig. 4.

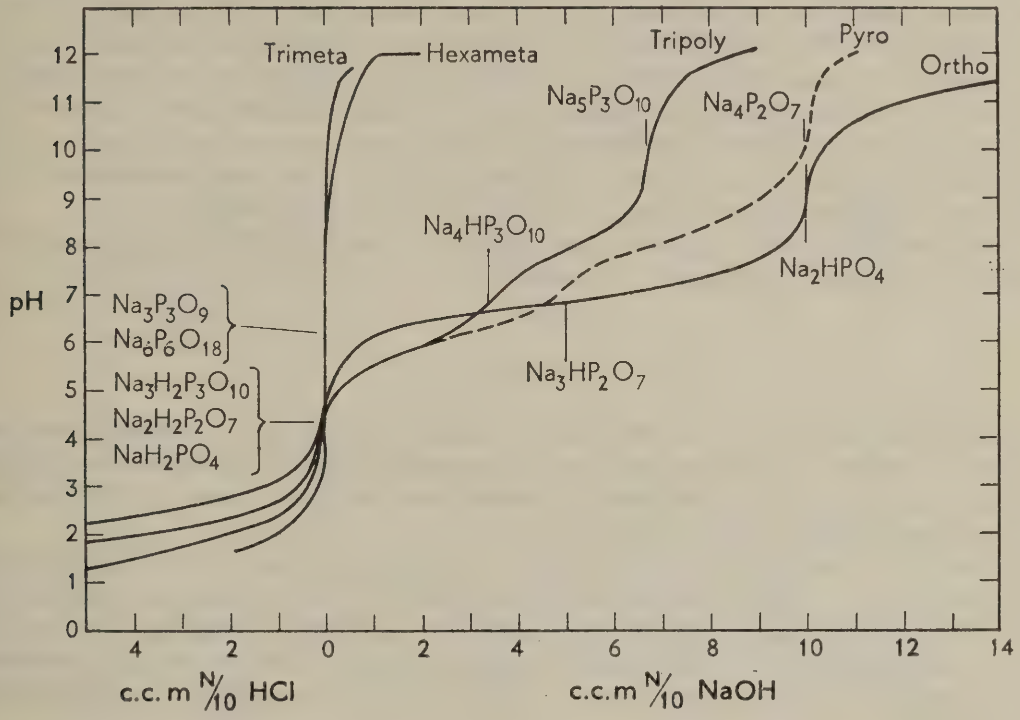


FIG. 4.—pH titration of linear and cyclic polyphosphoric acids

The main points of interest in these curves have been thoroughly discussed[51,61,66]; briefly, it has been stated that:

(i) for each phosphorus atom, in a linear polyphosphoric acid, there is one strongly dissociated hydrogen atom, $K_{\text{dissoc.}}$ approximately 10 to $10^{-3}$;
(ii) there is a weakly dissociated hydrogen atom attached to each of the phosphorus atoms at the ends of the chain, $K_{\text{dissoc.}}$ approximately $10^{-7}$ to $10^{-9}$;
(iii) strong inflection points on the titration curves occur, therefore, at pH values of about 4·5 and near to 10; the third hydrogen of orthophosphoric acid, $K_{\text{dissoc.}}$ about $10^{-13}$, is too weak to titrate;
(iv) pyrophosphoric and triphosphoric acids show three inflection points, a small change being observed near pH 7, in addition to the usual pronounced change points at pH 4·5 and 10;
(v) as the chain length of the polyphosphoric acid increases, the small middle inflection becomes less pronounced until the shape of the titration curve approaches that of the strongest of the phosphoric acids, namely the cyclic trimetaphosphoric and tetrametaphosphoric acids, and is similar to that of hydrochloric acid;
(vi) the strong acid portion of the diagram shows also that the titration curves approach the first neutralization point more gradually as the chain length increases. This behaviour is characteristic of polyelectrolytes and has been ascribed to ion-association due to electrostatic attraction.[61,66]

ACTION ON METALS

Generally speaking the corrosive action of the linear polyphosphoric acids on metals is much less than that of orthophosphoric acid itself, the effect becoming less pronounced as the concentration of phosphoric oxide increases. Aeration and the presence of impurities increase the rate of attack on most metals and at high temperature the acids are all very corrosive to both metals and ceramics, the best containers under these conditions, up to 350°C., being gold, platinum and graphite.

The corrosive action of polyphosphoric acid containing about 84% $P_2O_5$, a composition corresponding to tetraphosphoric acid, $H_6P_4O_{13}$, is slight on most metals at room temperature, the penetration of mild steel being only 0·001 in./year, rising to 0·016 in./year at 60°C. Most alloys show excellent resistance to this acid at 60°C., except nickel and lead alloys, which corrode rapidly. Plastics and rubber compositions are little affected up to this temperature. At higher temperatures, 120°–180°C., the casting alloys, such as Hastelloy and Illium, show excellent resistance, as does molybdenum-bearing stainless steel. At 240°C. this acid is very destructive to all metals and alloys and also to glass, silica being taken into solution.

Further details of the corrosive properties of polyphosphoric acids may be obtained by consulting references 34 and 67.

### Uses

Polyphosphoric acids in the composition range 76–84% $P_2O_5$ are useful reagents in organic syntheses involving inter- and intra-molecular dehydrations and in the Beckmann and Lossen rearrangements; several reviews with extensive biliographies have been compiled on this theme.[68–70,177–8]

Acids with a phosphoric oxide content near to 76% have been used in the production of fertilizers,[67] whilst those in the region of 80% $P_2O_5$, close to the composition required for pyrophosphoric acid, are useful for pickling,[71] cleaning[72] or polishing[73–6] metals and alloys; other uses for polyphosphoric acids are as high temperature lubricants[77] and in the preparation of silico-phosphate and other catalysts for the oil industry.[78–86]

The reaction products of metallic oxides and polyphosphoric acids have been suggested as bonding agents.[87]

Since the higher linear polyphosphates are precipitated under acid conditions, pH 2–4, by various dibasic amino-acids, dipeptides, guanidinium compounds and amines, such reactions may be used to separate basic biological compounds.[88]

## PYROPHOSPHORIC (OR DIPHOSPHORIC) ACID, $H_4P_2O_7$

### Preparation and Crystalline Forms

Syrupy liquids having a composition corresponding closely to pyrophosphoric acid, 79·79% $P_2O_5$, can be prepared by the evaporation of water from orthophosphoric acid or by heating it together with the required amount of phosphoric oxide. Such liquids are, however, mixtures of polyphosphoric acids, as first shown by classical[58] and later by chromatographic[36–7,40] methods of analysis. The approximate composition of liquids with phosphoric oxide contents in the pyrophosphoric acid region is shown in Table X.

Liquids containing 79–80% $P_2O_5$ do, however, crystallize on prolonged standing at or slightly below room temperature,[35,37,58,89–90] but the solid phase which is separable may not consist entirely of pyrophosphoric acid, for it has been reported[37] that orthophosphoric and other polyphosphoric acids can be identified by chromatographic analysis. The compositions of crystalline and liquid products, both containing 78·8% $P_2O_5$, are given in Table XI.

The reorganization of species is apparently reversible, for by just re-melting the crystalline solid,[92] or by tempering at more elevated temperatures,[37, 91] the composition of the cooled liquid soon reverts to that of the original mixture of polyphosphoric acids from which the solid separated.

The melting point of the hygroscopic solid crystallizing from a liquid of phosphoric oxide content corresponding to pyrophosphoric acid was first reported to be near 61°C.,[60, 89–90] but a more detailed study[59] by a slow melting technique of the phases separating from the phosphoric oxide–water system has revealed that pyrophosphoric acid can crystallize in two forms. The one usually obtained is metastable and melts at 54·3°C., the other at 71·5°C.; they can be distinguished and recognized by differences in their *X*-ray diffraction patterns.

*Table X.—Composition of Liquid Acids in the Region of Pyrophosphoric Acid*

| % $P_2O_5$ content | 79·45[36] | 79·0[37] | 79·1[40] |
|---|---|---|---|
| % total $P_2O_5$ present as | | | |
| Orthophosphoric acid | 16·7 | 29 | 22·1 |
| Pyrophosphoric acid | 43·3 | 47 | 46·3 |
| Triphosphoric acid | 22·1 | 16 | 20·3 |
| Tetraphosphoric acid | 10·7 | 6 | 7·8 |
| Pentaphosphoric acid | 4·5 | 2 | 2·3 |
| Hexaphosphoric acid | 1·9 | | 1·0 |
| Heptaphosphoric acid | 0·8 | | 0·3 |

*Table XI.—Compositions of Crystalline and Liquid Products both containing* 78·8% $P_2O_5$ [37]

| % total phosphorus present as $H_{n+2}P_nO_{3n+1}$ | | | | | |
|---|---|---|---|---|---|
| $n=$ | 1 | 2 | 3 | 4 | 5 |
| Solid state | 18·9 | 77·6 | 3·5 | nil | nil |
| Liquid state | 29·3 | 49·6 | 15·6 | 4·0 | 1·5 |

When a slurry containing the usual form, $H_4P_2O_7$–I, is heated over the range 50–54°C. without stirring, the solid melts and only a few crystals remain. With further increase in temperature the solid increases again until at 60°C. the entire mass solidifies to give the second stable form $H_4P_2O_7$–II.

The melting point diagram for the orthophosphoric–pyrophosphoric acid system based on available data[51, 59–60, 93] is shown in Fig. 5.

Beside the two forms of pyrophosphoric acid, provisionally designated $H_4P_2O_7$–I and $H_4P_2O_7$–II, a simple eutectic has been reported at 75·4% phosphoric oxide and 16°C., the lowest temperature at which a liquid phase was observed[51, 59]; the existence of reported[58] hydrated forms of pyrophosphoric acid has not been confirmed.

However, the system is far from ideal, containing several species in addition to the principal ones. The observed melting points in Fig. 5 relate to gross compositions and, in addition, it has been pointed out[59] that the values obtained depend to some extent on the thermal history of the sample being studied, to what extent the formation of solid solutions has occurred and what rearrangement of phosphate species has taken place in the liquid phase.

Dilute solutions of pure pyrophosphoric acid may best be prepared from recrystallized sodium pyrophosphate by cation exchange, or by the older method of treating aqueous suspensions of insoluble pyrophosphates, such as copper or lead, with hydrogen sulphide, filtering rapidly and aerating the well-cooled solutions to remove the excess hydrogen sulphide.[94] The evaporation of dilute aqueous solutions of pyrophosphoric acid obtained in these ways is not to be recommended on account of the risk of hydrolytic degradation to orthophosphoric acid, even at low temperatures. A laboratory method has been given for the preparation of pure crystalline pyrophosphoric acid.[179]

## Physical Properties of Pyrophosphoric Acid

### THERMO-CHEMICAL DATA

Thermo-chemical data for pyrophosphoric acid are scanty and the compound has received but little attention since the original work of Giran[90]; the following values, based on his results, and quoted by the National Bureau of Standards,[95] obviously require revision in view of the most recent investigations of the phase diagram:

| | | |
|---|---|---|
| Heat of formation at 25°C., | $H_4P_2O_{7(\mathrm{crystalline})}$ | −538 kcal./mole |
| | $H_4P_2O_{7(\mathrm{liquid})}$ | −545·9 kcal./mole |
| Heat of fusion at 61°C. | | 2·2 kcal./mole |
| Entropy of fusion | | 6·587 cal./mole/°C. |

### THE DISSOCIATION OF PYROPHOSPHORIC ACID IN WATER

The ionization of pyrophosphoric acid can, most simply, be regarded as taking place in four steps:

$$\begin{aligned} H_4P_2O_7 &\rightleftharpoons H^+ + H_3P_2O_7^- \\ H_3P_2O_7^- &\rightleftharpoons H^+ + H_2P_2O_7^{2-} \\ H_2P_2O_7^{2-} &\rightleftharpoons H^+ + HP_2O_7^{3-} \\ HP_2O_7^{3-} &\rightleftharpoons H^+ + P_2O_7^{4-} \end{aligned}$$

Measurements have been made of the dissociation constants of each stage by a variety of methods and under different conditions. Values have been derived from conductivity measurements,[94,96] electrometric or complex-ion stability titrations[23,97–106,154–6,180–1] and reversion rate studies.[107–8] Owing to the wide variation of ionic strengths and temperatures employed by different authors it is not always possible to compare results on the same basis. However, in dilute solutions of ionic strength $\mu = 0{\cdot}1$ at 25°C., approximate values for the apparent dissociation constants ($K$) of the four ionization stages referred to above, and their negative logarithms (p$K$) are:

| | | | |
|---|---|---|---|
| $K_1$ | $\sim 10^{-1}$ | p$K_1$ | 1 |
| $K_2$ | $\sim 1{\cdot}5 \times 10^{-2}$ | p$K_2$ | 2 |
| $K_3$ | $2{\cdot}7 \times 10^{-7}$ | p$K_3$ | 6·57 |
| $K_4$ | $2{\cdot}4 \times 10^{-10}$ | p$K_4$ | 9·62 |

Many other values for the thermodynamic constants at infinite dilution and for apparent constants at other concentrations, in the presence of differing swamping electrolytes and at various temperatures, are contained in the references quoted. The standard free energy, enthalpy and entropy of proton dissociation have also been reported.[157,180–1]

To account for the unexpectedly rapid overall rate of reversion of pyrophosphoric to orthophosphoric acid at 60°C., in the pH range 0·38–1·79, it has been suggested[108] (see also Refs. 151, 183), that the ionic species $H_5P_2O_7^+$ is present under such conditions and that the corresponding dissociation constant, calculated from the observed reversion rate constants, is $\geqq 1 \times 10^2$.

The calculation of ionization constants on the basis of molecular structure has been applied to pyrophosphoric acid.[106,109–10] It has been claimed[106] that the application of a particular set of rules, based on considerations of molecular symmetry, gives values of p$K_1$, p$K_2$, etc., which are within 0·3 p$K$ units of those observed for polyphosphoric acids, such as pyrophosphoric and triphosphoric acids. In the same reference the theory is advanced that the wide variations in p$K$ values often obtained from titration measurements can be attributed to various ionization equilibria, other than the simple stages referred to above, which occur simultaneously in defined ranges of pH. In particular, condensation and disproportionation reactions are invoked, of the type for example,

$$2H_2P_2O_7^{2-} \leftrightarrows H_2P_4O_{13}^{4-} + H_2O \rightleftharpoons H_2P_3O_{10}^{3-} + H_2PO_4^-$$

There is some evidence to support this theory from studies of the equilibria set up in orthophosphate solutions containing phosphatase enzymes,[111–2] but later investigations in more dilute solution failed to confirm the formation of pyrophosphate from orthophosphate in the presence of homogenates of intestinal mucosa.[113] In the absence of enzymatic influence, it has been claimed,[114] however, that at equilibrium at 100°C. 100 g. of a concentrated aqueous solution of monosodium dihydrogen orthophosphate, originally 60% by weight, contained 0·16 g. of pyrophosphate, calculated as $Na_2H_2P_2O_7$.

The thermodynamic equilibrium constant for the reaction:

$$H_2P_2O_7^{2-} + H_2O \rightleftharpoons 2H_2PO_4^-$$

is reported[114] to be $0{\cdot}22 \times 10^2$ at 100°C. and $2{\cdot}2 \times 10^2$ at 25°C., from which it was deduced that detectable amounts of pyrophosphate would not be present in orthophosphate solutions less concentrated than 30–35%. The importance and role of such equilibria in biological systems has been discussed.[106,114]

The corresponding equilibrium:

$$2H_3PO_4 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} H_4P_2O_7 + H_2O$$

has been studied by an electrical conductivity method. The following thermodynamic values were obtained:

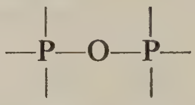
$$\begin{aligned}\Delta H^\circ &= 3{\cdot}3 \pm 1 \text{ kcal./mole}\\ \Delta F^\circ &= 1{\cdot}9 \pm 0{\cdot}2 \text{ kcal./mole}\\ \Delta S^\circ &= +4 \text{ e.u. at } 0\text{–}100^\circ\end{aligned}$$

The activation energy associated with $k_1$ is found to be $20 \pm 1$ kcal., and with $k_2$ 17 kcal./mole.[182]

A method has been developed for calculating the concentration of the ionic species present in pyrophosphoric acid solutions of differing hydrogen ion concentration, using selected values for the dissociation constants of each ionization stage.[115]

### THE HYDROLYTIC DEGRADATION OF PYROPHOSPHORIC ACID

In aqueous solution all linear and cyclic polyphosphoric acids and their salts hydrolyze at their

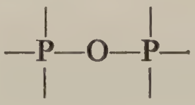


$$-\overset{|}{\underset{|}{\mathrm{P}}}-\mathrm{O}-\overset{|}{\underset{|}{\mathrm{P}}}-$$

linkages, being ultimately degraded to the thermodynamically stable orthophosphate ion. In respect of hydrolytic degradation they are similar to other polyacids, but differ from polysulphates, polyborates and possibly polysilicates inasmuch as instead of hydrolyzing almost as fast as solution occurs, their stability is very much greater. The half-life of the above linkage at room temperature, at neutral pH and in 1% aqueous solution is of the order of magnitude of years.

The hydrolytic breakdown of polyphosphates has been widely studied in order to ascertain the kinetics and mechanism of the processes involved and to assess the practical utility of aqueous solutions, since their ability to form soluble complexes with di- and tri-valent cations diminishes on hydrolysis, because the final reversion product does not possess this property in any significant degree.

The value of much of the early and some of the later work on this subject is diminished because experimental conditions were not adequately controlled and suitable analytical methods were not then available. An informative documented general review of the hydrolytic scission of



$$-\overset{|}{\underset{|}{\mathrm{P}}}-\mathrm{O}-\overset{|}{\underset{|}{\mathrm{P}}}-$$

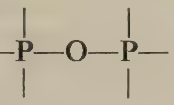
linkages is available[51]; it contains the following list (see Table XII) of environmental factors which influence hydrolysis in aqueous solution, in decreasing order of effectiveness.

*Table XII.—Factors affecting the Rates of Degradation of Polyphosphates*[51]

| Factor | Approximate effect on rate |
|---|---|
| Temperature | $10^5$–$10^6$ faster from freezing to boiling |
| pH | $10^3$–$10^4$ slower from strong acid to base |
| Enzymes | as much as $10^5$–$10^6$ faster |
| Colloidal gels | as much as $10^4$–$10^5$ faster |
| Complexing cations | very many-fold faster in most instances |
| Concentration | roughly proportional |
| Ionic environment in solution | several-fold change |

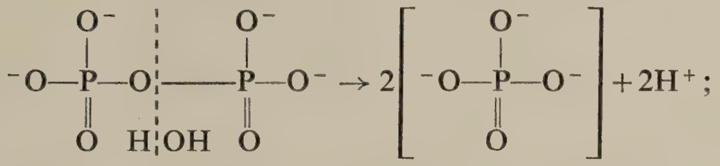
The hydrolytic scission of the pyrophosphate ion obeys first order kinetics over a wide range of pH, the reaction being acid catalyzed[107–8, 116–20, 182, 185] and having an activation energy of about 23 kcal./mole.

Hydrolysis of the



$$-\overset{|}{\underset{|}{P}}-O-\overset{|}{\underset{|}{P}}-$$

linkage is accompanied by an increase in the acid hydrogen concentration, for example



$$^{-}O-\overset{O^-}{\underset{O}{\overset{|}{\underset{\|}{P}}}}-\underset{H}{O}\,\vdots\,\underset{OH}{\text{———}}\,\overset{O^-}{\underset{O}{\overset{|}{\underset{\|}{P}}}}-O^- \rightarrow 2\left[\,^{-}O-\overset{O^-}{\underset{O}{\overset{|}{\underset{\|}{P}}}}-O^-\right]+2H^+;$$

for rate measurements, it is, therefore, important to control pH, or as some investigators have preferred,[107] to make the determinations by radioactive tracer technique at such low molarities that changes in hydrogen ion concentration can be neglected. Table XIII contains first-order rate constants obtained under controlled pH conditions at the concentrations and by the analytical procedure stated. Further data based on dissociation constants measured under the conditions of the kinetic experiments ($10^{-4}$–$10^{-1}$ M., temperatures, 50–70°C., pH 1·25–6·85, ionic strength 0·301–1·14), are given in reference 184.

When the rate constant at 65·5°C. was plotted against pH a smooth curve was obtained,[117] which is shown in Fig. 6, but later it was reported from a more detailed study of the reversion rates at 60·03°C. over a narrower pH range, that this curve had a stepped portion in the region pH 2 to pH 5, with the rate of hydrolysis rising sharply again over the range pH 1·79 to pH 0·38[108] (see Fig. 7).

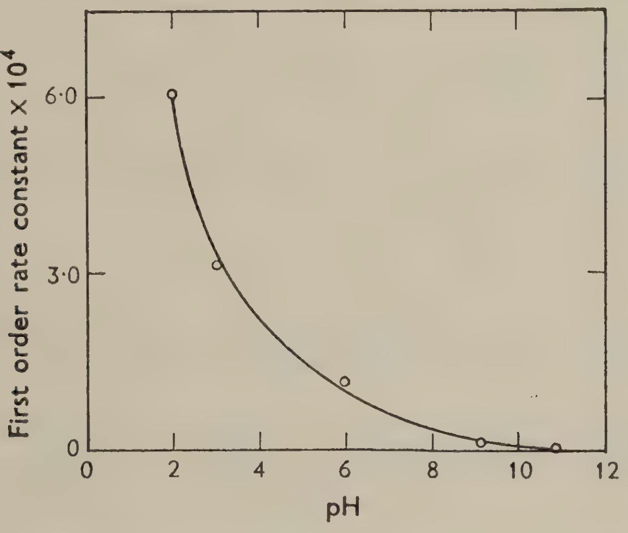


FIG. 6.—Effect of pH on the rate of hydrolysis of sodium pyrophosphate in solution

Attempts have been made to calculate the overall rate constants from a summation of the contributions of individual rate constants of the different ionic species of pyrophosphate present at the particular pH.[98, 107–8, 122] For example, if $k$ represents a rate constant, $x$ the mole fraction of the total pyrophosphate in solution, and the subscripts 4, 3, 2, 1 and 0 refer to the species $H_4P_2O_7$, $H_3P_2O_7^-$, $H_2P_2O_7^{2-}$, $HP_2O_7^{3-}$ and $P_2O_7^{4-}$ respectively, then the overall rate constant may be regarded as:

$$k_{\text{obs.}} = k_4x_4+k_3x_3+k_2x_2+k_1x_1+k_0x_0$$

*Table XIII.—First Order Rate Constants, k, min.$^{-1}$, for the Pyrophosphate Ion at Different Temperatures and pH Values*

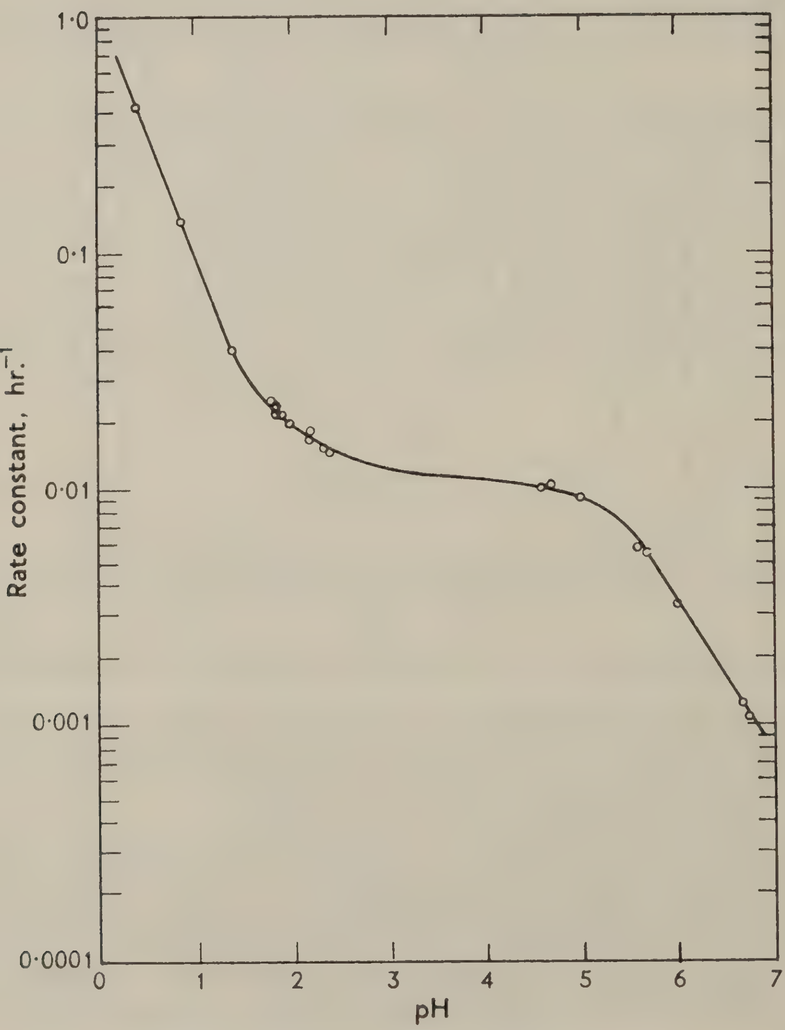

FIG. 7.—Aqueous reversion of pyrophosphate ion at 60·03°C.

However, in order to explain the rapid rise in the rate constant at low pH, it has been suggested that the effect of a second order reaction, involving the hydronium ion, $H_3O^+$, should be considered, although the data were insufficient to test this hypothesis quantitatively.[107] A second explanation has been advanced,[108] based on the data shown in Fig. 7, by which a parameter, $k_5x_5$, additional to those shown in the equation above, is required to give a good fit between observed and calculated rate constants, and which refers to the ionic species $H_5P_2O_7^+$. Such an assumption, if correct, would lead to the proportions of the $H_5P_2O_7^+$ ion, at different pH values, shown in Table XIV.

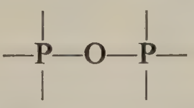
*Table XIV.—% proportion of* $H_5P_2O_7^+$ *Ions at Different pH Values*

| pH | 0·38 | 0·80 | 1·37 | 1·73 | 1·85 |
|---|---|---|---|---|---|
| % $H_5P_2O_7^+$ ion | 92 | 78 | 33 | 11 | 6 |

A similar ionic species, $H_4PO_4^+$, has been suggested to account for abnormalities in the conductivity of pure orthophosphoric acid.[122-3] No evidence could, however, be found for the existence of the metaphosphate ion, $PO_3^-$, as a reaction intermediate. The kinetic form of the hydrolysis and the values of the Arrhenius parameters suggest that the mechanism falls into the A2 category.[185, 186]

The catalytic accelerative effect of metal cations on the hydrolytic degradation of the pyrophosphate ion in neutral solution at 60°C. has been studied[124, 151] and the previous work on this subject reviewed. Kinetic measurements showed that trivalent cations, e.g. $Al^{+++}$, were more effective than divalent, e.g. $Ca^{++}$, $Ba^{++}$ or $Sr^{++}$, or monovalent, e.g. $H^+$, $Li^+$ or $K^+$, and that anions had little effect. However, in the presence of sodium chloride the rate of hydrolysis was slightly reduced at pH 4·5 and markedly slower at pH 2·0. A somewhat higher concentration of magnesium chloride than of sodium chloride was required before noticeable changes in reversion rates occurred. This is not unexpected for the hydrolytic catalyst at low pH is probably $H_3O^+$.[125]

The presence of molybdenum groups within the co-ordination sphere of the phosphorus atoms in pyrophosphoric acid is said to result in instability of the



$$-\overset{|}{\underset{|}{P}}-O-\overset{|}{\underset{|}{P}}-$$

linkages,[126] the first order rate constants at 25°C., in N.$H_2SO_4$, for pyro- and molybdopyrophosphoric acids being $4{\cdot}86 \times 10^{-6}$ sec.$^{-1}$ and $1{\cdot}31 \times 10^{-6}$ sec.$^{-1}$ respectively.

Enzymatic phosphatases, under the right conditions, degrade linear polyphosphates quite rapidly and pyrophosphates appear to be hydrolyzed to orthophosphates by passage through the bodies of rats and rabbits.[127]

## TRIPHOSPHORIC ACID, $H_5P_3O_{10}$

Triphosphoric acid occurs in varying amounts as a constituent of polyphosphoric acids containing more than about 72% of phosphoric oxide.[40] Dilute solutions of the pure acid can most readily be prepared by passing a cold solution of the recrystallized sodium salt, $Na_5P_3O_{10}$,$6H_2O$, through a cationic resin ion exchanger.[23, 128]

The successive dissociation constants of acid prepared in this manner have been calculated from its pH-titration curve[101, 106, 129-30]; the first ionization constant is very large, typical values for the others, at infinite dilution at 25°C., being[130]:

$$K_2 = 10^{-1}$$
$$K_3 = 10^{-2{\cdot}3}$$
$$K_4 = 10^{-6{\cdot}50}$$
$$K_5 = 10^{-9{\cdot}24}$$

Calculations of the successive ionization constants of triphosphoric acid have been made, in a manner similar to that described for pyrophosphoric acid,[106] on the basis of structural considerations. Values obtained were in fair agreement with those derived by the author from electrometric titration curves, but did not agree so well with those of other investigators.[101-2, 129-30, 154-6] The possibility of ionization equilibria due to condensation and disproportionation reactions in defined pH ranges, in addition to the normal simple dissociation stages, has been suggested, as with pyrophosphoric acid, to account for the reported discrepancies between the values of p$K$ calculated from titration curves.[106]

Values of the free energy, enthalpy and entropy of ionization of triphosphoric acid have been reported.[157, 181]

The hydrolytic degradation of the triphosphate ion has been studied under a wide variety of conditions and is affected by the same factors as those already described under pyrophosphoric acid. Although quite stable at room temperature in aqueous solution at pH 7 to pH 9, $P_3O_{10}^{5-}$ undergoes rapid hydrolytic breakdown under more acid conditions and at high temperatures, in two stages:

$$(a) \qquad [P_3O_{10}]^{5-} + H_2O \rightarrow [HP_2O_7]^{3-} + [HPO_4]^{2-}$$

$$(b) \qquad [HP_2O_7]^{3-} + H_2O \rightarrow [HPO_4]^{2-} + [H_2PO_4]^{1-}$$

Both stages of the hydrolysis are first order reactions over the range pH 2·0 to pH 12·0, the latter proceeding independently of the former at about one-third the rate[117] (see also Refs 121, 149, 187).

*Table XV.—Overall First Order Rate Constants, k, min.$^{-1}$, for the Triphosphate Ion at Different pH Values at* 65·5°C.[117]

| pH | $k$, min.$^{-1}$ |
|---|---|
| 2·0 | $2{\cdot}19 \times 10^{-3}$ |
| 3·0 | $9{\cdot}4 \times 10^{-4}$ |
| 5·0 | $2{\cdot}89 \times 10^{-4}$ |
| 9·3 | $1{\cdot}5 \times 10^{-5}$ |
| 12·0 | $1{\cdot}41 \times 10^{-4}$ |

Reversion rates for the triphosphate ion at 65·5°C., at a concentration equivalent to 0·0951 moles of phosphorus per litre, are contained in Table XV and shown graphically in Fig. 8.

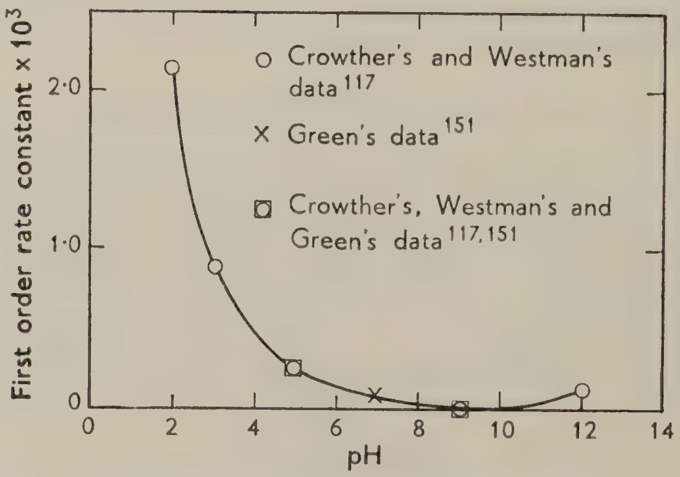


FIG. 8.—Effect of pH on the rate of hydrolysis of sodium triphosphate in solution

## TETRAPHOSPHORIC ACID, $H_6P_4O_{13}$, AND OTHER LINEAR POLYPHOSPHORIC ACIDS OF THE GENERAL FORMULA $H_{n+2}P_nO_{3n+1}$

Tetraphosphoric acid occurs, along with other polyphosphoric acids, when the concentration of phosphoric oxide in the mixture exceeds about 76%[40]; the pure acid could, in principle, be obtained by ion exchange from the neutral hexaguanidinium, the dihydrogen-tetra-acridinium[131] or the ammonium salt,[132-3] which can be prepared substantially free from other phosphate species by alkaline cleavage of cyclic sodium tetrametaphosphate in aqueous solution at not too high temperatures.

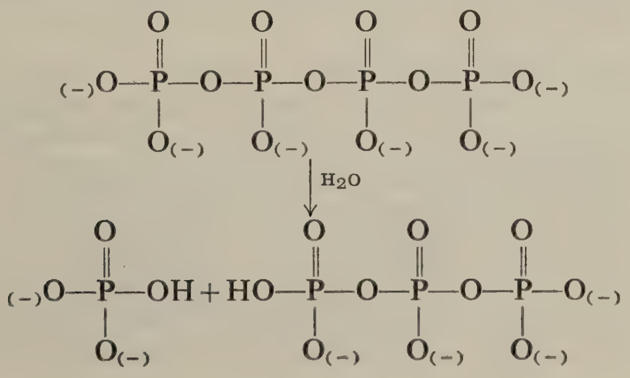
Dilute solutions of more highly polymerized acids have been obtained by the ion-exchange technique from long-chain phosphates including those known as Kurroll, Maddrell or Graham salts.[134-8]

As outlined in Table I, tetraphosphoric acid has a linear chain structure and its electrometric titration curve shows it to possess four strongly and two weakly dissociated hydrogen ions; some tentative values have been calculated for the ionization constants for some of the stages of both tetra- and so-called hexaphosphoric acids from electrometric titration data,[106] but these are not confirmed by independent measurements.[102,158] A selection of these is given in Table XVI, and values for pyrophosphoric acid and triphosphoric acid are included for comparison. As expected, values of $pK_N$ decrease and values of $pK_{N-1}$ increase with increasing chain length in the series of polyphosphoric acids $H_NP_{N-2}O_{3N-5}$. An exception to this rule is the anomalously low value for $pK_{N-1}$ in $H_5P_3O_{10}$; it is possible that the configuration of the $HP_3O_{10}^{4-}$ ion is particularly stable[158] since similar anomalies have been observed in its N.M.R. spectrum.[159] There is some evidence that free polyphosphoric acids are only dissociated to about 30% in aqueous solution, although all the hydroxyl groups present except the two terminal ones behave as strong acids on titration.[188]

*Table XVI.—Ionization Constants for Chain Polyphosphoric Acids* $H_NP_{N-2}O_{3N-5}$ *at 25°C. and Ionic Strength* $\mu = 1$

| Acid | N | $pK_N$ | $pK_{N-1}$ | $pK_{N-2}$ | $pK_{N-3}$ | Reference |
|---|---|---|---|---|---|---|
| Pyrophosphoric | 4 | 8·7 | 6·0 | 2·0 | 1·7 | 102 |
| Triphosphoric | 5 | 8·6 | 5·7 | 2·0 | 1·2 | 102 |
| | | 8·8 | 5·8 | 2·1 | 1·1 | 158 |
| Tetraphosphoric | 6 | 8·3 | 6·6 | 2·2 | 1·4 | 158 |
| 'Hexaphosphoric' | 8 | 8·1 | 6·0 | 2·2 | 2·1 | 102 |
| | 18 | 8·1 | 6·5 | 2·9 | 2 | 102 |
| | 62 | 8·2 | 7·2 | — | — | 102 |

The hydrolytic degradation of the tetraphosphate anion, $P_4O_{13}^{6-}$, has been studied; it follows first-order kinetics for most of the course of the reaction,[133] the cleavage occurring predominantly at the ends of the chain to form ortho(mono)- and triphosphate ions, respectively, e.g.,



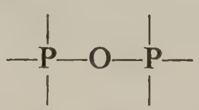
Some evidence has been reported for an alternative route for hydrolytic degradation,[131,139] namely attack on the middle oxygen bridge to form two pyrophosphate ions. However, on account of the limitations of the analytical methods employed and because of the obscuring effect of the rapid hydrolysis of the triphosphate ion produced by the first route, especially at low pH, it is thought likely that hydrolysis of the tetraphosphate ion occurs almost exclusively by the attack of water on an end oxygen bridge,[133] and that pyrophosphate arises from a bimolecular reaction between the orthophosphate and triphosphate so formed.[191] However, there is good evidence that pentaphosphate and hexaphosphate degrade by two routes, the first and faster producing orthophosphate, together with a polyphosphate chain shorter by one $PO_4$ unit, while the second produces trimetaphosphate with a chain shorter by three units.[189,191] The first mechanism is catalyzed by the copper(II) chelate of poly-*L*-lysine, and the second by the copper(II) chelate of ethylenediamine.[190] The yield of trimetaphosphate increases with polyphosphate chain length[191] (see Section XXVII, page 756).

The tetraphosphate ion is less stable than the triphosphate ion over the whole pH range; typical values for the overall constant, at 65·5°C. and a concentration of 0·17 atom weights of phosphorus per litre, are contained in Table XVII.[133]

*Table XVII.—Overall First Order Rate Constants, k, min.⁻¹, for the Tetraphosphate Ion at Different pH Values, at* 65·5°C.[133]

| pH | $k$, min.$^{-1}$ |
|---|---|
| 2·55 | $1{\cdot}8\times10^{-3}$ |
| 5·35 | $8{\cdot}3\times10^{-4}$ |
| 9·8 | $2{\cdot}5\times10^{-4}$ |
| 13·3 | $2{\cdot}5\times10^{-4}$ |

The interpretation of the mechanism of the hydrolytic degradation of polyphosphoric acids and their salts, with chains longer than tetraphosphoric acid, has proved difficult because of the variety of routes available for the process to occur. During the hydrolysis of polyphosphates of medium chain length, $n \geqq 5$, in not too acid media, pH $\geqslant 3{\cdot}5$, the formation of cyclic anions has been observed[140-2] and possible mechanisms for this phenomenon have been discussed.[142-5] In acid solutions, the hydrolysis of long chain polyphosphates is thought to proceed, to an increasing extent, by cleavage of middle



$$-\overset{|}{\underset{|}{P}}-O-\overset{|}{\underset{|}{P}}-$$

linkages, compared with the lower members of the series, thus leading to the formation of mixtures of polyphosphates with smaller degrees of condensation.[144-5] The mechanism is said to involve splitting off $PO_3^-$ groups as the activated complex.[30] Typical overall first-order rate constants and half-life times, at 60°C., for a long-chain polyphosphate ion with an average chain length of 1000, are given in Table XVIII.[30,147]

*Table XVIII.—Overall First Order Rate Constants, k, min.⁻¹, for Long Chain Polyphosphate Ion, at* 60°C., *at Different pH Values and Half-life Times*

| pH | $k$, min.$^{-1}$ | Half-life times |
|---|---|---|
| 1 | $30{\cdot}4\times10^{-3}$ | 22·8 min. |
| 3 | $1{\cdot}72\times10^{-3}$ | 6·7 hr. |
| 5 | $\sim0{\cdot}10\times10^{-3}$ | 4·4 days |
| 8 | $0{\cdot}011\times10^{-3}$ | 45·4 days |

A procedure has been described, involving solvent extraction and ion exchange by which gram quantities of essentially pure tetra-, penta-, hexa-, hepta-, and octaphosphoric acid have been prepared from a mixed polyphosphoric acid. The corresponding phosphates were hydrolyzed at pH values of 4, 7, and 11, and temperatures of 30° and 60°C. First-order specific rate constants were determined for the overall degradation of each species (see Fig. 9 for data at 60°), and for the separate degradation routes involving the splitting off of one- and three-phosphorus fragments. The activation energies for these processes were also given and discussed. It was shown that the specific rate constants for orthophosphate (end group) removal are a regular function of the number of electrons in outer valence shells divided by the number of P–O–P linkages: e.g. from $P_2O_7^{4-}$ (56 electrons, 1 P–O–P) to $P_8O_{25}^{10-}$ (200 electrons, 7 P–O–P's).[192]

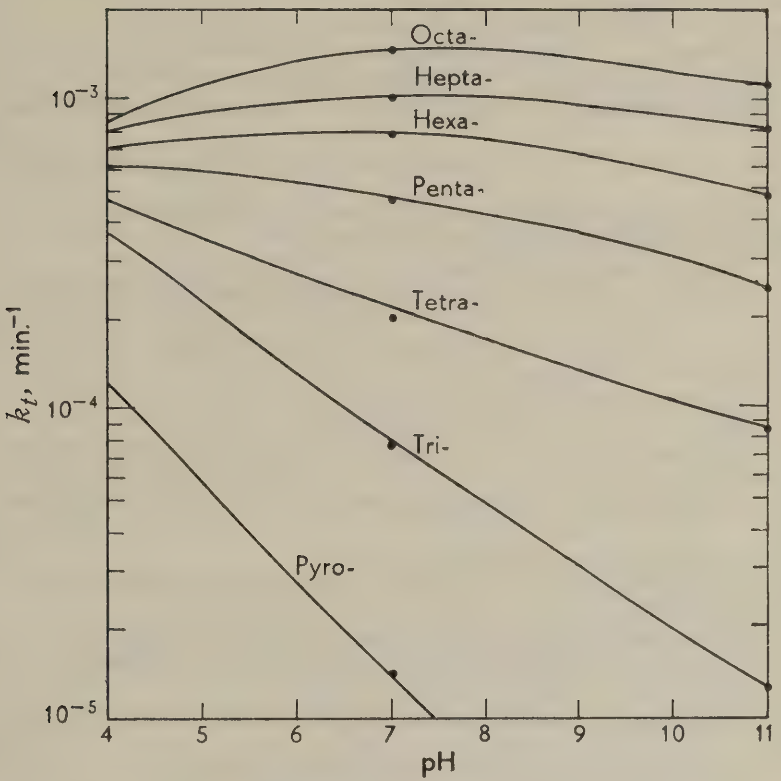


FIG. 9.—Specific rate constants for sodium polyphosphates as a function of pH at 60°: pyro- and tri- values from ref. 116

The 'glacial metaphosphoric' acids of commerce, often used as reagents for the precipitation of proteins,[147–8] contain up to 18% of sodium oxide, $Na_2O$, in addition to phosphoric oxide and water, in order to render the otherwise very sticky viscous acids easier to handle.[37, 149–50] Pure acids with a composition corresponding closely to $HPO_3$ contain branching points, are not regarded as truly linear polyphosphoric acids, and are discussed more fully in Section XXVII (page 755).

## SECTION XXVII

# CYCLIC AND BRANCHED POLYPHOSPHORIC ACIDS

BY J. E. SUCH

THE combination of middle group phosphate structural units (see page 727), can be regarded as the basis of the formation of:

(*a*) ring molecule ions, the cyclic polyphosphates, to which branching points may be introduced to attach;
(*b*) rings to chains, and finally to form;
(*c*) cross-linked polymers, by introducing branching points into linear polyphosphates.

(*a*) The well-known cyclic trimetaphosphate and tetrametaphosphate anions, for example, shown in Fig. 1, are metaphosphates, for their composition is $(PO_3)_n^{n-}$ and they are not to be confused with the polymeric polyphosphate anions $(P_nO_{3n+1})^{(n+2)-}$, of which the ends of the chains are terminated by hydroxyl groups (Section XXVI).

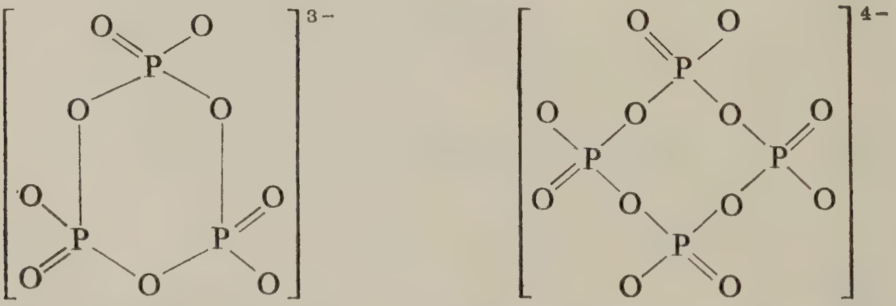

FIG. 1.—The cyclic trimetaphosphate, $(PO_3)_3{}^{3-}$, and tetrametaphosphate, $(PO_3)_4{}^{4-}$, anions

(*b*) Molecule ions, with one or more branching points linking chains to rings, of the type shown in Fig. 2, which are isomeric with their wholly cyclic counterparts,

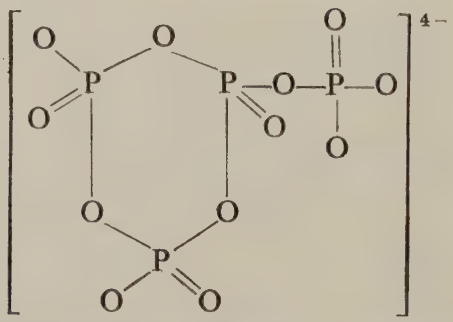

FIG. 2.—Polyphosphate ion containing ring and chain (*iso*-tetrametaphosphate ion $(P_4O_{12})^{4-}$)

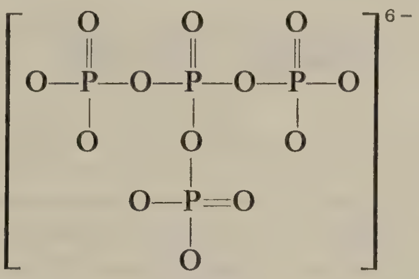
Refs. p. 758

have been suggested, the example quoted, in particular, being considered a transitory intermediate in the stepwise hydration of phosphoric oxide (see Section X, page 394). Neither the acid formulated in Fig. 2 nor its salts has been individually characterized. It was formerly proposed that etherolysis of phosphoric oxide produced compounds of this type, in which OH was replaced by OR,[1-2] but more recent work has disclosed only straight chain polyphosphoric acids and esters.[45]

(*c*) Branched, or cross-linked polyphosphoric acids, sometimes referred to as ultraphosphoric acids, are usually defined as acids in which the ratio of $H_2O/P_2O_5$ is less than unity, and are thought to contain branching points at which tertiary $PO_4$ tetrahedra are linked by three of their oxygen atoms to neighbouring phosphorus atoms.[3-5] A simple example of an acid of this type is the hypothetical *iso*-tetraphosphoric acid, postulated in the stepwise hydrolytic degradation of phosphoric oxide, and shown in Fig. 3.



$(P_4O_{13})^{6-}$

FIG. 3.—The *iso*-tetraphosphoric acid ion

It has also been suggested[6] that cross-linkage of chain polymers can occur by loss of water, on condensation, as in Fig. 4.

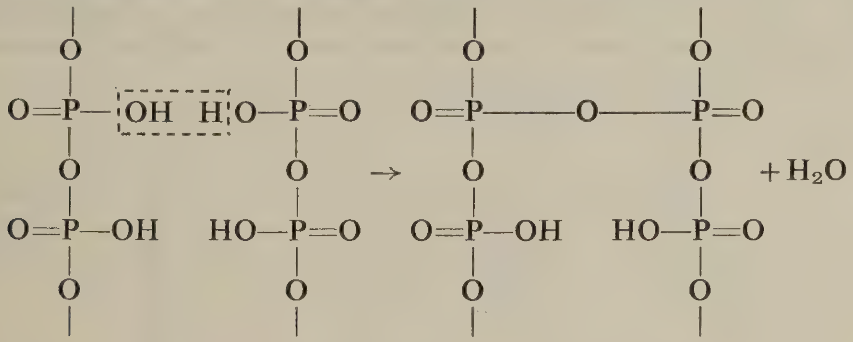


FIG. 4.—Cross-linkage of linear polyphosphates

The consequences of the hydrolysis of compounds having these two types of cross-links have been discussed in terms of the acid strength of the resultant (OH) groups.[5]

In contrast to the –P–O–P– linkages in linear and cyclic polyphosphate anions, those of the bridges in the cross-linked species are much more readily hydrolyzed in aqueous solution. Such behaviour was predicted from theoretical considerations[3] and verified by measurements of the rate constant for the hydrolytic cleavage of –P–O–P– linkages which converted a branching point into a middle group.[7-8] The rate of hydrolysis is about a thousand times faster for branching points than for linkages in the middle or at the end of chains, and is practically independent of the concentration, pH, ionic strength and presence of added salts.

The existence of branching points in compounds suspected of containing them can be deduced from the rapid drop in viscosity and parallel increase in the pH value of their aqueous solutions, both being caused by this ready hydrolysis.[9-10]

The cyclic tri- and tetra-metaphosphoric acids may be prepared[3,11-5]:

(*a*) from dilute aqueous solutions of the corresponding sodium salts by passage through hydrogen ion-exchangers (though it would be difficult to concentrate them further owing to their hydrolytic instability).

(*b*) by decomposition of their relatively insoluble corresponding heavy metal salts, for example of lead or copper, by passing hydrogen sulphide into a suspension in water, filtering off the heavy metal sulphide and removing the excess of hydrogen sulphide in vacuo at low temperature.

Both trimeta- and tetrameta-phosphates have been identified by chromatographic analysis as minor constituents of solutions prepared from polyphosphoric acid containing more than 86·1% of phosphoric oxide,[5] or from sodium polyphosphates of Na/P ratio 0·71–0·88.[46] It is possible, however, that they may have arisen from extensively cross-linked acids, similar to those described earlier, by hydrolysis during the preparation of the samples for analysis.[16] Alternatively they may arise from the hydrolysis of linear polyphosphates, which at pH 6 has been shown to yield cyclic anions, principally trimetaphosphate, as shown in the table below.[52]

*Yield of trimetaphosphate from the degradation of polyphosphates of varying chain length* (*pH*$=6$; t$=80$°C.)

| Chain length *n* | 2–4 | 5 | 6 | 7 | 8 | ∞ |
|---|---|---|---|---|---|---|
| Yield of trimetaphosphate in % P | 0 | 5–8 | 15–17 | ~25 | ~38 | ≥60 |

Partial hydrolysis of the volatile (H) form of phosphoric oxide, $P_4O_{10}$, by long-chain polyphosphoric acids, instead of by water, could also lead to the formation of ring compounds more complex than those typified in Fig. 2.[16] However, tetrametaphosphoric acid is the main product of the hydrolysis of phosphoric oxide by an excess of water in an organic medium, whilst limited amounts of water yield linear polyphosphoric acids of varying molecular weights.[44]

Since all the hydroxyl groups of the cyclic polyphosphoric acids have practically the same large dissociation constants, they may be considered as strong acids; in consequence, their electrometric pH titration curves show a single strong inflection,[17–20] similar to that given by hydrochloric acid, for example (Fig. 5).

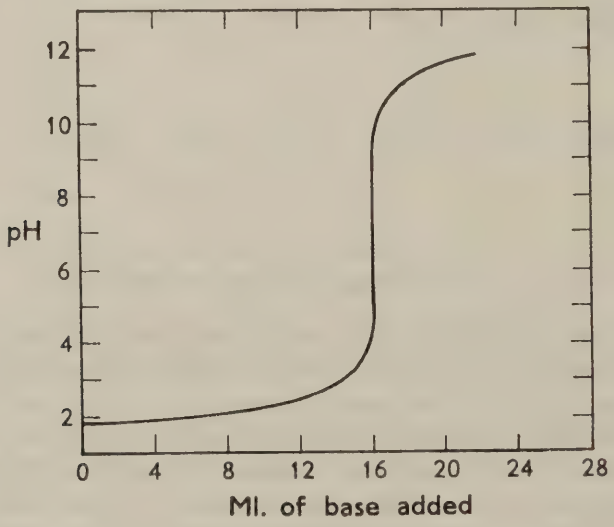

FIG. 5.—pH titration of trimetaphosphoric acid

From potentiometric titration curves, the values calculated at 25°C. for all three thermodynamic ionization constants, $pK_1$, $pK_2$ and $pK_3$, of trimetaphosphoric acid are very large,[21] but the fourth hydrogren ion of tetrametaphosphoric acid is reported to be appreciably weaker than the other three[22] and a value of 2·78 for $pK_4$ has been quoted.[21]

Measurement of the conductance of dilute solutions of trimeta- and tetrametaphosphoric acids indicates that they dissociate into singly charged ions and triply or quadruply charged ions respectively and thus supports the tri- and tetra-meric formulation of these compounds.[22] The rate of inversion of sucrose in $H_3P_3O_9/Na_3P_3O_9$

or $H_4P_4O_{12}/Na_4P_4O_{12}$ solutions at 25°C. could also roughly be interpreted on the same basis, although the values of $K_1$ obtained were about twice those deduced from the conductimetric experiments. The new value of $K_1$ (trimetaphosphate) also accounted well for the effect of trimetaphosphate on the kinetics of the chromate–iodide and iodate–iodide reactions.[47]

Whilst practically stable at 20°C. under neutral conditions, cyclic trimetaphosphate and tetrametaphosphate ions readily hydrolyze in acidic aqueous solution. The hydrolytic degradation follows a first-order law as long as the pH is held constant, and proceeds in stages, the reaction rate for each of which is strongly temperature and pH dependent, the magnitude of the effect varying for the successive reactions:

$$(a) \quad (P_3O_9)^{3-} + H_2O \rightarrow (H_2P_3O_{10})^{3-} + H_2O \rightarrow (H_2P_2O_7)^{2-} + (H_2PO_4)^{-} + H_2O \rightarrow 3(H_2PO_4)^{-} \quad ^{23-9}$$

$$(b) \quad (P_4O_{12})^{4-} + H_2O \rightarrow (H_2P_4O_{13})^{4-} + H_2O \rightarrow (H_2P_3O_{10})^{3-} + (H_2PO_4)^{-} + H_2O \rightarrow (H_2P_2O_7)^{2-} + 2(H_2PO_4)^{-} + H_2O \rightarrow 4(H_2PO_4)^{-} \quad ^{24-5,28,30-4}$$

The ammonolysis of tetrametaphosphate yields, *inter alia*, ammonium triphosphate.[48]

Many values for first-order reaction constants for the hydrolytic degradation of cyclic polyphosphate anions are available in the references given; they are not quoted here, as varying conditions under which the measurements were made render comparisons difficult. However, the following tabulation by Thilo[35] and others,[49] Table I, contains useful typical comparative data for first order reaction constants, half-life values and activation energies, for the different types of polyphosphate ions described in this and other Sections.

*Table I.—Kinetic Constants for the Hydrolytic Degradation of Various Polyphosphate Anions*

| Type of anion | pH | °C. | First order $k \times 10^3$ min.$^{-1}$ | Half-life value | Activation energy kcal./mole |
|---|---|---|---|---|---|
| Cyclic trimetaphosphate $(P_3O_9)^{3-}$ | 1 | 60 | 39·8 | 17 min. | |
| | 3 | 40 | 0·03 | | |
| | | 60 | 0·29 | 1·7 days | 21·8 |
| | 5 | 60 | 0·04 | 15·1 days | |
| | 7 | 60 | 0·0069 | 69·3 days | |
| | | 80 | 0·026 | | 19·6 |
| Cyclic tetrametaphosphate $(P_4O_{12})^{4-}$ | 1 | 40 | 0·67 | | |
| | | 60 | 4·71 | 2·48 hr. | 20·0 |
| | 3 | 50 | 0·027 | | |
| | | 60 | 0·072 | 6·5 days | 20·0 |
| | 7 | 60 | 0·003 | 116·5 days | |
| Cyclic hexametaphosphate $(P_6O_{18})^{6-}$ | 4 | 30 | 0·00035 | > 1 yr. | 9 |
| | | 60 | 0·0013 | ,, | |
| | 7 | 30 | 0·00036 | ,, | 6 |
| | | 60 | 0·0009 | ,, | |
| | 11 | 30 | 0·00032 | ,, | 6 |
| | | 60 | 0·00096 | ,, | |
| Linear polyphosphate $(P_nO_{3n+1})^{(n+2)-}$ $n \geqq 3$ | 1 | 40 | 7·04 | | |
| | | 60 | 30·4 | 22·8 min. | 15·1 |
| | 3 | 40 | 0·19 | | |
| | | 60 | 1·72 | 6·7 hr. | 22·8 |
| | 5 | 60 | ~0·10 | 4·4 days | |
| | 8 | 60 | 0·0106 | 45·4 days | 25·0 |
| Branched polyphosphates | Independent of pH | 40 | 26 | | 15·4 |

**Refs. p. 758**

Under comparable conditions the cyclic hexametaphosphate ion is more stable than any of the others which have been investigated. The low value of the activation energy observed in this case, corresponding to a decreased influence of temperature on the hydrolysis, may be due to the ability of the large and flexible hexametaphosphate ring to absorb thermal energy without rupture.[49] As with linear polyphosphate ions, the hydrolytic stability of the cyclic anions is greatly reduced in the presence of added cations[26, 36-8] and enzymes.[41] Cyclic phosphoric acids are also rapidly decomposed by an excess of hydrogen peroxide[50] or by fluoride ions.[51] In the latter case the $(FP_3O_9)^{4-}$ and the $(FP_4O_{12})^{5-}$ ions are formed from trimetaphosphate and tetrametaphosphate respectively.

The hydrolytic scission of –P–O–P– linkages of all types has been extensively reviewed.[39]

The alkali metal salts of trimetaphosphoric and tetrametaphosphoric acids are readily soluble in water, but those of the alkaline earth metals are not; collected references to these salts are available.[39]

Although the presence of cyclic anions containing as many as six to eight phosphorus atoms has been inferred from the paper chromatographic analysis of aqueous hydrolysates of phosphate glasses,[40-2] so far only the cyclic hexametaphosphate has been isolated from the $LiPO_3$–$Li_4P_2O_7$ system. The free acid was liberated by ion exchange, and isolated as the sodium salt $(NaPO_3)_6,6H_2O$.[49]

Cross-linked polyphosphoric acids containing branching points may be prepared by thermal dehydration of acids with higher water contents. For example, when orthophosphoric acid is heated in a platinum–gold alloy container to about 450°C. at atmospheric pressure, the product on cooling forms a glassy solid containing cross-linked in addition to linear polyphosphoric acids.[6, 43]

Azeotropic phosphoric acid, b.p. 864°C. at 760 mm., has a mole ratio $H_2O/P_2O_5$ of 0·65 and is believed to be highly cross-linked, for when the solidified transparent glass is put into water it decrepitates and breaks up into fibrous fragments. This behaviour is thought to be connected with the rapid hydrolysis of branching points near the surface of the solid glass, and consequent strain in the structure.[6, 39] It has been calculated that as much as one-third of all the phosphorus atoms in such a glassy polyphosphoric acid are linked by branching points to their neighbours.[39]

Polyphosphoric acids with more than the azeotropic composition of 92% $P_2O_5$ can be prepared by combining a small amount of water or orthophosphoric acid with phosphoric oxide, but little is known about these compounds which probably approach in character the vitreous forms of phosphoric oxide itself.

## SECTION XXVIII

# AMIDO- AND IMIDO-PHOSPHORIC ACIDS AND THEIR SALTS

BY D. A. PALGRAVE

### Nomenclature

CONSIDERABLE divergences of opinion exist regarding the nomenclature of the oxyacids of phosphorus in which partial replacement of the oxygen atoms by amido or imido groups has taken place. A serious attempt at unambiguous nomenclature was made by Audrieth *et al.*[1] on the basis of a more general system for nitrogen compounds.[2] Typical examples of this system include:

| $PO(NH_2)(OH)_2$ | $PO(NH_2)_2OH$ |
|---|---|
| amidophosphoric acid | diamidophosphoric acid |

$PO(NH_2)_3$
phosphoryl triamide

| $(HO)_2PO(NH)PO(OH)_2$ | $(HO)_2PO(NH)PO(OH)NHPO(OH)_2$ |
|---|---|
| imidodiphosphoric acid | di-imidotriphosphoric acid |

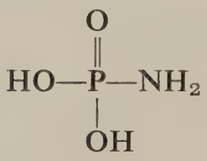
$(HO)_2PO(NH)PO(OH)(NH)PO(OH)(NH)PO)OH)_2$
tri-imidotetraphosphoric acid

However, subsequent usage indicates that this system of nomenclature has not found universal adoption. Recent convention favours the terms 'phosphoramidic' and 'phosphorodiamidic' instead of 'amidophosphoric' and 'diamidophosphoric', particularly when referring to organic derivatives of these acids. The cyclic compounds are normally called 'metaphosphimic acids' rather than 'phosphonitrilic acids', the simple prefixes tri- or tetra- being used to denote the degree of polymerization. Infrared evidence[21] indicates the presence of

$$-\underset{\displaystyle H}{\underset{|}{N}}-$$

groupings in these ring compounds and has rendered the term phosphonitrilic acid inappropriate.

## MONOAMIDOPHOSPHORIC (PHOSPHORAMIDIC) ACID AND ITS SALTS



$$HO-\overset{\displaystyle O}{\overset{\|}{\underset{\displaystyle OH}{\underset{|}{P}}}}-NH_2$$

### Formation and Preparation

The techniques discovered by Stokes (*Mellor*, VIII, 705) remain the most satisfactory methods of preparing the monoamidophosphates. The use of primary and secondary amines instead of ammonia has been shown to produce compounds containing substituted amido groups.

A monofluorophosphate may be used in place of a monochlorophosphate derivative to prepare monoamidophosphate.[3] The reaction takes place at 90°–110°C. at a pressure of 5–20 atm., in the presence of sodium hydroxide:

$$Na_2PO_3F + \tfrac{1}{2}H_2O + NH_3 \rightarrow Na_2PO_3NH_2,\tfrac{1}{2}H_2O + HF$$

Disodium monoamidophosphate is also formed by the interaction of a 60:40 sodamide:potassamide mixture with sodium trimetaphosphate. Recrystallization of the crude reaction product from aqueous acetic acid gives pure sodium hydrogen amidophosphate which can be reconverted to crystalline disodium amidophosphate hexahydrate by neutralization with sodium hydroxide and precipitation with alcohol. The anhydrous salt results from the dehydration of the hydrate at 60–110°C. and 15 mm.[125]

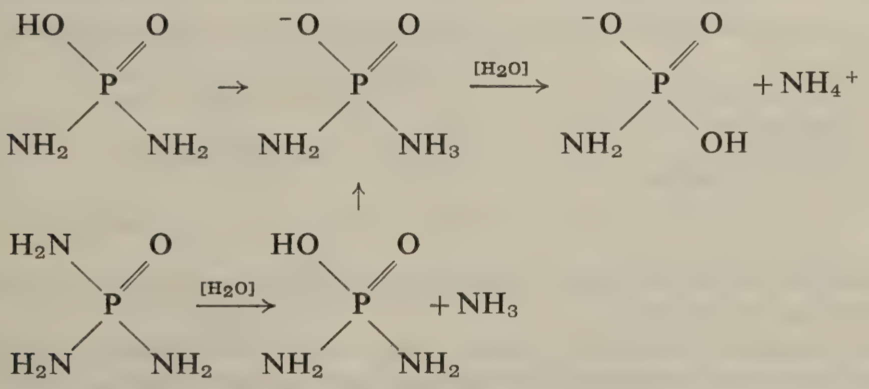
Monoamidophosphoric acid has been obtained in 51% yield by the catalytic hydrogenation of diphenyl phosphoramidate in the presence of platinum dioxide.[4] This is an improvement on the original method of Stokes, and enables several of his stages to be by-passed. The acid may be prepared from its salts either by ion exchange[5] or by displacement using a stronger acid such as perchloric acid.[6] The monohydrate, $H_2PO_3NH_2,H_2O$, decomposes to the anhydrous acid and water at 31°C.[29]

Many investigators have studied the reaction between phosphorus pentoxide and ammonia. There is considerable variation in the reported results. Under exceedingly dry conditions no reaction between gaseous ammonia and solid phosphorus pentoxide could be detected,[7] although this is contrary to the reports of other observers. It had been maintained[8] that a thin film formed on the surface of the phosphorus pentoxide retarded further absorption, but this was not confirmed.[9] In general glassy substances are obtained as reaction products which contain a variety of species including monoamidophosphates.[10] Claims have been made that pure monoamidophosphoric acid can be manufactured in this way.[11] However, most authorities in this field have concluded that this reaction usually results in the formation of polyamidoimidopolyphosphates (*q.v.*) or polymetaphosphimates (*q.v.*), together with some ammonium polyphosphates. The reaction of alkali metal amides with phosphorus pentoxide in an inert medium at ~200°C. gives good yields of phosphoramidates.[126]

Monoamidophosphates are readily obtained from other monoamidophosphates by metathesis[12]:

$$Ag_2PO_3NH_2 + 2NaBr \rightarrow 2AgBr + Na_2PO_3NH_2$$

Unique methods of preparing ammonium salts exist, as the amido group is fairly readily converted to ammonia or the ammonium ion. Thus the action of moist air on diamidophosphoric acid[13] or phosphoryl triamide[14] yields monoammonium monoamidophosphate:



Such zwitter-ion formation appears to be a feature of this class of compounds.

## Physical Properties

The infra-red spectra of several monoamidophosphates have been examined.[15, 21, 30, 82] The principal absorption regions are listed in Table I.

*Table I.—Infra-red Absorption Spectra of Monoamidophosphates*

| Absorption region (cm.$^{-1}$) | Assignment |
|---|---|
| 3500–3200 | $\nu_{as}NH_2$ |
| 3070–2860 | $\nu_{as}NH$ |
| 2610–2450 | $\nu_{s}NH_3$ |
| 1700–1600 | $\omega\delta_{as}NH_3$ |
| 1480–1435 | $\delta_{s}NH_3$ |
| 1205–1160 | $\rho NH_3$ |
| 1195–1130 | $\nu_{as}PO_3$ |
| 1075–1070 | $\rho NH_2$ |
| 1020 | $\rho NH_3$ |
| 1023–993 | $\nu_{s}PO_3$ |
| 845–710 | $\nu PN$ |
| 550–527 | $\delta_{s}PO$ |
| 515–500 | $\delta_{as}PO$ |

The silver and zinc salts are somewhat anomalous, exhibiting low frequencies associated with stretching and internal deformation of the N–H groups and no absorption corresponding to external N–H deformation. This suggests the possibility of some metal–nitrogen coordination within these compounds. In the disodium salt $Na_2PO_3NH_2$[82] the $NH_2$ bending and rocking vibrations are assigned at 1610 and 1098 cm.$^{-1}$ respectively. The symmetrical and antisymmetrical $PO_3$ stretching vibrations are assigned at 980 and 1141/1188 cm.$^{-1}$ respectively. The assignment of symmetrical and asymmetrical stretching frequencies to $NH_3$ groups is substantiated by an *X*-ray diffraction study of monosodium monoamidophosphate.[16]

Its structure, determined by three-dimensional Fourier synthesis, indicates that each phosphorus atom is surrounded by one nitrogen and three oxygen atoms disposed tetrahedrally. There is threefold symmetry about the P–N bond compatible with a trihedral distribution of hydrogen atoms about the nitrogen atom. Hydrogen bonding is thought to take place between any one nitrogen and the oxygen atoms in three adjacent anions. Thus zwitter-ions exist in the solid state in this three-dimensional framework (see Figs. 1 and 2). The crystallographic data are summarized in Table II.

*Table II.—Crystallographic Data for Monosodium Monoamidophosphate*

| | |
|---|---|
| System | Hexagonal, 2 molecules per cell |
| Unit cell dimensions | $a$ 5·773 ± 0·003 $b$ 6·031 ± 0·003 A. |
| Space group | $P6_3$ |
| Indicatrix | Uniaxial—optically negative |
| Refractive indices | $\omega$ 1·56 $\epsilon$ 1·52 |

The structure of this ion bears a striking resemblance to that of the isoelectronic sulphamate ion, $NH_3{}^+SO_3{}^-$.

Nuclear magnetic resonance spectra for mono- and disodium monoamidophosphates have been observed;[22-3] relevant data are tabulated on p. 182 together with corresponding data for related compounds.

* Relative to 85% phosphoric acid.

**Refs. p. 813**

From potentiometric titrations,[13] first and second ionization constants for monoamidophosphoric acid have been calculated. At 20°C. $K_1$ is $1{\cdot}19 \times 10^{-3}$ and $K_2$, $2{\cdot}10 \times 10^{-8}$. Other results given for these constants[83-4] are $K_1 = 2{\cdot}5 \times 10^{-5}$, $K_2 = 2{\cdot}0 \times 10^{-8}$ at 10°C. and $pK = 8{\cdot}2$ at 25°C.

## Chemical Properties

Monoamidophosphoric acid being dibasic[13] shows the characteristic double inflexion when titrated.

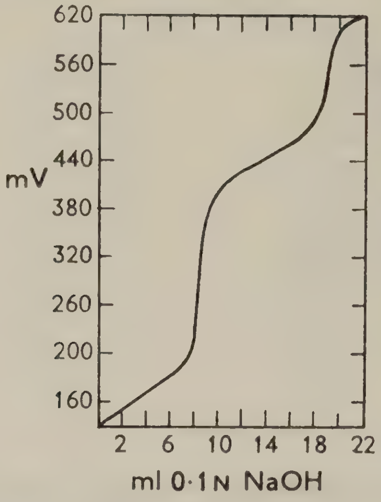

FIG. 3.—Potentiometric titration of monoamidophosphoric acid

The formation of zwitter-ions is consistent with the mechanism postulated for the hydrolysis of monoamidophosphates[17]:

$$HPO_3^-NH_3^+ + HOH \rightarrow H_2PO_4^- + NH_4^+$$

Chain extension can also occur by the following routes:

$$HPO_3^-NH_3^+ + H_2PO_4^- \rightarrow H_2P_2O_7^{2-} + NH_4^+$$
$$HPO_3^-NH_3^+ + H_2P_2O_7^{2-} \rightarrow H_2P_3O_{10}^{3-} + NH_4^+$$

although the probability of the last reaction taking place is low. The rate of hydrolysis[85] has been measured in media of various pH from 0·09 N. sodium hydroxide to 1·5 N. perchloric acid by following the formation of ammonia. The acid is not hydrolyzed in basic solution but below pH 7 the hydrolysis rate rises rapidly with decreasing pH. At pH 4 the rate is increased by added fluoride ion. The rates of hydrolysis of monoamidophosphoric acid are given in Table IV.

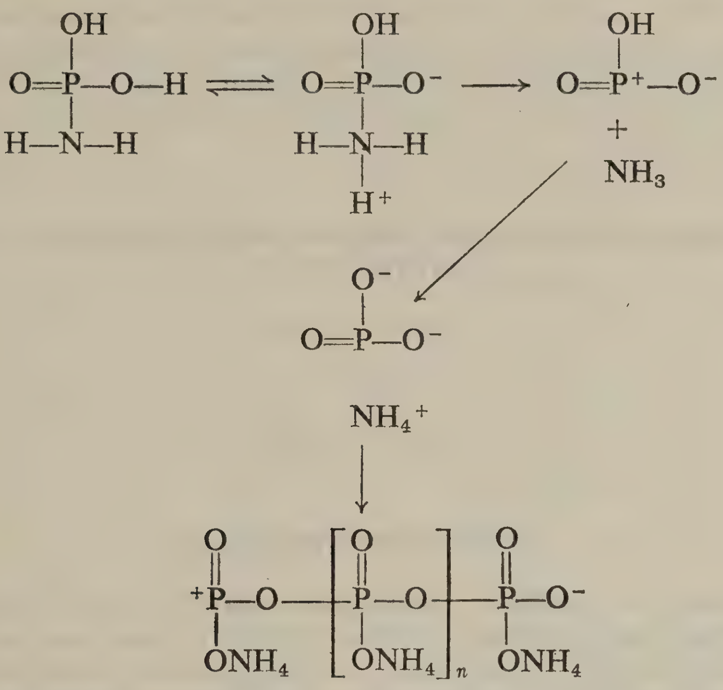
*Table IV.—Hydrolysis of Phosphoramidic Acid in* 0·217 M. $HClO_4$ *at various Temperatures*

| Temp. °C. | $10^4k$ (sec.$^{-1}$) | $\Delta E$ (kcal./mole) | $\Delta S$ (e.u.) |
|---|---|---|---|
| 10 | 0·79 | 16·8 | −14·06 |
| 25 | 3·28 | | |
| 35 | 8·35 | | |

The products of hydrolysis at pH 4·40 at 40·0°C. were examined by quenching[86] and examining the samples by ion exchange analysis. The hydrolysis was found to be a first-order reaction with $k = 3{\cdot}60 \times 10^{-2}$ min.$^{-1}$. During the course of the hydrolysis small quantities of pyrophosphate were detected. In the special case of monoammonium monoamidophosphate, hydrolysis gives rise to diammonium orthophosphate[13]:

$$NH_4HPO_3NH_2 + HOH \rightarrow (NH_4)_2HPO_4$$

A quantitative conversion of monoamidophosphoric acid to ammonium polyphosphate can be effected in 3 hr. at temperatures of 100–110°C., or more slowly at lower temperatures. The following intramolecular rearrangement[39] is envisaged:



Monoamidophosphates readily lose ammonia on heating, the extent of the loss depending on the temperature at which the deamination is conducted. These thermal decompositions are usually carried out *in vacuo*. At about 80°C. disodium monoamidophosphate hexahydrate loses its water only[18]:

$$Na_2PO_3NH_2,6H_2O \rightarrow Na_2PO_3NH_2 + 6H_2O$$

However, as the temperature is increased tetrasodium imidodiphosphate, hexasodium nitridotriphosphate and tetrasodium pyrophosphate are formed successively:

$$2Na_2PO_3NH_2 \xrightarrow[\text{in vacuo}]{210^\circ\text{C}} Na_4P_2O_6NH + NH_3{}^{18-9}$$

$$3Na_2PO_3NH_2 \xrightarrow[\text{in vacuo}]{450^\circ\text{C}} (Na_2PO_3)_3N + 2NH_3{}^{18}$$

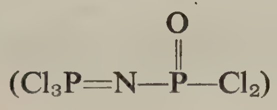
$$2Na_2PO_3NH_2 + H_2O \xrightarrow[\text{in air}]{1000^\circ\text{C}} Na_4P_2O_7 + 2NH_3{}^{20}$$

Slight variations in the reaction at 1000°C. are observed if the experiment is undertaken at a very low pressure in a quartz apparatus when, in addition to the pyrophosphate, reddish-brown materials having an odour of phosphine are produced.

An infra-red study of the decomposition of the potassium salt supported this mechanism.[129]

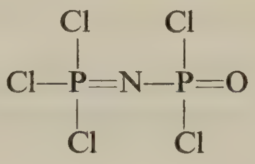
The acid reacts[87] with phosphorus pentachloride to give a crystalline product trichlorophosphonitridophosphoryl dichloride,

$P_2NOCl_5$



$$(Cl_3P{=}N{-}\overset{\overset{\large O}{\|}}{P}{-}Cl_2)$$

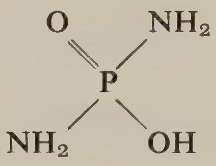
The structure of trichlorophosphonitridophosphoryl dichloride has been investigated by nuclear magnetic resonance,[88] the evidence supporting the structural formula:



$$\mathrm{Cl{-}PCl_2{=}N{-}PCl_2{=}O}$$

This product, which may also be formed by the reaction of phosphorus trichloride and dinitrogen tetroxide or phosphorus pentachloride and hydroxylamine salts,[87, 89-91] $P_2NOCl_5$, hydrolyzes in a restricted amount of acid to give monoamidophosphoric acid. In dilute alkali the hydrolysis product is the alkali salt of imidodiphosphoric acid.

## DIAMIDOPHOSPHORIC (PHOSPHORODIAMIDIC) ACID AND ITS SALTS



### Formation and Preparation

Although Stokes was unable to obtain pure crystalline alkali and alkaline earth diamidophosphates, his techniques (*Mellor*, VIII, 707) have been improved[24] and sodium diamidophosphate hexahydrate has been isolated after saponifying the phenyl ester. The hexahydrate, which can be readily dehydrated *in vacuo* at 80°C.,[18] has also been prepared by treating the silver salt, $AgPO_2(NH_2)_2$, with sodium bromide solution, removing the resultant silver bromide by filtration, and cooling the filtrate to −30°C. with simultaneous addition of ethyl alcohol. Similarly diamidophosphoric acid has been prepared from the silver salt and hydrobromic acid.[13] The acid is most readily prepared by catalytic hydrogenation of the phenyl ester[4] (cf. monoamidophosphoric acid).

Ammonolyses of halogen-containing compounds afford convenient preparative routes[25-6] for ammonium diamidophosphate. Thus a solution of pyrophosphoryl chloride in ether may, when treated with excess of ammonia in the presence of moisture, give the ammonium salt in yields between 85 and 92%. Polymeric phosphorus dioxychloride reacts with liquid ammonia almost quantitatively when maintained under pressure at room temperature for about 10 days:

$$(PO_2Cl)_x + 4xNH_3 \rightarrow xNH_4PO_2(NH_2)_2 + xNH_4Cl$$

In contrast with reactions which introduce amido groups into the molecule, it is possible to prepare diamidophosphates by eliminating an amido group from a compound containing three. Thus phosphoryl triamide is converted to sodium diamidophosphate by the action of warm 2 N. sodium hydroxide solution:

$$PO(NH_2)_3 + NaOH \rightarrow NaPO_2(NH_2)_2 + NH_3 \quad [13-4]$$

If acetone is added and the solution cooled to −30°C., sodium diamidophosphate tetrahydrate crystallizes.

## Physical Properties

Measurements of the conductivity of aqueous solutions of sodium diamidophosphates[13] have been made and corresponding values of the dissociation constant calculated for the acid:

| | 18°C. | 25°C. |
|---|---|---|
| Equivalent conductivity ($ohm^{-1}$ $cm.^2$) | 84·69 | 96·88 |
| Dissociation constant ($\times 10^{-5}$) | 1·20 | 1·49 |

Nuclear magnetic resonance spectra of aqueous solutions of the acid have been examined.[23] At 7140 gauss a chemical shift of $+3{\cdot}5$ p.p.m. is observed, relative to 85% orthophosphoric acid. Minor peaks occur at $+10$ and $+25$.

The infra-red spectrum of diamidophosphoric acid has been carefully examined.[30] Several assignments have been made and these are presented in Table V.

*Table V.—The Infra-red Spectrum of Diamidophosphoric Acid*

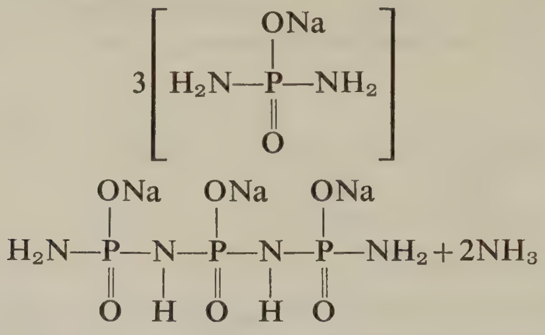
| Absorption frequency ($cm.^{-1}$) | Assignment |
|---|---|
| 3400 | as $NH_2$ |
| 3300 | s $NH_2$ |
| 2900 | as $NH_3$ |
| 2920 | |
| 2600 | s $NH_3$ |
| 2500 | |
| 1640 | as NH |
| 1620 | |
| 1460 | s $NH_3$ |
| 1200 | as $PO_2$ |
| 1000 | s $PO_2$ |
| 900 | PN |
| 700 | PN |
| 520 | s PO |
| 460 | as PO |

As with the monoamidophosphate ion the infra-red data provide evidence of zwitter-ion formation. The spectrum obtained from the zinc salt[21] is very similar to that observed[28] in the case of the lead salt.

## Chemical Properties

Free crystalline diamidophosphoric acid is not particularly stable, the action of moist air bringing about hydrolysis to ammonium monoamidophosphate[13]; if the crystals are dissolved in water this decomposition proceeds further to yield diammonium orthophosphate. Nevertheless the diamidophosphate ion is more stable than the monoamidophosphate[67] ion.

When a diamidophosphate or diamidophosphoric acid is heated, deamination tends to occur and gives rise to polymers containing P–N(H)–P bridges. The chain length of such polymers seems to depend on the temperature of reaction, higher temperatures being associated with higher molecular weights. At very high temperatures (*ca.* 900°C.) nitrogen can be completely eliminated from sodium diamidophosphate to give Graham's salt $(NaPO_3)_n$, provided that the heating is carried out in the presence of moist air.[20] An amorphous hygroscopic ammonium polyphosphimate results when diamidophosphoric acid is heated at 100°–110°C.[10] If sodium diamidophosphate is heated *in vacuo* to between 155° and 165°C., trisodium diamido-di-imidotriphosphate is obtained[18]:



$$3\left[\mathrm{H_2N{-}\overset{\displaystyle ONa}{\underset{\displaystyle O}{\overset{|}{\underset{\|}{P}}}}{-}NH_2}\right]$$

$$\mathrm{H_2N{-}\overset{\displaystyle ONa}{\underset{\displaystyle O}{\overset{|}{\underset{\|}{P}}}}{-}\underset{\displaystyle H}{\underset{|}{N}}{-}\overset{\displaystyle ONa}{\underset{\displaystyle O}{\overset{|}{\underset{\|}{P}}}}{-}\underset{\displaystyle H}{\underset{|}{N}}{-}\overset{\displaystyle ONa}{\underset{\displaystyle O}{\overset{|}{\underset{\|}{P}}}}{-}NH_2} + 2NH_3$$

More usually at these temperatures a mixture of homologues of general formula $Na_nP_nO_{2n}(NH)_{n-1}(NH_2)_2$ is formed[19]; at 200°C. $n$ is 6 and at 250°C. $n$ has a value in the region of 18.[24] An infra-red study of the decomposition of barium diamidophosphate confirmed these results, and showed that nitridotriphosphate does not occur among the decomposition products.[129]

The chemistry of the silver diamidophosphates has been reinvestigated[18] and the results differ from those reported by Stokes (*loc. cit.*). The monosilver salt is readily derived from the sodium salt or the free acid by precipitation with silver nitrate, under slightly acid or neutral conditions, respectively.[13] If the monosilver salt is treated with 30% potassium hydroxide, a potassium salt is obtained in which one of the hydrogen atoms in each of the amido groups is replaced by silver, i.e. $KPO_2(NHAg)_2,2H_2O$, which, when washed with boiling water, decomposes to a pentasilver salt, $AgPO_2(NAg_2)_2$:

$$5KPO_2(NHAg)_2 + 2H_2O \rightarrow 2AgPO_2(NAg_2)_2 + 3KPO_2(NH_2)_2 + 2KOH$$

Previously, the constitution of the pentasilver diamidophosphate was thought to be $(AgO)_3P(NHAg)_2$ (*Mellor*, VIII, 704), but on the basis of the evidence of analytical data, and of its reaction with methyl iodide in a sealed tube at 95°C.,

$$AgPO_2(NAg_2)_2 + 4CH_3I \rightarrow AgPO_2(N(CH_3)_2)_2 + 4AgI$$

in which only four of the silver atoms are replaced, the formula involving the disilver-substituted amido groups is preferred.

The pentasilver compound (*vide supra*), already known to undergo rapid spontaneous decomposition (*Mellor*, VIII, 705) has been shown to deposit metallic silver slowly if left for about a week.[13] Cleavage of the P–N bonds may also be effected by traces of rare-earth metal ions.[27] Thus at 37°C. and at pH 8·6 diamidophosphoric acid is decomposed by trivalent ions of cerium and lanthanum.

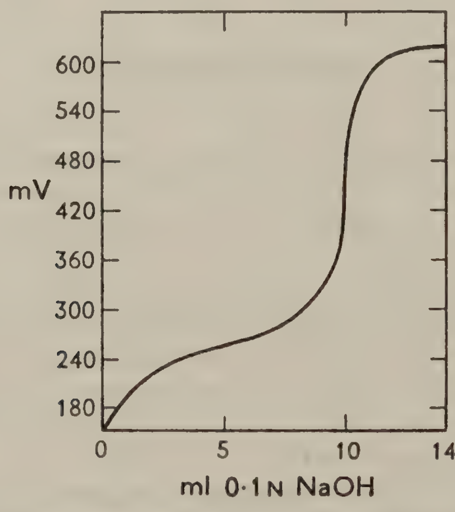


FIG. 4.—Potentiometric titration of diamidophosphoric acid

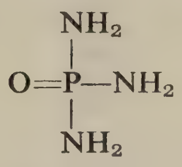
Diamidophosphoric acid titrates against decinormal alkali as a strong monobasic acid. Results obtained potentiometrically[13] show the neutral point to be at pH 8·5. Diamidophosphoric acid reacts with phosphorus pentachloride to give a crystalline compound, $P_2NOCl_7$ (see p. 481).[87]

## PHOSPHORYL TRIAMIDE



$$\begin{array}{ccc} & NH_2 & \\ & | & \\ O{=} & P & {-}NH_2 \\ & | & \\ & NH_2 & \end{array}$$

### Preparation

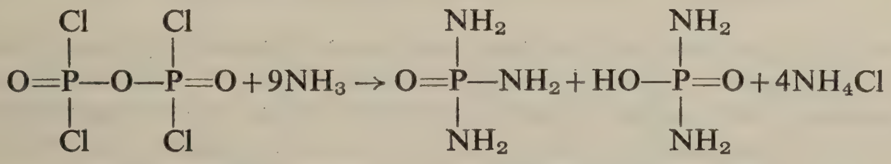
The amination of phosphoryl trichloride was formerly considered a somewhat doubtful preparative technique (*Mellor*, VIII, 707). However, 94% yields of phosphoryl triamide have been obtained[32] by treating phosphoryl trichloride with liquid ammonia,

$$POCl_3 + 6NH_3 \rightarrow PO(NH_2)_3 + 3NH_4Cl$$

or alternatively by passing gaseous ammonia into a solution of phosphoryl trichloride in chloroform at −10°C. and refluxing the precipitate with a mixture of diethylamine and chloroform to free it from ammonium chloride.[14] Reaction of phosphorus pentachloride with ammonia[40] and water according to the equation:

$$PCl_5 + 8NH_3 + H_2O \rightarrow O{=}P(NH_2)_3 + 5NH_4Cl$$

gives a good yield of phosphoryl triamide. The amide may be recrystallized from methyl alcohol. Condensed phosphoryl chlorides behave similarly[25] yielding condensed phosphoryl amides but, if the reaction is allowed to take place in the presence of excess of ammonia and some moisture, phosphoryl triamide usually occurs among the other products, e.g.:



$$\begin{array}{ccccccccc} & Cl & & Cl & & & NH_2 & & NH_2 & \\ & | & & | & & & | & & | & \\ O{=} & P & {-}O{-} & P & {=}O + 9NH_3 \rightarrow O{=} & & P & {-}NH_2 + HO{-} & P & {=}O + 4NH_4Cl \\ & | & & | & & & | & & | & \\ & Cl & & Cl & & & NH_2 & & NH_2 & \end{array}$$

If phosphorus pentachloride is treated with ammonia, an intermediate of indeterminate composition, possibly phosphorimidyl triamide, is formed, which hydrolyzes to phosphoryl triamide[33,40]:

$$PCl_5 + 9NH_3 \rightarrow NH{:}P(NH_2)_3 + 5NH_4Cl$$
$$NH{:}P(NH_2)_3 + H_2O \rightarrow O{:}P(NH_2)_3 + NH_3$$

### Physical Properties

This compound is slightly soluble in absolute methanol (0·7 g. per 100 ml. at 20°C.) but virtually insoluble in other common solvents, e.g. pyridine, nitrobenzene, acetone, ether, chloroform and ethanol.[67]

Infra-red and Raman spectra have been examined,[21,30,92,130] the peaks and their assignments being listed in Table VI. The assignments are compatible with $C_{3v}$ symmetry for the molecule.[130]

The solution in water is neutral (pH = 6), the low specific conductivity of a 0·1 M. solution at 20°C., viz. $10^{-4}$ ohm$^{-1}$ cm.$^{-1}$, indicating little ionization under these conditions.[67]

*Table VI.—The Infra-red and Raman Spectra of Phosphoryl Triamide*

| Raman frequencies (aqueous solution) | Infra-red frequencies (in potassium bromide) | Assignment |
|---|---|---|
| | 3390 cm, $^{-1}$ | $\nu_{as}$NH |

## Chemical Properties

Phosphoryl triamide is a fairly stable compound when dry, but if exposed for several weeks to a damp atmosphere it hydrolyzes to ammonium monoamidophosphate. If it is heated on a water-bath with dilute sodium hydroxide solution, monosodium diamidophosphate is produced[14]:

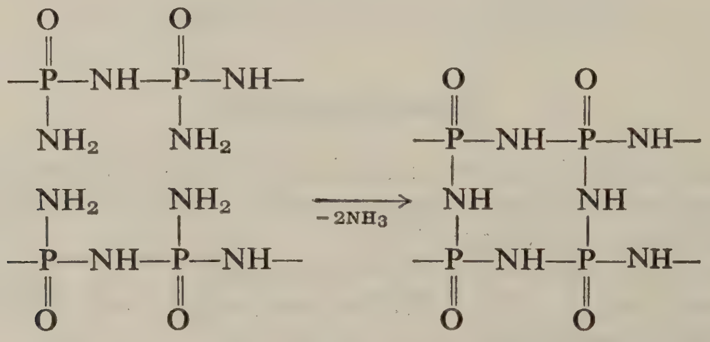
$$PO(NH_2)_3 + NaOH \rightarrow NaPO_2(NH_2)_2 + NH_3$$

As with many compounds containing P–N bonds, there is a marked tendency for self-condensation to occur, resulting in larger molecules. Thus condensed materials of the general formula $P_nO_n(NH)_{n-1}(NH_2)_{n+2}$ are formed by boiling a suspension of phosphoryl triamide in an organic medium such as benzene or toluene. The value of $n$ varies between 2 and 5[20]:

$$2PO(NH_2)_3 \rightarrow NH_3 + (NH_2)_2PO(NH)PO(NH_2)_2, \quad \text{etc.}$$

Water-soluble products of this type have been separated by paper chromatography.[20] When heated to 180°C. phosphoryl amide[93–4, 130–1] condenses rapidly to form phosphoryl imidoamide which is relatively stable at this temperature. The reaction is of at least second order, giving a polymeric product. The reaction–time curve is shown in Fig. 5 and the graph for third-order kinetics in Fig. 6.

Further heating results in the polymer cross-linking to form a product with the empirical formula $P_2O_2N_3H_3$. A temperature of 300°C. was required to give rapid cross-linking (see Fig. 5). The amount of ammonia evolved suggested a condensation of the type:



This polymer is a white amorphous powder insoluble in water and fairly resistant to hydrolysis. It is stable at 300°C., and temperatures of the order of 600°C. are required to convert it to phosphorus oxynitride P≡N=O.

The mechanism of these condensation reactions usually involves the elimination of ammonia. Hence the addition of a suitable reagent such as dry hydrogen chloride, to combine with the ammonia, favours the process.[19, 34] The chain length of the products depends upon the temperature and the concentration of the hydrogen chloride in the inert medium in which the reagents are suspended or dissolved. When hydrogen chloride is passed into a solution of phosphoryl triamide in diethyl ether for a period of 3 hr. at a temperature of −15°C. the dimer is obtained, in 100% yield, whilst at about 30°C. the passage of hydrogen chloride for 4 hr. gives the trimer in 86% yield.[35]

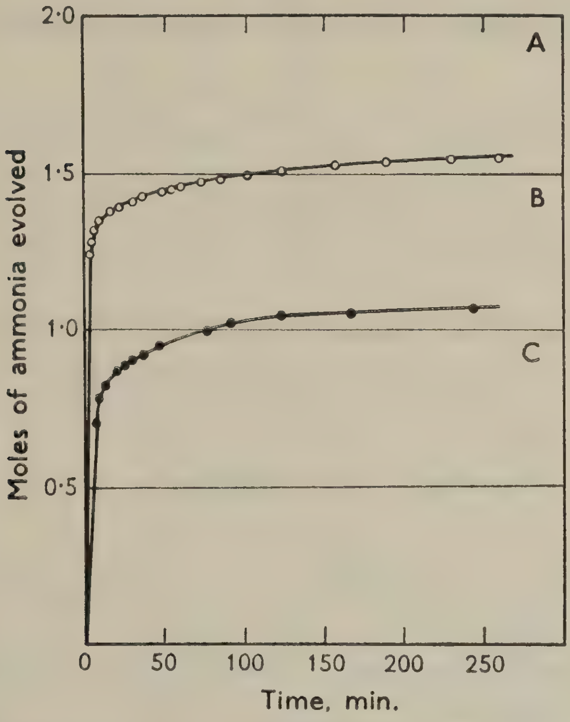


FIG. 5.—Condensation of phosphoramide at 180° (○) and 300° (●)

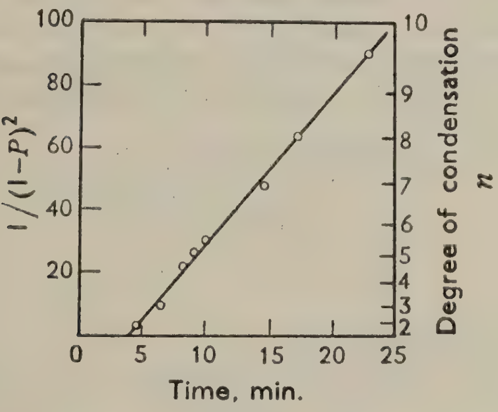

FIG. 6.—Condensation of phosphoramide at 180° plot of $1/(1-P)^2$ against time for third-order kinetics
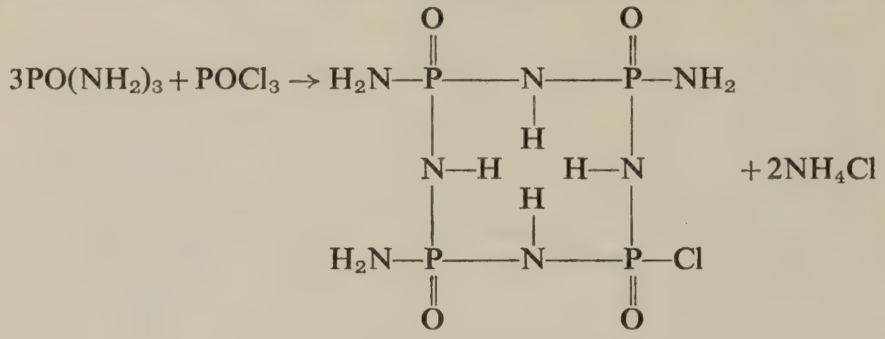
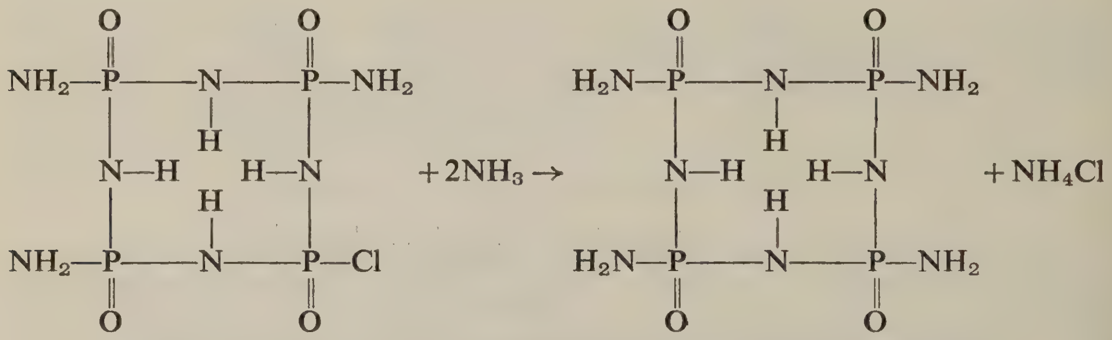
$P$ = mole fraction reacted

A similar reaction occurs in the presence of phosphoryl trichloride. Phosphoryl triamide and phosphoryl trichloride when shaken together for 3 hr. in the cold yield a precipitate which when filtered off under dry nitrogen, washed with chloroform, liquid ammonia and finally water, gives polyphosphoryl polyamide. However, by dissolving the precipitate in formamide and adding acetone, an intermediate, possibly tetrametaphosphimic chloride triamide, has been isolated,[57] although its constitution is uncertain:

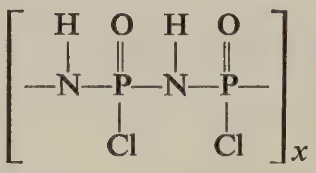


The action of liquid ammonia removes the ammonium chloride and ammonolyzes the chlorine atom:



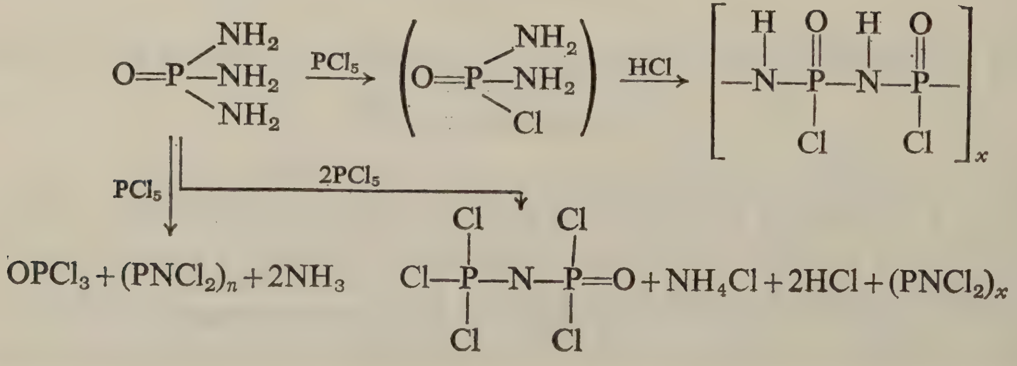
However, the tetrametaphosphimic tetramide has not been isolated, the final product being an amorphous polymer, $(HNPONH_2)_n$.

It seems very likely that this capacity for self-condensation has led to the adoption of phosphoryl triamide as a flame retardant for various combustible materials, including paint, textiles and wood.[36-8, 95-7] Phosphoryl triamide reacts[87] with phosphorus pentachloride to give a mixture consisting of a crystalline compound of the formula $P_2NOCl_5$ (see p. 481), phosphonitrilic chlorides and a polymer



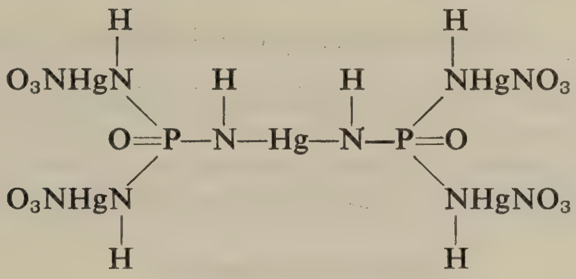
$$\left[-\overset{H}{N}-\underset{Cl}{\overset{O}{P}}-\overset{H}{N}-\underset{Cl}{\overset{O}{P}}-\right]_x$$

the possible reaction paths being:

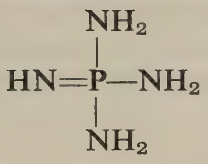


The electrochemical fluorination of phosphoryl triamide in hydrogen fluoride yielded $OF_2$, $N_2$, $N_2O$ and $NF_3$. The same products, with the exception of oxygen difluoride, were formed from phosphorimidyl triamide (see below). In neither case could volatile phosphorus compounds be detected in the products.[132]

From a methanolic solution of phosphoryl triamide, silver nitrate precipitates a complex $[(PO(NH_2)_3)Ag]NO_3$ as silky leaflets, whilst in aqueous solution mercuric nitrate yields an insoluble white flocculent compound $Hg_5[(PO(NH)_3)_2(NO_3)_4]$, which is not a complex but a genuine amidate represented by the structure[14]:



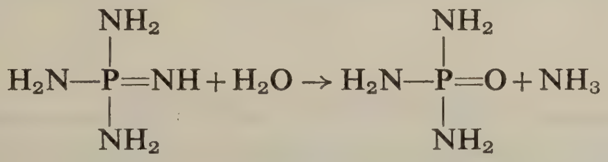
## PHOSPHORIMIDYL TRIAMIDE



$$\mathrm{HN{=}\overset{NH_2}{\underset{NH_2}{P}}{-}NH_2}$$

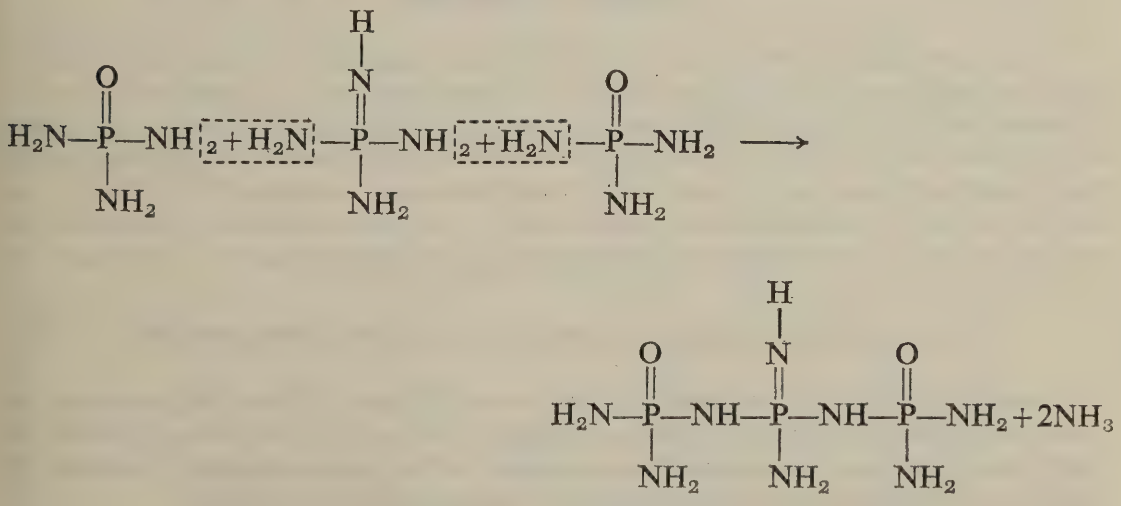
This compound has been postulated as an intermediate in the reaction of phosphorus pentachloride with ammonia.[33] Other authorities differ[54–6] but the existence of such an intermediate would satisfactorily explain the subsequent formation of phosphoryl triamide, tri-imidotriphosphoric pentamide and polyammonium polyimidopolyphosphate, as the reaction conditions varied.

Assuming phosphorimidyl triamide were produced, the action of moisture would most probably give rise to phosphoryl triamide:



$$\mathrm{H_2N{-}\overset{NH_2}{\underset{NH_2}{P}}{=}NH + H_2O \rightarrow H_2N{-}\overset{NH_2}{\underset{NH_2}{P}}{=}O + NH_3}$$

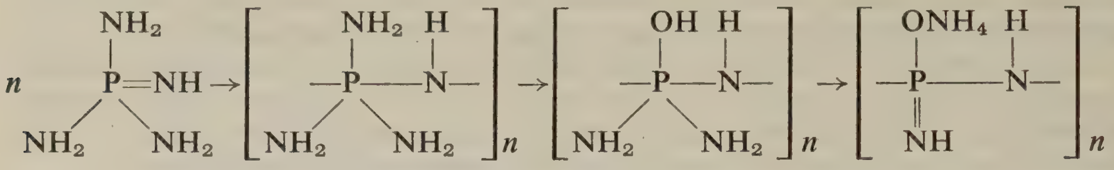
Furthermore the formation of tri-imidotriphosphoric pentamide is adequately explained by considering the deamination of 2 molecules of phosphoryl triamide and one molecule of phosphorimidyl triamide:



$$\mathrm{H_2N{-}\overset{O}{\overset{\|}{\underset{NH_2}{P}}}{-}NH\boxed{_2+H_2N}{-}\overset{\overset{H}{|}}{\overset{N}{\overset{\|}{\underset{NH_2}{P}}}}{-}NH\boxed{_2+H_2N}{-}\overset{O}{\overset{\|}{\underset{NH_2}{P}}}{-}NH_2 \longrightarrow}$$

$$\mathrm{H_2N{-}\overset{O}{\overset{\|}{\underset{NH_2}{P}}}{-}NH{-}\overset{\overset{H}{|}}{\overset{N}{\overset{\|}{\underset{NH_2}{P}}}}{-}NH{-}\overset{O}{\overset{\|}{\underset{NH_2}{P}}}{-}NH_2 + 2NH_3}$$

The following mechanism has been suggested for the formation of polyammonium polyimidopolyphosphate:

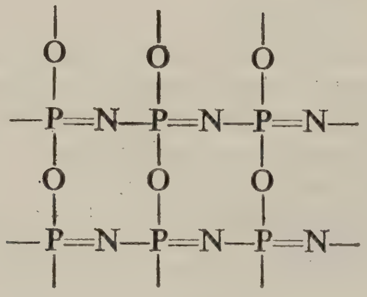


## PHOSPHORUS OXYNITRIDE

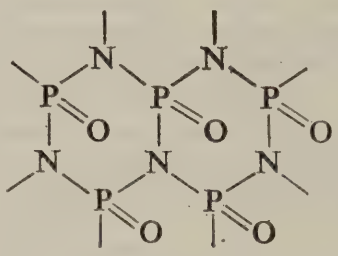
Phosphorus oxynitride, $(PON)_x$, is obtained by heating phosphoryl imidoamide to red-heat[98-100] in the absence of air. The material was at first thought to be monomeric but Oddo[101] suggested a dimeric structure to account for its stability. The true molecular weight must, however, be very much higher than this.

### Physical Properties

The compound[93] is an involatile white powder which melts above 1000°C. to form a glass. The glass exists in at least three forms: opaque, crystalline-transparent and black. The powder is amorphous to *X*-rays but shows two wide absorption bands in the infra-red at 900–1050 cm.$^{-1}$ and 1200–1400 cm.$^{-1}$ Two possible basic structures are:



I



II

The former is supported by the similarity between the oxynitride and the reaction product of polyphosphonitrilic compounds and metal oxides. The similar properties of the oxynitride and silica also suggest that their structures are isoelectronic which would be the case with structure I.

### Chemical Properties

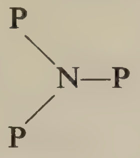
At low pressures above 750°C.[102] phosphorus oxynitride decomposes slowly to give phosphorus pentoxide, phosphorus nitride and nitrogen. It is insoluble in normal solvents and is not attacked by aqueous dilute acids and alkalis. Fusion with alkalis decomposes the oxynitride to give ammonia and the alkali metal phosphate. Concentrated sulphuric acid decomposes it to give ammonium phosphate. Water hydrolyzes the oxynitride[103] at temperatures above 200°C. to give ammonium phosphate and phosphoric acid. Further data on this compound are given in Section VIII (page 371).

## POLYPHOSPHORIC ACIDS CONTAINING P–N BONDS

Several possibilities arise depending on the environment of the nitrogen atoms in a particular molecule. Amido, imido and nitrido derivatives are distinguishable. So many permutations and combinations are possible that, understandably, no coherent pattern of the chemistry of these compounds seems to have emerged.

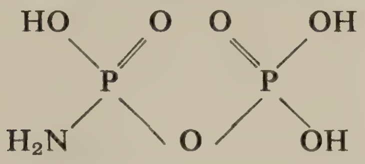
The category above therefore includes the following:

(*a*) Straight chains containing P–O–P or P–N(H)–P bridges or both.
(*b*) Branched chains containing



forks and bridges as indicated above.
(*c*) Any combination of P–$NH_2$ groupings with the bridges and forks together with the rare occurrence of P=NH groupings.

## MONOAMIDODIPHOSPHORIC ACID



By treating phosphorus pentoxide with ammonia under various conditions, the diammonium and triammonium salts of this acid have been prepared.[41] The action of gaseous ammonia on solid phosphorus pentoxide, phosphorus pentoxide suspended in an inert liquid or phosphorus pentoxide prepared *in situ* by burning red phosphorus in oxygen, yielded diammonium monoamidodiphosphate, which on further ammoniation was converted to triammonium monoamidodiphosphate:

$$P_2O_5 + 3NH_3 + H_2O \rightarrow (NH_4)_2HP_2O_6NH_2$$
$$(NH_4)_2HP_2O_6NH_2 + NH_3 \rightarrow (NH_4)_3P_2O_6NH_2$$

By increasing the humidity it was possible to improve the yields in these reactions.

### Physical and Chemical Properties

Both the di- and tri-ammonium amidodiphosphates are hygroscopic and soluble in water.

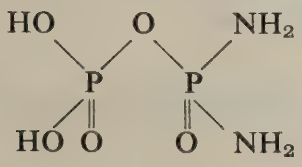
The above two salts are alkaline to methyl orange, but although the former is acid to phenolphthalein, the latter seems neutral.

Even at ambient temperature the amidodiphosphate ion decomposes in aqueous solution to orthophosphate. At boiling temperature or in the presence of a mineral acid such decomposition is accelerated.

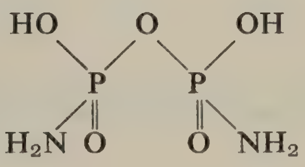
If the salts are heated in an inert gas stream, they lose most of their nitrogen, gradually turn yellow, then red, melt at about 260°C., and subsequently solidify to a glassy mass.

## DIAMIDODIPHOSPHORIC ACID

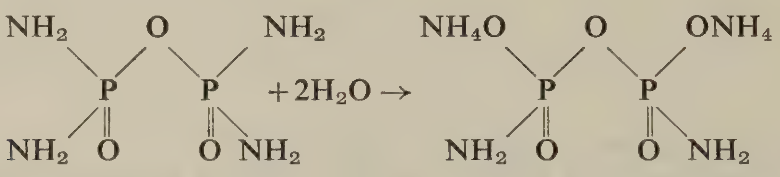
Two isomers are possible:



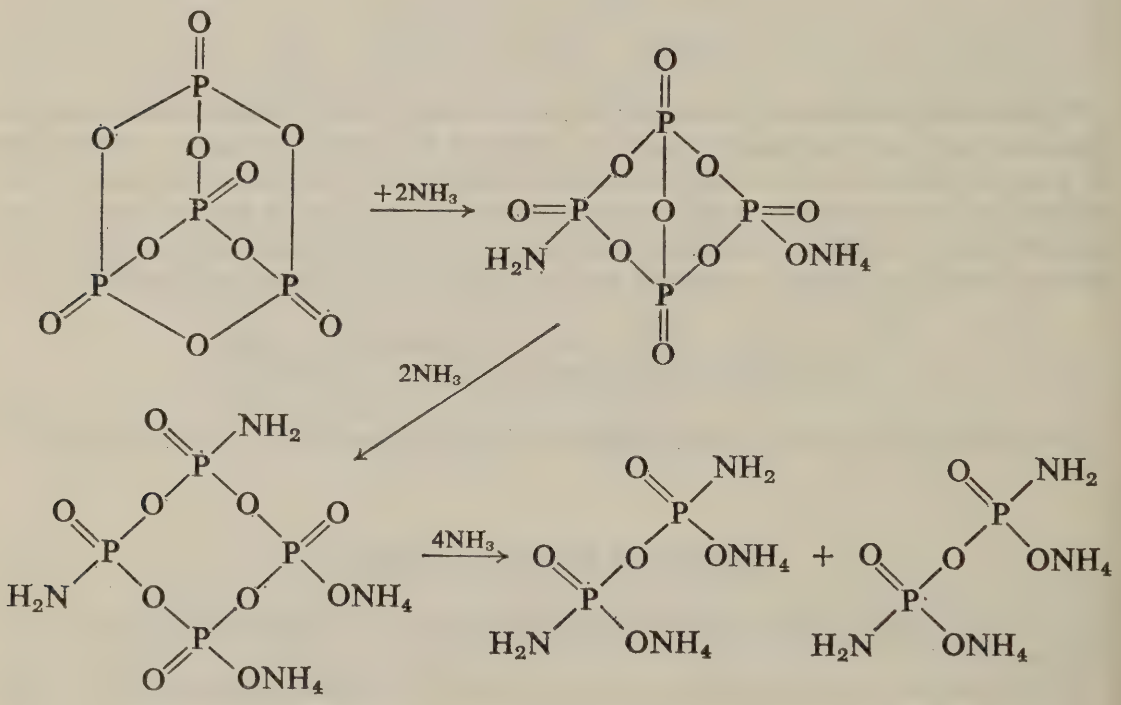
and



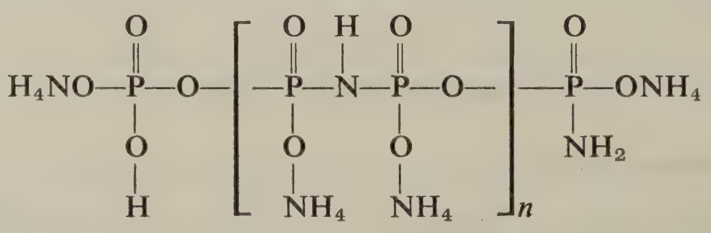
Previously (*Mellor*, VIII, 710) no attempt had been made to distinguish between these alternatives. However, when the diammonium salt was isolated from a solution of pyrophosphoryl tetramide by the addition of acetone and subsequent desiccation of the resultant oil, it was regarded[42] as the symmetrical form:



It has been claimed[10] that diammonium diamidodiphosphate can also be prepared by leaving a mixture of phosphorus pentoxide and excess of liquid ammonia in a sealed tube at room temperature for 5 or 6 weeks. The following mechanism has been suggested:

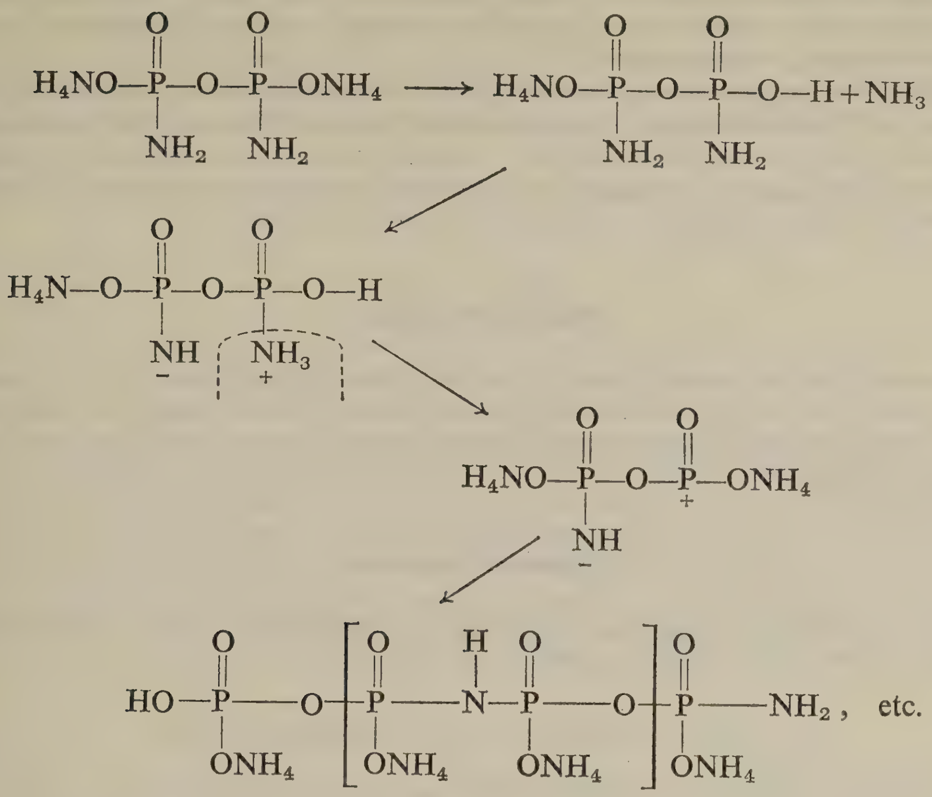


If this compound, together with any co-products, is heated, a chain compound is obtained containing both P–$\underset{\underset{H}{|}}{N}$–P and P–O–P bridges:

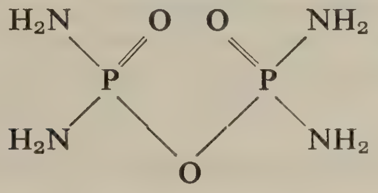


$$H_4NO{-}\underset{\underset{\displaystyle H}{\overset{|}{O}}}{\overset{\overset{\displaystyle O}{\|}}{P}}{-}O{-}\left[{-}\underset{\underset{\displaystyle NH_4}{\overset{|}{O}}}{\overset{\overset{\displaystyle O}{\|}}{P}}{-}\overset{\overset{\displaystyle H}{|}}{N}{-}\underset{\underset{\displaystyle NH_4}{\overset{|}{O}}}{\overset{\overset{\displaystyle O}{\|}}{P}}{-}O{-}\right]_n{-}\underset{\underset{\displaystyle NH_2}{|}}{\overset{\overset{\displaystyle O}{\|}}{P}}{-}ONH_4$$

where *n* is about 4. To explain this reaction the following mechanism has been postulated:

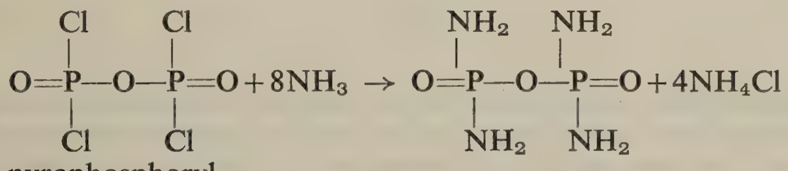


## PYROPHOSPHORYL TETRAMIDE



### Formation and Preparation

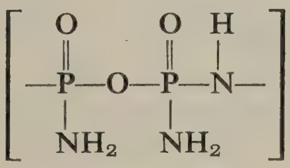
The application of the general method of aminating the appropriate chloro-derivative has proved successful:



$$O{=}\underset{Cl}{\overset{Cl}{P}}{-}O{-}\underset{Cl}{\overset{Cl}{P}}{=}O+8NH_3 \rightarrow O{=}\underset{NH_2}{\overset{NH_2}{P}}{-}O{-}\underset{NH_2}{\overset{NH_2}{P}}{=}O+4NH_4Cl$$

pyrophosphoryl chloride

By treating pyrophosphoryl chloride with liquid ammonia, 89% yields were obtained.[35] However, an intermediate polymeric form tends to appear[25, 43, 133-4] containing



$$\left[-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}{-}O{-}\underset{NH_2}{\overset{O}{\overset{\|}{P}}}{-}\overset{H}{N}-\right]$$

units, which needs to be further treated with liquid ammonia to obtain pyrophosphoryl tetramide in a pure state. Diamidophosphoric acid and phosphoryl triamide are also observed as by-products.[134]

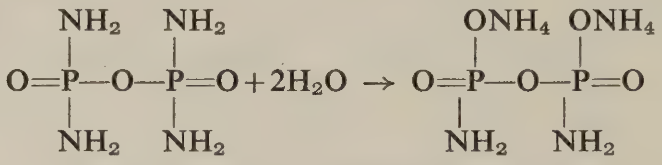
The reaction has also been effected by dissolving each of the reactants in chloroform, and adding the solution of pyrophosphoryl chloride dropwise to the ammoniacal solution in a vessel cooled to 0°C. The ammonium chloride was removed by extraction with liquid ammonia,[42] or better with cold absolute alcohol,[134] resulting in an overall yield of 74%.

## Physical Properties

Pyrophosphoryl tetramide forms colourless, odourless, hygroscopic crystals which are reported[42] to have a sweet taste. It is insoluble in most organic solvents. In the presence of ammonia it is sparingly soluble in water. It is also only sparingly soluble in liquid ammonia.[43]

## Chemical Properties

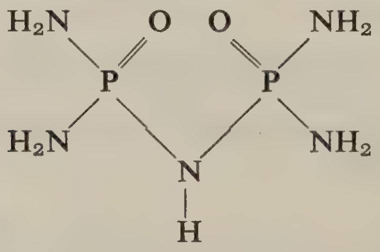
It is impossible[42] to dissolve pyrophosphoryl tetramide in water without decomposition of two of the amido groups to ammonium ions:



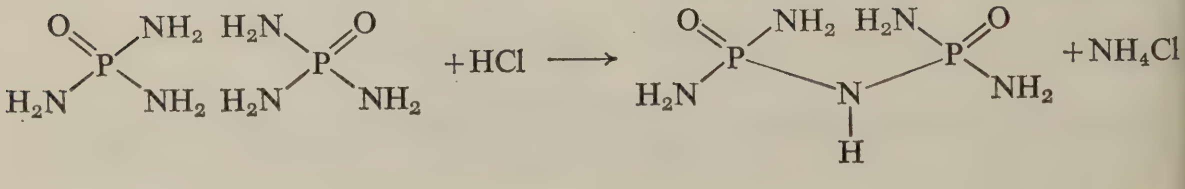
$$O{=}\overset{NH_2}{\underset{NH_2}{P}}{-}O{-}\overset{NH_2}{\underset{NH_2}{P}}{=}O + 2H_2O \rightarrow O{=}\overset{ONH_4}{\underset{NH_2}{P}}{-}O{-}\overset{ONH_4}{\underset{NH_2}{P}}{=}O$$

thus yielding diammonium diamidodiphosphate (*q.v.*). The thermal decomposition of pyrophosphoryl tetramide alone, or in xylene, at 300°–600°C. gives products of lower N:P ratios which contain P–NH–P bonds but no $P{-}N{=}(P)_2$ groups.[134]

## PYROPHOSPHORIMIDYL TETRAMIDE

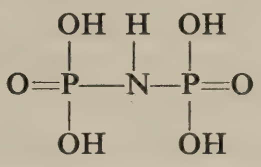


This compound has been obtained by an anionic deamination technique.[19] Dry hydrogen chloride was passed into a suspension of phosphoryl triamide in ether at −15°C. After 3 hr. the mixture of ammonium chloride with pyrophosphorimidyl tetramide (or imidodiphosphoric acid tetramide) was treated with liquid ammonia. This process removed the ammonium chloride, leaving white crystals, easily soluble in water[35]:



A 0·03 M. solution has pH of 4·3 at 35°C., but on standing for 25 hr. this rises to 6·85 because of hydrolytic decomposition. The addition of sodium hydroxide brings about the evolution of 2 moles of ammonia per mole of pyrophosphorimidyl tetramide. The diffraction pattern obtained by *X*-ray powder photography bears a striking resemblance to that obtained from pyrophosphoryl tetramide.[42]

## IMIDODIPHOSPHORIC ACID

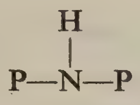


$$O{=}P(OH)_2{-}N(H){-}P(OH)_2{=}O$$

Of the imidodiphosphoric acids mentioned before (*Mellor*, VIII, 712), only the tetra-basic acid seems plausible. All other possibilities involve four-membered rings which, from general stereochemical considerations, seem unlikely to remain stable. Furthermore, three of the hypothetical acids which were described were thought to be identical with mono-, di- and tri-amidodiphosphoric acids (*loc. cit.*) and in the light of their properties and more recent data this view seems correct.

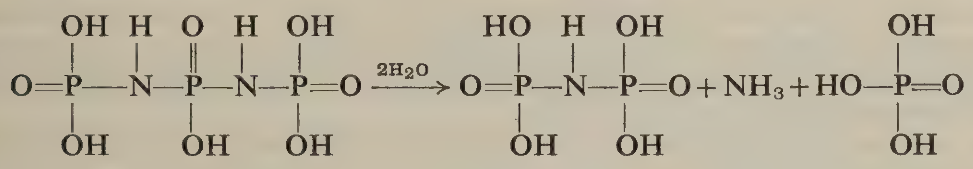
### Formation and Preparation

Imidodiphosphates tend to occur as minor components in the hydrolysates of larger molecules or ions containing the

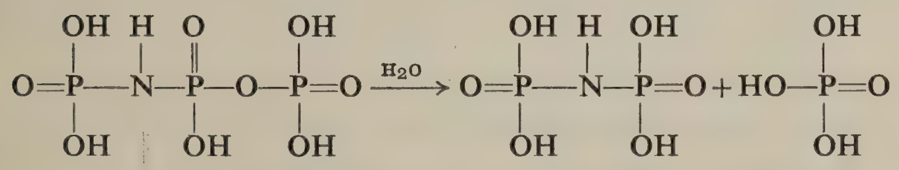


$$P{-}N(H){-}P$$

grouping, e.g. trimetaphosphimates (*Mellor*, VIII, 712), di-imidotriphosphates[17, 45–6] and monoimidotriphosphates[17, 46]:



$$O{=}P(OH)_2{-}N(H){-}P(O)(OH){-}N(H){-}P(OH)_2{=}O \xrightarrow{2H_2O} O{=}P(OH)_2{-}N(H){-}P(OH)_2{=}O + NH_3 + HO{-}P(OH)_2{=}O$$



$$O{=}P(OH)_2{-}N(H){-}P(O)(OH){-}O{-}P(OH)_2{=}O \xrightarrow{H_2O} O{=}P(OH)_2{-}N(H){-}P(OH)_2{=}O + HO{-}P(OH)_2{=}O$$

Degradative reactions of this type are not particularly convenient preparative techniques. However, condensation of two smaller molecules with the elimination of ammonia[12, 18–9, 24] provides a useful device for obtaining good yields of the salts:

$$2Na_2PO_3NH_2 \rightarrow Na_4P_2O_6NH + NH_3$$
$$2Ag_2PO_3NH_2 \rightarrow Ag_4P_2O_6NH + NH_3$$

It is necessary to carry out these reactions *in vacuo* under controlled conditions as the degree of condensation seems to depend on the temperature. Thus tetrasodium imidodiphosphate was obtained by heating disodium amidophosphate for 7 days *in vacuo* at 210°C. The yield is reported to be improved by the addition of a fluxing agent such as an alkali metal formate or phenoxide.

There have been obtained 95% yields of tetrasodium imidodiphosphate by saponifying a diphenyl ester with excess of sodium hydroxide and phenol under reflux at 135°C. for 15 min.[22] though the presence of the latter does not seem essential.[104] Lower yields were obtained when the reaction took place under pressure in the absence of phenol. The technique is claimed to be applicable to the preparation of any of the alkali metal salts.

The free acid, which Stokes (*Mellor*, VIII, 713) was unable to prepare, has been made by treating an aqueous solution of the tetrasodium salt with the hydrogen form of a cation exchange resin, although it could not be obtained solid.[12, 22]

Tetrathallium imidodiphosphate was obtained by neutralization[22]:

$$H_4P_2O_6NH + 4TlOH \rightarrow Tl_4P_2O_6NH + 4H_2O$$

but most salts can be prepared by metathesis. Soluble salts like tetrapotassium and tetrammonium imidodiphosphates were isolated by treating the silver salt with the appropriate sulphide.

Acid salts arise when the pH of solutions of the normal salts is lowered by the addition of acetic acid:

$$K_4P_2O_6NH + 2HOAc \rightarrow K_2H_2P_2O_6NH + 2KOAc$$
$$(NH_4)_4P_2O_6NH + 2HOAc \rightarrow (NH_4)_2P_2O_6NH + 2NH_4OAc$$

The tetrammonium salt which occurs as a trihydrate loses both water and ammonia in the atmosphere to give triammonium imidodiphosphate with 1·5 molecules of water of crystallization:

$$(NH_4)_4P_2O_6NH,3H_2O \rightarrow (NH_4)_3HP_2O_6NH,1{\cdot}5H_2O + NH_3 + 1{\cdot}5H_2O$$

## Physical Properties

The imidodiphosphates tend to resemble the pyrophosphates. Thus *X*-ray diffraction data[12, 18] indicate that tetrasodium imidodiphosphate decahydrate and tetrasodium pyrophosphate decahydrate are isomorphous. However, sodium imidodiphosphate is rather more soluble than the pyrophosphate, the solubilities of the decahydrates at 25°C. being 34·8 and 11·6 g./100 ml. of water respectively.[22]

Measurements of nuclear magnetic resonance spectra of tetrasodium imidodiphosphate at a frequency of 16·192 Mc. indicated a chemical shift of −2·5 p.p.m. of the applied field with respect to 85% phosphoric acid. The chemical shift for tetrasodium pyrophosphate was +5·5 p.p.m.

The infra-red spectra of several imidodiphosphates have been examined,[21] including the normal sodium, potassium, zinc and thallium salts, together with the dihydrogen dipotassium salt and its deuterated analogue. Typical assignments are presented in Table VII.

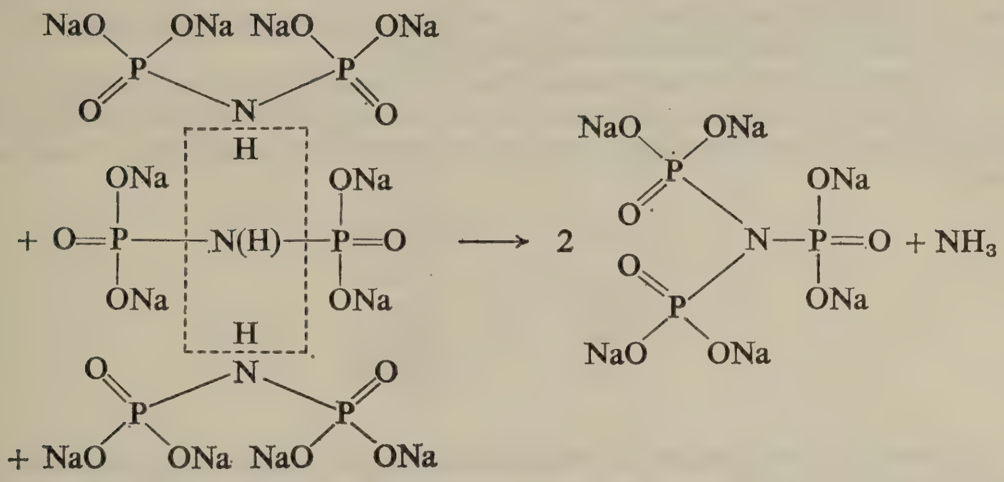
*Table VII.—Infra-red Absorption Spectra of Imidodiphosphates*

| Frequency range (cm.$^{-1}$) | Assignment |
|---|---|
| 3200–2900 | $\rangle$N—H* stretching |
| *c.* 2350 | $\rangle$N—D stretching |
| 2700–2560 | P—OH |

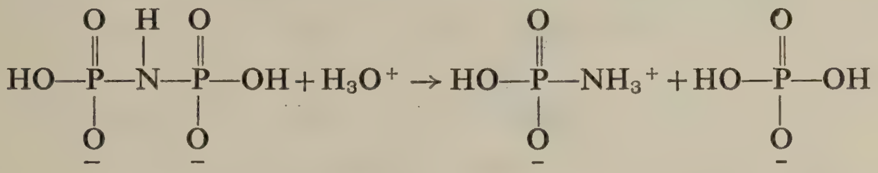
*The pentasilver salt does not contain an N–H bond and this frequency is therefore absent.

## Chemical Properties

The deamination procedure used to prepare imidodiphosphates need not stop at this point. Thus if tetrasodium imidodiphosphate is heated *in vacuo* at a temperature of 450°C., further loss of ammonia takes place to yield hexasodium nitridotriphosphate:

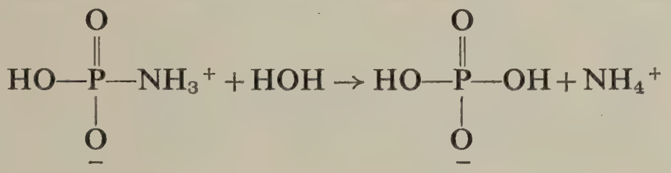


The hydrolysis of condensed imidophosphoric acids has been studied in detail.[17, 46] Very plausible mechanisms have been suggested. A hydroxonium ion may approach the —NH group and bring about fission at this point:

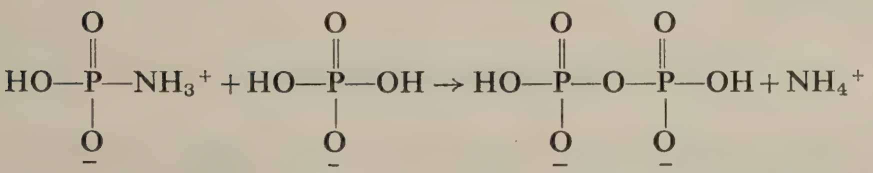


$$\mathrm{HO-\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}-\overset{\overset{H}{|}}{N}-\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}-OH + H_3O^+ \rightarrow HO-\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}-NH_3{}^+ + HO-\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}-OH}$$

The amidophosphate thus produced may be decomposed by water to orthophosphate and ammonium ions, or alternatively may eject an ammonium ion and recombine with an orthophosphate residue resulting in a pyrophosphate ion:



$$\mathrm{HO-\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}-NH_3{}^+ + HOH \rightarrow HO-\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}-OH + NH_4{}^+}$$



$$\mathrm{HO-\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}-NH_3{}^+ + HO-\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}-OH \rightarrow HO-\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}-O-\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}-OH + NH_4{}^+}$$

This scheme would satisfactorily account for several reactions that have been observed.[12]

Thus silver imidodiphosphate hydrolyses to pyrophosphate:

$$Ag_4P_2O_6NH + H_2O \rightarrow Ag_4P_2O_7 + NH_3$$

and sodium imidodiphosphate decomposes to monoamidophosphate and orthophosphate:

$$Na_4P_2O_6NH + H_2O \rightarrow Na_2PO_3NH_2 + Na_2HPO_4$$

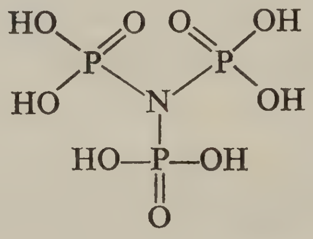
Analysis[86] by ion exchange chromatography of quenched samples from the hydrolysis at pH 4·40 and 40·0°C. showed that the reaction was first order with $k \sim 10^{-1}$ min.$^{-1}$. A small amount of pyrophosphate was also detected. The free acid decomposes similarly although there is also a tendency for the amidophosphate to break down further to orthophosphate and ammonia.

The reaction giving rise to pyrophosphate is slow and that to orthophosphate more rapid. However, in general the rate of decomposition is dependent upon the pH.[17] Tabulated below are the quarter lives of the imidodiphosphate ion at selected pH values:

| pH | Time (min.) |
|---|---|
| 1 | *c.* 10 |
| 3·5 | 3 |
| 8·0 | 30–40 |
| 11·0 | 300–400 |

The condensed phosphates are well known for their sequestering properties. The presence of the –N(H)– group enhances this effect,[22] so that at pH 12, 100 g. of tetrasodium imidodiphosphate decahydrate sequesters 3·0 g. of calcium (cf. 2·3 for corresponding pyrophosphate).

## NITRIDOTRIPHOSPHORIC ACID AND ITS SALTS



Two acids, containing no amido- or imido-hydrogen, have been described before, namely nitrilodiphosphoric acid (Mellor, VIII, 714,) and nitrilotrimetaphosphoric acid (*ibid.*, 720). Both of their structures were thought to involve four-membered rings, but from general structural considerations this seems unlikely.

The evidence afforded by the preparative technique for the latter compound suggests that this acid may have been nitridotriphosphoric acid, although this is by no means certain.

### Formation and Preparation

If disodium monoamidophosphate is heated *in vacuo* at 210°C., tetrasodium imidodiphosphate is formed, which on further heating at 450°C. loses more ammonia to yield hexasodium nitridotriphosphate[12, 18]:

$$Na_2PO_3NH_2 + H_2NPO_3Na_2 \rightarrow Na_2PO_3N(H)PO_3Na_2 + NH_3$$
$$3Na_2PO_3N(H)PO_3Na_2 \rightarrow 2Na_6(PO_3)_3N + NH_3$$

The free acid has not been isolated.

### Physical Properties

The structure of the nitridotriphosphate ion is thought to be analogous to that of the nitridotrisulphonate, although it is much less stable, and the infra-red spectrum does not exclude the possibility of a linear structure.[129]

Few physical data are available although the infra-red spectrum of the sodium salt has been reported[30] (see Table VIII).

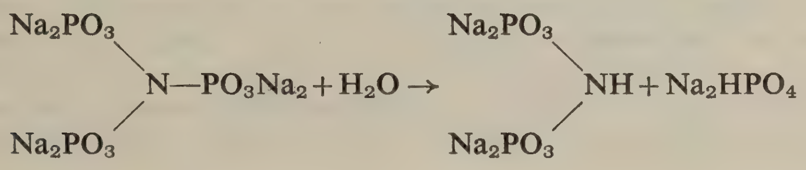
*Table VIII.—Infra-red Spectrum of Hexasodium Nitridotriphosphate*

| Frequency cm.$^{-1}$ | Intensity |
|---|---|
| 1163 | v.s. |
| 1150 | — |
| 1140 | — |
| 1038 | s. |
| 995 | m. |
| 930 | v.s. |
| 740* | s. |
| 617 | w. |
| 580 | v.s. |
| 570 | — |
| 525 | m. |
| 495 | s. |
| 468 | m. |

* Almost certainly antisymmetrical P.N. vibrations.

### Chemical Properties

Hexasodium nitridotriphosphate is very unstable and in the presence of moisture instantly hydrolyzes[12] to yield tetrasodium imidodiphosphate and disodium orthophosphate:

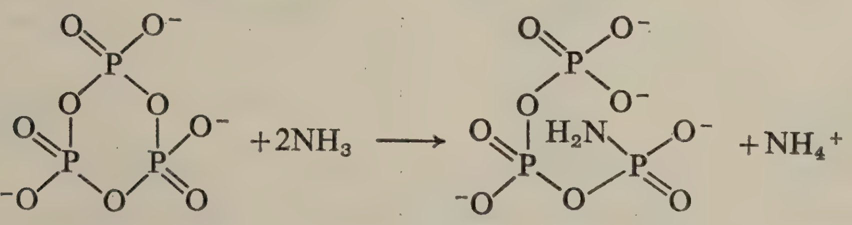


$$(Na_2PO_3)_2N—PO_3Na_2 + H_2O \rightarrow (Na_2PO_3)_2NH + Na_2HPO_4$$

## MONOAMIDOTRIPHOSPHORIC ACID AND ITS SALTS

### Formation and Preparation

Concentrated aqueous ammonia seems capable of severing the trimetaphosphate ring to produce a monoamidotriphosphate. After a solution of trisodium trimetaphosphate and concentrated ammonium hydroxide had been kept at approximately pH 12 for 3 days at 27°C., it was possible to precipitate the barium salt, $Ba_2P_3O_9NH_2$,[48] and other salts by addition of the appropriate cation:



Reaction kinetics were studied using nuclear magnetic resonance techniques. At 26°C., using 0·27 M. trimetaphosphate and 5·8 M. ammonia solution, a first-order reaction constant of $10^{-2}$ min.$^{-1}$ is obtained. In comparison solutions of sodium hydroxide–sodium chloride at the same pH are less effective in bringing about cleavage of the metaphosphate ring.

### Physical Properties

Nuclear magnetic resonance spectra have been obtained from solutions of sodium amidotriphosphate. Measurements were made in an applied field of 9400 gauss at a frequency of 16·2 Mc. The results, expressed in Table IX, give details of the $^{31}P$ multiplets and chemical shifts with respect to 85% orthophosphoric acid.

*Table IX.—Nuclear Magnetic Resonance Spectrum of the Amidotriphosphate Ion*

| Multiplet | Chemical shift (p.p.m. applied field) | Assignment |
|---|---|---|
| Doublet | 0·2 | terminal $PO_4$ |
| Doublet | 5·4 | terminal $PO_3NH_2$ |
| Triplet | 20·7 | central $PO_4$ |

The presence of an amido group displaces the terminal phosphate doublet to a somewhat lower value.

### Chemical Properties

If solutions containing the amidotriphosphate ion are slightly adjusted to pH 3 or 4, the trimetaphosphate ring reforms:

$$2P_3O_9NH_3{}^{3-} \rightarrow P_3O_9{}^{3-} + P_3O_9NH_2{}^{4-} + NH_4{}^{+} \xrightarrow{2H_3O^+} P_3O_9{}^{3-} + NH_4{}^{+} + 2H_2O$$

Evidence of this has been afforded by paper chromatography.[48] The kinetics of this cyclization[105] show that the reaction takes place in two stages. It is acid catalyzed with an average rate constant of $1{\cdot}52 \times 10^{-4}$ min.$^{-1}$ over the pH range 4·5–6·0 (concn. approx. 1 mMol/10 c.c.). Hydrolysis of a 2·3 molar solution of amidotriphosphate with 2 moles of HCl per mole of amidotriphosphate can be shown by paper chromatography to give penta- and hexa-phosphates, presumably by reactions of the type:

$$2P_3O_9NH_2{}^{4-} + 2H^+ + H_2O \rightarrow P_6O_{19}{}^{8-} + 2NH_4{}^{+}$$

Ammonolysis of the amidotriphosphate produces a diamidomonophosphate.

The reaction of trimetaphosphate with primary and secondary amines has also been shown to be reversible, and of first order in both directions, the rate increasing with the dissociation constant of the amine concerned (see Tables X and XI).[135]

*Table X.—Ammonolysis (Aminolysis) of* $[P_3O_9]^{3-}$

Conc. 0·5 mol $Na_3P_3O_9$ and 0·5 mol $NH_3$ (amine)/l.

| Amine | Dissocn. const. of amine $K \times 10^5$ | Time to reach equilibrium (hr.) | $[P_3O_9NHR]^{4-}$/ original $[P_3O_9]^{3-}$ |
|---|---|---|---|
| $NH_3$ | 1·79 | 20 | 0·48 = 96% |
| $NH_2CH_3$ | 43·8 | 3 | 0·46 = 92% |
| $NH(CH_3)_2$ | 52·0 | 0·5 | 0·40 = 80% |
| $N(CH_3)_3$ | 56·5 | no reaction | |

*Table XI.—Recyclization of Amidotriphosphates*
0·1 M. soln., 20°C. pH 6

| Amidotriphosphate | Dissocn. const. of amine $K \times 10^5$ | 1st order velocity const. $k(\text{min.}^{-1}) \times 10^2$ | Half-life (min.) | $k/K$ |
|---|---|---|---|---|
| $[P_3O_9NH_2]^{4-}$ | 1·79 | 1·14 | 60·7 | 637 |

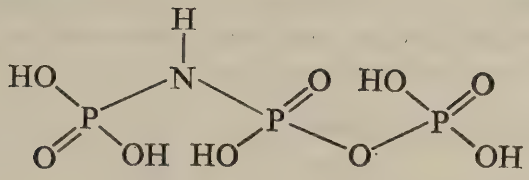
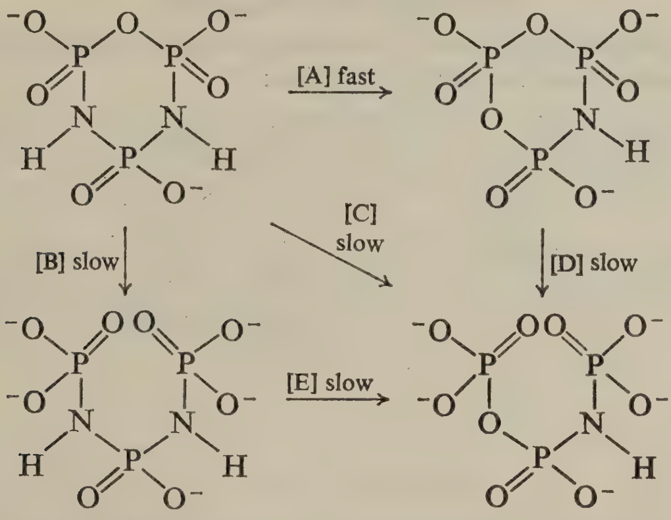
| $[P_3O_9N(CH_3)_2]^{4-}$ | 52·0 | 30·2 | 2·30 | 581 |

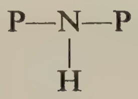
## MONOIMIDOTRIPHOSPHORIC ACID AND ITS SALTS



The imidotriphosphate ion arises as an intermediate in the sequence of reactions resulting from the hydrolysis of trimetaphosphimates, mono- and di-imidotrimetaphosphates or di-imidotriphosphates[46]:

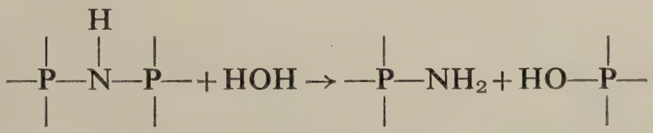


Three distinct reaction mechanisms are involved,[17] namely fission, replacement and condensation;



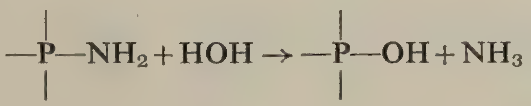
$$\underset{\substack{|\\ \mathrm{H}}}{\mathrm{P{-}N{-}P}}$$

bridges are severed hydrolytically:



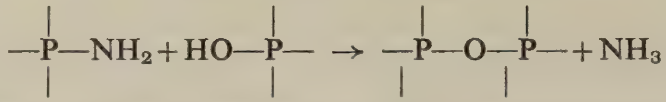
$$-\overset{|}{\underset{|}{P}}-\overset{\mathrm{H}}{\overset{|}{N}}-\overset{|}{\underset{|}{P}}- + \mathrm{HOH} \rightarrow -\overset{|}{\underset{|}{P}}-\mathrm{NH_2} + \mathrm{HO}-\overset{|}{\underset{|}{P}}-$$

and the $-NH_2$ group is replaced by $-OH$:



$$-\overset{|}{\underset{|}{P}}-\mathrm{NH_2} + \mathrm{HOH} \rightarrow -\overset{|}{\underset{|}{P}}-\mathrm{OH} + \mathrm{NH_3}$$

Alternatively deamination occurs with the resultant formation of a P–O–P bridge[49–50]:



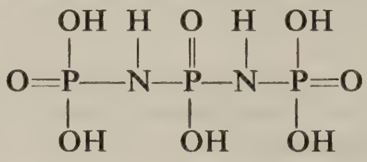
$$-\underset{|}{\overset{|}{P}}-NH_2+HO-\underset{|}{\overset{|}{P}}- \rightarrow -\underset{|}{\overset{|}{P}}-O-\underset{|}{\overset{|}{P}}-+NH_3$$

Naturally this series of reactions does not end at the imidotriphosphate stage, and this ion decomposes into triphosphate, orthophosphate and imidodiphosphate, or monoamidophosphate and pyrophosphate, or very occasionally orthophosphate and amidodiphosphate, which in turn eventually decompose to orthophosphate:

$$P_3O_9NH^{5-}+H_2O \rightarrow P_3O_{10}{}^{5-}+NH_3$$
$$P_3O_9NH^{5-}+2OH^- \rightarrow P_2O_6NH^{4-}+PO_4{}^{3-}+H_2O$$
$$P_3O_9NH^{5-}+OH^- \rightarrow P_2O_7{}^{4-}+PO_3NH_2{}^{2-}$$
$$P_3O_9NH^{5-}+OH^- \rightarrow P_2O_6NH_2{}^{3-}+PO_4{}^{3-}$$

From these reactions it is evident that the decomposition is pH-sensitive, and quarter-lives of the various species have been determined at several pH values. At pH 3·5 imidotriphosphate has a quarter-life of 25 min.[17]

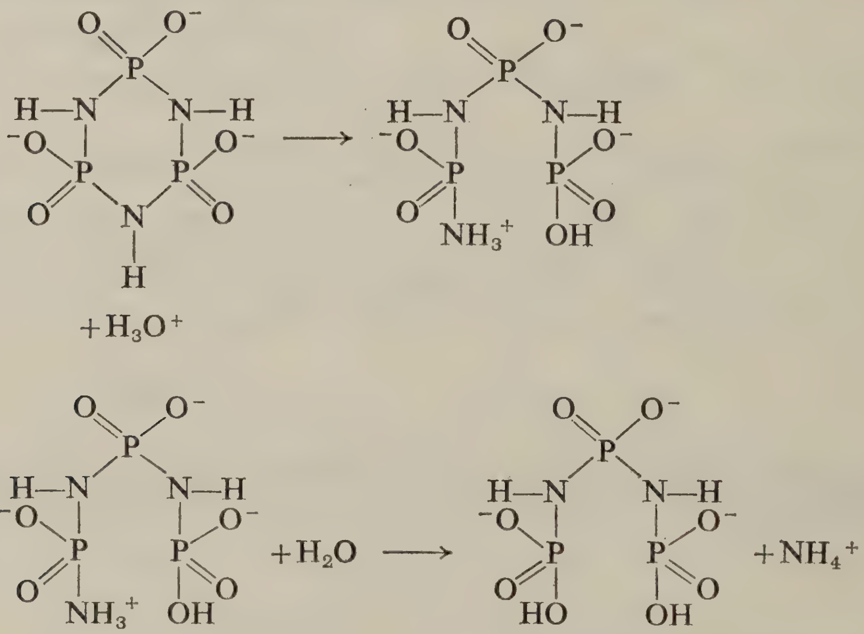
## DI-IMIDOTRIPHOSPHORIC ACID AND ITS SALTS



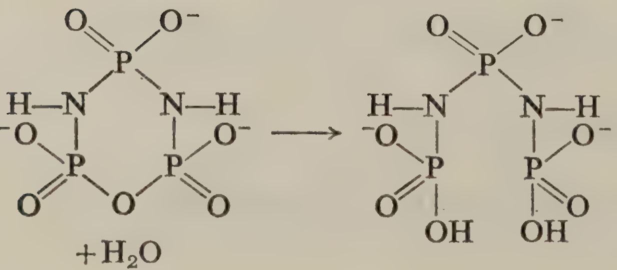
$$O=\underset{OH}{\overset{OH}{P}}-\overset{H}{N}-\underset{OH}{\overset{O}{\overset{\|}{P}}}-\overset{H}{N}-\underset{OH}{\overset{OH}{P}}=O$$

### Formation and Preparation

The di-imidotriphosphate ion arises by the hydrolysis of both trimetaphosphimate and di-imidotrimetaphosphate ions,[17, 45–6] i.e.:



and,

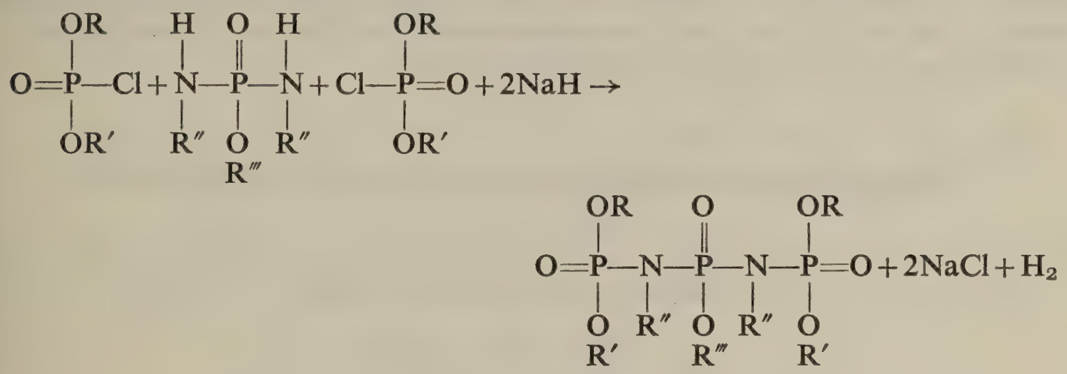


The use of 30% sodium hydroxide solution at 75°C. deposits crystals of sodium di-imidotriphosphate hexahydrate. Because this sort of mechanism operates, various phosphonitrilic derivatives may also give rise to di-imidotriphosphoric acid[51] when hydrolyzed, e.g. trimeric phosphonitrilic diamidotetrachloride:

$$P_3N_3Cl_4(NH_2)_2 + 8H_2O \rightarrow H_5P_3O_8(NH)_2 + 3NH_4Cl + HCl$$

Straight chain materials containing the appropriate skeleton, such as trisodium diamidodi-imidotriphosphate (*q.v.*), can be oxidized in cold aqueous solution by the action of sodium nitrite and perchloric acid.[18] Pentasilver di-imidotriphosphate is precipitated by the addition of silver ions.

It is also possible to produce a di-imidotriphosphate chain by controlled condensation of smaller molecules. Thus it has been claimed that sodium hydride, in the presence of an inert diluent, brings about condensation of diamidophosphates and monochlorophosphates[52]:



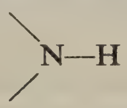
$$O{=}\overset{OR}{\underset{OR'}{P}}{-}Cl + \overset{H}{\underset{R''}{N}}{-}\overset{O}{\underset{OR'''}{P}}{-}\overset{H}{\underset{R''}{N}} + Cl{-}\overset{OR}{\underset{OR'}{P}}{=}O + 2NaH \rightarrow$$

$$O{=}\overset{OR}{\underset{OR'}{P}}{-}\underset{R''}{N}{-}\overset{O}{\underset{OR'''}{P}}{-}\underset{R''}{N}{-}\overset{OR}{\underset{OR'}{P}}{=}O + 2NaCl + H_2$$

### Physical Properties

Trisodium di-imidotriphosphate is very soluble in water, being precipitated by the addition of alcohol as microscopic granules. With slow crystallization the habit is planar, but increases in the rate of crystal growth favour the formation of acicular crystals.

The infra-red spectra of the pentasodium, monosodiumdizinc and pentathallium di-imidotriphosphates show a characteristic absorption region in the range 2900–3200 cm.$^{-1}$ which has been attributed to

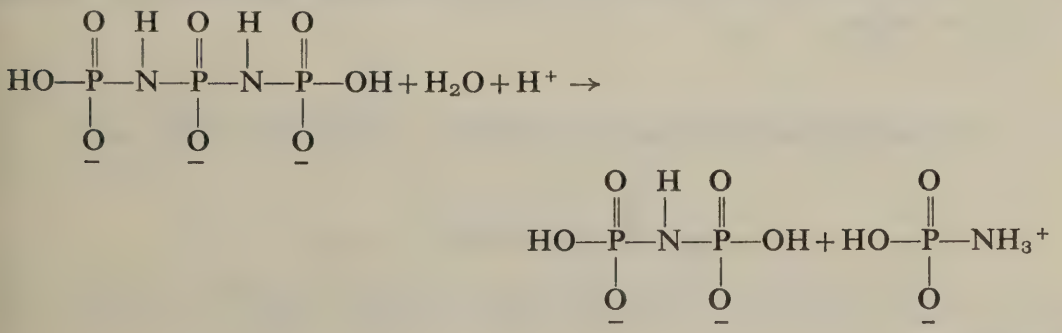


stretching.[21]

### Chemical Properties

Although di-imidotriphosphoric acid is pentabasic, only three inflexions were observed in conductivity[45,53] (see Fig. 7, page 220) and titrimetric[46] curves. The two end points corresponding to pH values 5·0 and 8·6 were very sharp, but that at approximately 10·8 was ill defined.

The appearance of di-imidotriphosphate ion, in the sequence of reactions following the hydrolysis of trimetaphosphimate, provides evidence of its stability. It rapidly decomposes to imidodiphosphate[17,46]:



$$HO{-}\overset{O}{\underset{\underline{O}}{P}}{-}\overset{H}{N}{-}\overset{O}{\underset{\underline{O}}{P}}{-}\overset{H}{N}{-}\overset{O}{\underset{\underline{O}}{P}}{-}OH + H_2O + H^+ \rightarrow$$

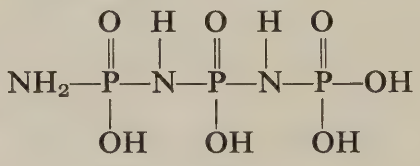
$$HO{-}\overset{O}{\underset{\underline{O}}{P}}{-}\overset{H}{N}{-}\overset{O}{\underset{\underline{O}}{P}}{-}OH + HO{-}\overset{O}{\underset{\underline{O}}{P}}{-}NH_3^+$$

although there is also a rather slower reaction resulting in the formation of imidotriphosphate. To a very limited extent cyclization may also occur. These hydrolyses are pH sensitive and tabulated below is the quarter-life at three selected pH values:

| pH value | quarter-life (min.) |
|---|---|
| 3·5 | 8 |
| 8·0 | 20–30 |
| 11·0 | $(1{\cdot}2\text{–}4) \times 10^3$ |

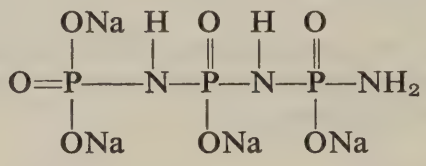
At very high pH values the di-imidotriphosphate ion is very stable and is attacked only slowly by ammonia.[48] Study of the hydrolysis products[106] by the ion exchange technique suggests that the breakdown occurs primarily by protonation of the NH group. The products of hydrolysis have been identified as monoamido, diamido, imidodi, amidodi, ortho- and pyro-phosphates. The last must have formed by condensation between amido and orthophosphates.

## AMIDODI-IMIDOTRIPHOSPHORIC ACID AND ITS SALTS



$$NH_2{-}P(=O)(OH){-}N(H){-}P(=O)(OH){-}N(H){-}P(=O)(OH){-}OH$$

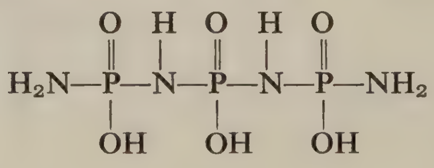
Stoke's observation (Mellor, VIII, 717) of a sodium trimetaphosphimate containing *four* sodium ions per molecule had been regarded as evidence of a linear compound, tetrasodium monoamidodi-imidotriphosphate:



$$O{=}P(ONa)(ONa){-}N(H){-}P(=O)(ONa){-}N(H){-}P(=O)(ONa){-}NH_2$$

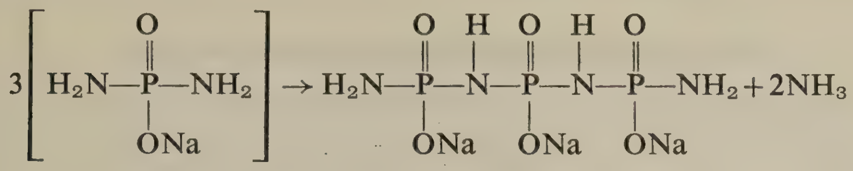
However, the ease with which the free base could be removed by the action of ethanol, and its direct titration, which indicated the presence of one mole of sodium hydroxide per formula weight, suggested the likelihood of an addition compound. By preparing the thallium analogue in the anhydrous state, to avoid masking the infra-red spectra by moisture, it was possible to show that these compounds did not have a linear structure terminating in an amido group. It seems almost certain that the sodium compound has the constitution $Na_3(PO_2NH)_3{,}NaOH{,}8H_2O$, a conclusion supported by the nuclear magnetic resonance spectrum which shows only one type of phosphorus substitution to be present.[21] Later evidence[136] claiming to support the existence of amidodi-imidotriphosphate could be interpreted in terms of the double salt above, but the question could be settled conclusively by an *X*-ray crystal structure determination.

## DIAMIDODI-IMIDOTRIPHOSPHORIC ACID AND ITS SALTS



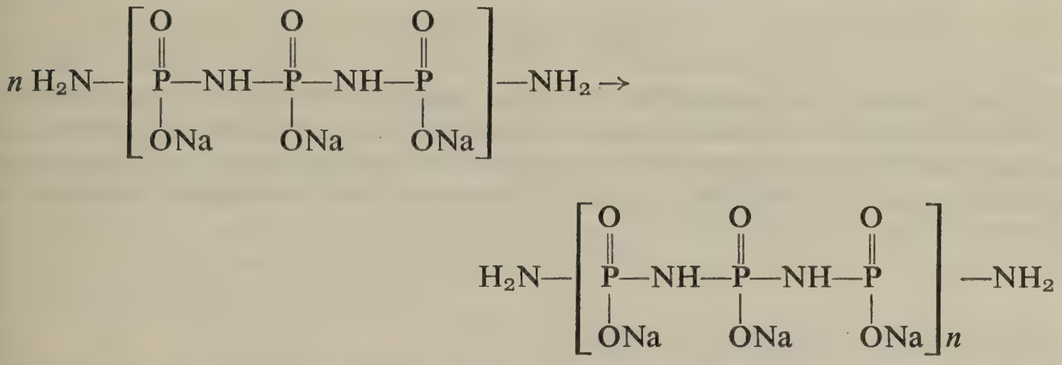
$$H_2N{-}P(=O)(OH){-}N(H){-}P(=O)(OH){-}N(H){-}P(=O)(OH){-}NH_2$$

The free acid is unknown but the trisodium salt is produced[18, 24] by heating monosodium diamidophosphate at 155–165 °C. *in vacuo*:



$$3\left[H_2N-\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}-NH_2\right] \rightarrow H_2N-\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}-\overset{\overset{H}{|}}{N}-\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}-\overset{\overset{H}{|}}{N}-\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}-NH_2+2NH_3$$

Prolonged heating causes further condensation to longer chain compounds, e.g.:

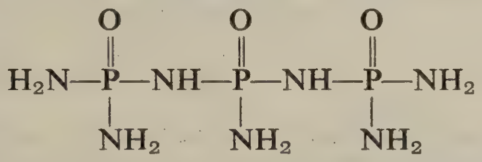


$$n\,H_2N-\left[\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}-NH-\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}-NH-\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}\right]-NH_2 \rightarrow$$

$$H_2N-\left[\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}-NH-\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}-NH-\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}\right]_n-NH_2$$

The action of aqueous sodium nitrite and perchloric acid in removing amido groups, provides a convenient method of preparing a di-imidotriphosphate (*q.v.*).

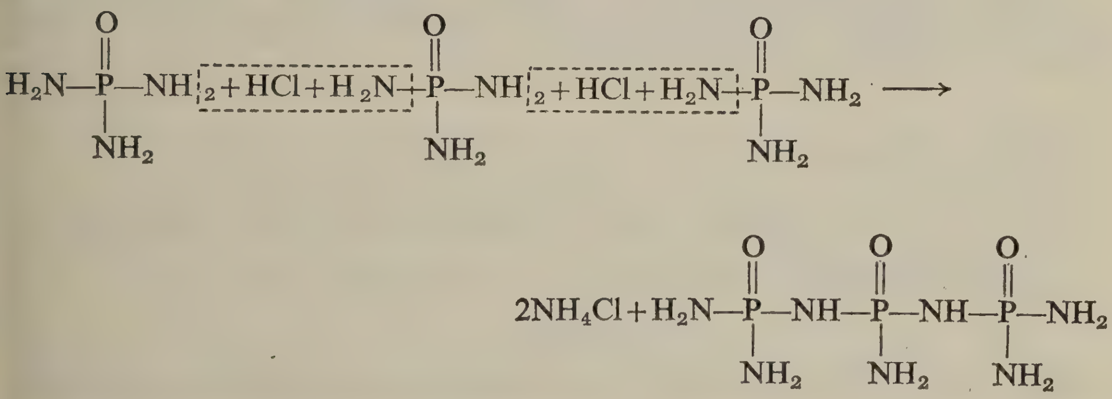
## DI-IMIDOTRIPHOSPHORIC PENTAMIDE



$$H_2N-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH_2$$

### Preparation

Di-imidotriphosphoric pentamide is conveniently prepared by deamination. A suspension of phosphoryl triamide in diethyl ether is treated with dry hydrogen chloride at 28°–30°C. for 4 hr.



$$H_2N-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH\boxed{{}_2+HCl+H_2N}-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH\boxed{{}_2+HCl+H_2N}-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH_2 \longrightarrow$$

$$2NH_4Cl+H_2N-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH_2$$

An 86% yield has been claimed.[35]

To remove traces of ammonium chloride the reaction product is leached with liquid ammonia.

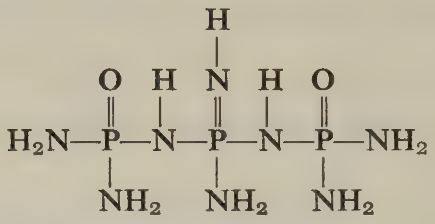
### Properties

Di-imidotriphosphoric pentamide forms white crystals easily soluble in water. When heated the crystals begin to decompose, without melting, at 75°C., losing

**Refs. p. 813**

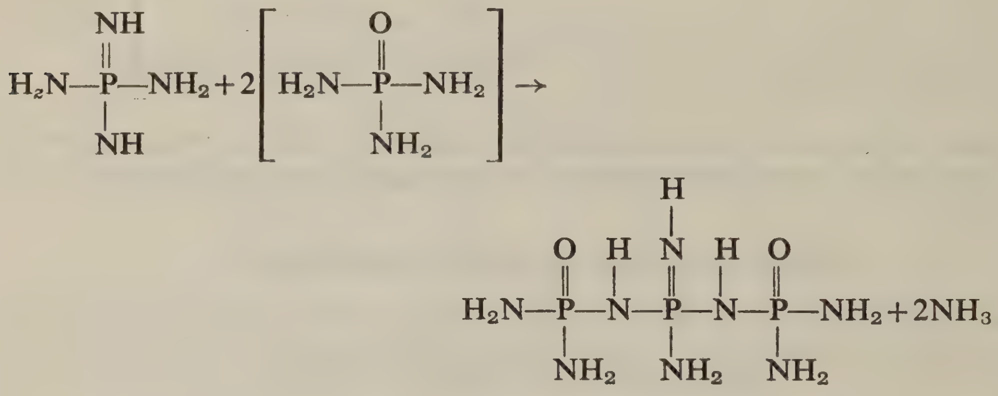
ammonia. The action of sodium hydroxide also brings about the evolution of ammonia, one mole of pentamide yielding 3 moles of ammonia.

## TRI-IMIDOTRIPHOSPHORIC PENTAMIDE



$$H_2N-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-\overset{\overset{H}{|}}{N}-\underset{\underset{NH_2}{|}}{\overset{\overset{\overset{H}{|}}{N}}{\overset{\|}{P}}}-\overset{\overset{H}{|}}{N}-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH_2$$

Various products are obtainable from the reaction between phosphorus pentachloride and ammonia depending upon the temperature and physical state of the reactants, etc.[33, 54-6] (see page 773). Phosphorimidyl triamide (*q.v.*), which has been suggested as an intermediate, is said to condense with phosphoryl triamide as follows:

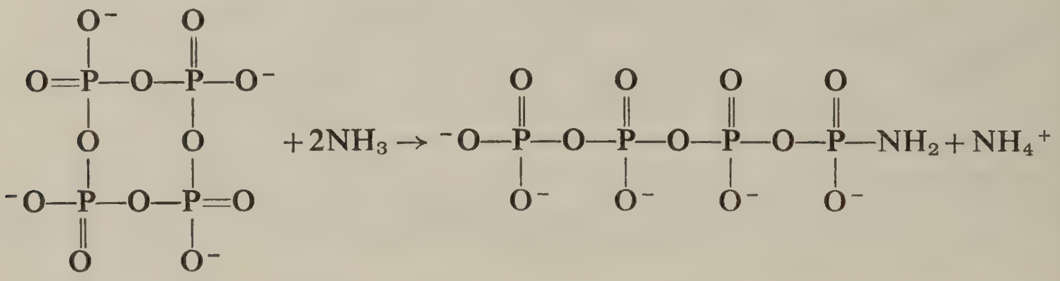


$$H_2N-\underset{\underset{NH}{|}}{\overset{\overset{NH}{\|}}{P}}-NH_2+2\left[H_2N-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH_2\right]\rightarrow H_2N-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-\overset{\overset{H}{|}}{N}-\underset{\underset{NH_2}{|}}{\overset{\overset{\overset{H}{|}}{N}}{\overset{\|}{P}}}-\overset{\overset{H}{|}}{N}-\underset{\underset{NH_2}{|}}{\overset{\overset{O}{\|}}{P}}-NH_2+2NH_3$$

The isolation of tri-imidotriphosphoric pentamide has been reported,[33] the average yield being about 50%. The analysis agreed very well with the calculated composition, but no other information has been published.

## MONOAMIDOTETRAPHOSPHORIC ACID AND ITS SALTS

Concentrated ammonia severs the tetrametaphosphate ring[105] giving rise to amidotetrametaphosphates, the barium salt of which, $[Ba_5(P_4O_{12}NH_2)_2,5H_2O]$, has been isolated. The equation for the reaction is:



Further attack by ammonia results in the production of ammonium triphosphate:

$$P_4O_{12}NH_2^{5-}+2NH_3 \rightarrow P_3O_{10}^{5-}+PO_2(NH_2)_2^{-}+NH_4^{+}$$

## POLYAMIDOPOLYIMIDOPOLYPHOSPHORIC ACIDS AND THEIR SALTS

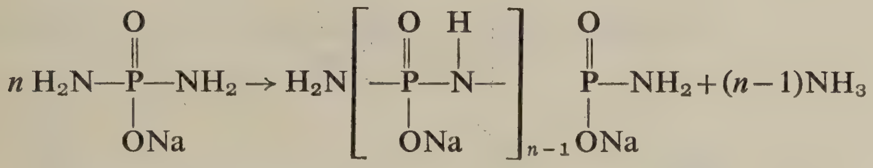
As the chain length of this type of compound increases, the ease with which particular molecules or ions can be separated from each other decreases. Hence, it is convenient to consider under one heading all those acids and salts containing four or more phosphorus atoms, linked in straight or branched chains.

### Formation and Preparation

In general, these compounds are prepared by condensing together smaller molecules containing amido groups, although frequently it is easier to arrange for this condensation, and ammonolysis of halides, oxides, etc., to occur simultaneously. Nevertheless, there are one or two modes of formation which do not fit into this pattern.

One possible method involves the hydrolytic fission of metaphosphimate rings,[58] when chain imidophosphates may be formed momentarily. Another method claims that the treatment of condensed phosphates with ammonia, under high temperature and pressure, gives rise to polyamidopolyimidopolyphosphates.[59] The proportion of amide/imide nitrogen in a given product may be increased by the incorporation of up to 20% by weight of ammonium salts in the reaction mixture, any excess of ammonium salts in the product being removed by leaching with liquid ammonia. Sodium polyphosphates are normally used as starting materials, but potassium and ammonium salts are also suitable.

The most straightforward method of preparing polyamidopolyimidopolyphosphates is to heat the appropriate amidophosphate, preferably *in vacuo* to aid elimination of ammonia. Thus if sodium diamidophosphate is heated *in vacuo* at temperatures between 165° and 200°C., a mixture of diamidopolyimidopolyphosphates is obtained[24]:



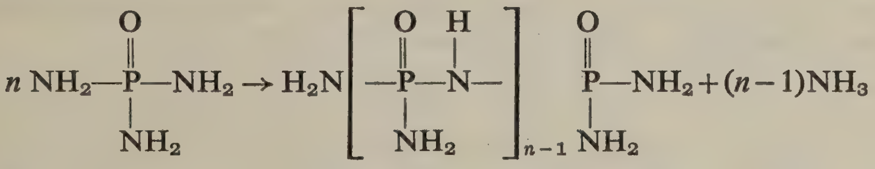
$$n\,H_2N-\underset{ONa}{\overset{O}{\overset{\|}{P}}}-NH_2 \rightarrow H_2N\left[-\underset{ONa}{\overset{O}{\overset{\|}{P}}}-\overset{H}{\overset{|}{N}}-\right]_{n-1}\underset{ONa}{\overset{O}{\overset{\|}{P}}}-NH_2+(n-1)NH_3$$

where $n$ varies between 3 and 6. The degree of condensation seems to depend upon the temperature of reaction, since at a temperature of 230°C. *in vacuo*, chains of approximately 18 phosphate tetrahedra result.[18,24] The molecular weight of these polymeric species has been established in the following way.

The silver salt which is precipitated from an aqueous solution of the sodium compound reacts with ethyl iodide to give a partial yield of the di-ethyl derivative, $NH_2[PO(OEt)N(Et)]_nPO(OEt)NH_2$, in which both imidohydrogen and metal are replaced by ethyl radicals. It is then possible to determine the molecular weight of the ethyl polyethylimidopolyphosphate and hence of the polymeric ion from which it was derived.

By employing an ion exchange resin in the fluoride form[106] the components of the condensation reaction may be separated. Precipitation of the silver salts from the appropriate eluant fraction has led to the isolation of silver diamidoimidodiphosphate, $Ag_2P_2O_4.NH(NH_2)_2$; trisilver diamidoimidodiphosphate, $Ag_2P_2O_4.NAg(NH_2)_2$; silver diamidodi-imidotriphosphate, $Ag_3P_3O_6(NH)_2(NH_2)_2$; pentasilver diamidodi-imidotriphosphate, $Ag_3P_3O_6(NAg)_2(NH_2)_2$, and silver diamidotri-imidotetra-phosphate, $Ag_4P_4O_8(NH)_3(NH_2)_2$.

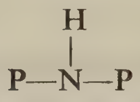
Phosphoryl triamide is readily condensed by boiling its solution in an organic solvent, such as benzene or toluene[19-20]:



$$n\,NH_2-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}-NH_2 \rightarrow H_2N\left[-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}-\overset{H}{\overset{|}{N}}-\right]_{n-1}\underset{NH_2}{\overset{O}{\overset{\|}{P}}}-NH_2+(n-1)NH_3$$

when polyimidopolyphosphoryl polyamides of chain lengths up to 5 are produced.

This type of reaction is also useful if the diamido-derivative contains an organic radical, since stable non-flammable resins are produced[60-4] containing long



$$\overset{\displaystyle H}{\underset{}{\text{P—}\overset{|}{\text{N}}\text{—P}}}$$

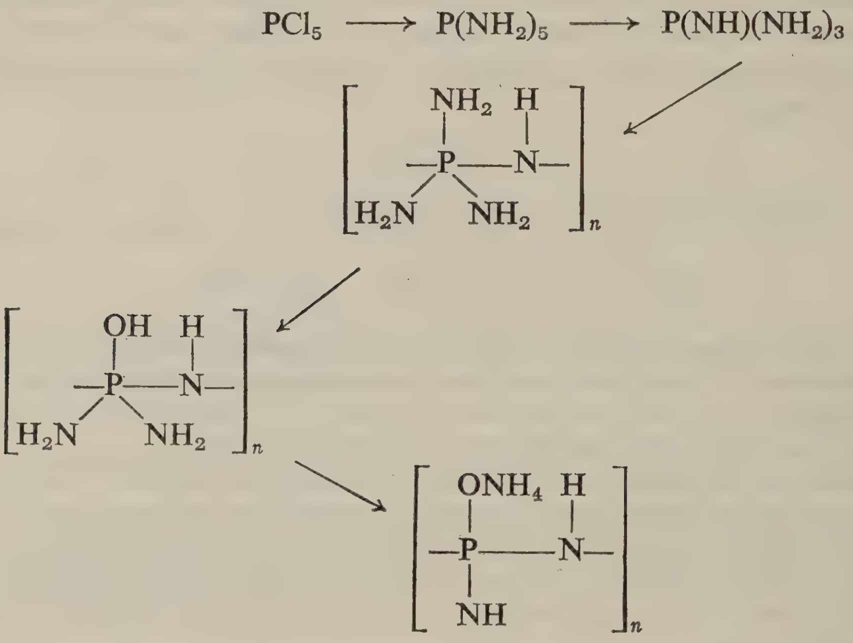
chains. The use of starting materials containing substituted amido groups is also claimed, giving rise to the corresponding substituted imido-polymers.

Often the deamination is encouraged by the presence of a suitable reagent to remove the ammonia. Phosphoryl triamide can be condensed into long chains by treating its suspension in an inert medium with dry hydrogen chloride.[19,34] The chain length seems to depend on the concentration of the hydrogen chloride and the reaction temperature.

Polyamidoimidopolyphosphates do not normally result from the ammonolysis of simple chlorides of phosphorus unless at some stage hydrolysis is allowed to take place.[55] In general polyamides are produced:

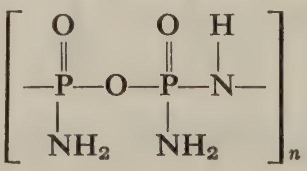
$$PCl_n + 2n\ NH_3 \rightarrow PCl_n{,}2n\ NH_3$$
$$PCl_n{,}2n\ NH_3 \rightarrow P(NH_2)_n + n\ NH_4Cl$$

However, in the presence of a trace of moisture the following reaction sequence has been reported[33]:



Treatment of phosphoryl chloride or its homologues with ammonia has frequently been described.[25,38,43,65-6] In the complete absence of moisture a product of empirical formula $POCl_3{,}6NH_3$ was obtained[55] which could not be rendered free from chlorine by treatment with liquid ammonia. Under similar conditions other workers claimed the formation of a water-insoluble chlorine-free product.[38] If this reaction is carried out in an inert liquid, polymeric products of molecular weights in the range of 180 to 300, and N:P ratios between 2·1 and 2·3 to 1 result. This reaction is general and may be utilized for the preparation of substituted polymers, by using organic amines as alternatives to ammonia.[65]

Provided that the addition of pyrophosphoryl chloride to liquid ammonia is carried out as rapidly as possible, a polymer $(P_2O_3N_3H_5)_x$, i.e.:



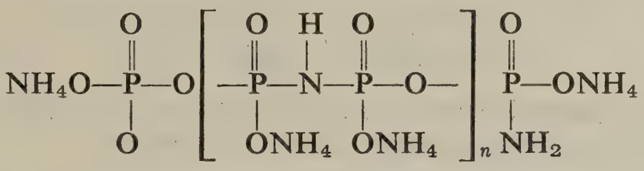
$$\left[ -\underset{\underset{\displaystyle NH_2}{|}}{\overset{\overset{\displaystyle O}{\|}}{P}}-O-\underset{\underset{\displaystyle NH_2}{|}}{\overset{\overset{\displaystyle O}{\|}}{P}}-\overset{\overset{\displaystyle H}{|}}{N}- \right]_n$$

is obtained,[25, 43, 133] which can be washed free from chloride ion by ice-cold water. Prolonged treatment with ammonia tends to bring about depolymerization to yield very short chain compounds.[25]

The most widely applied methods of preparing polyamidopolyimidopolyphosphates involve the ammonolysis of oxides of phosphorus, frequently prepared *in situ*, under conditions which favour simultaneous deamination. As in the halide ammonolyses (mentioned above) the presence of moisture seems necessary. Although very dry ammonia has been kept for several years over phosphorus pentoxide with no apparent evidence of reaction,[7] it has been reported[9] that even under such dry conditions reaction does take place and is not confined to the solid surfaces.[8]

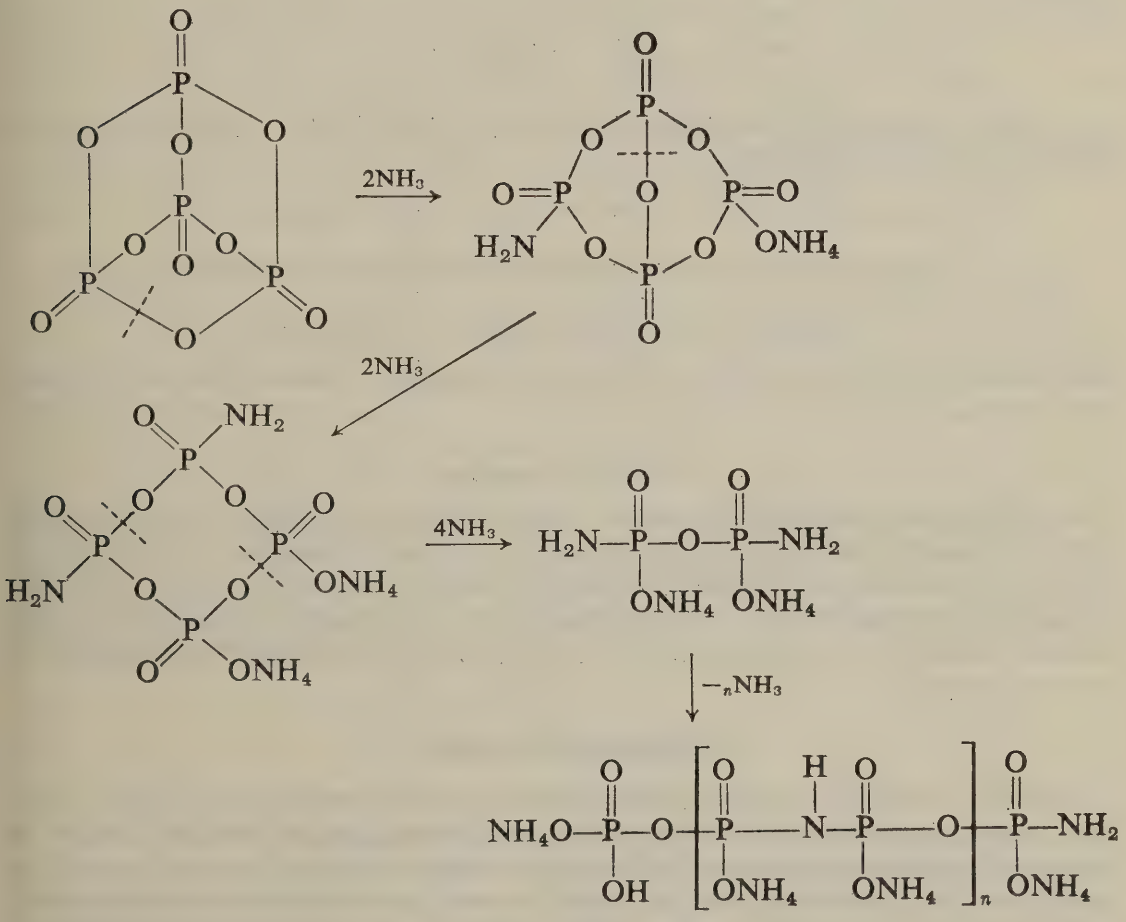
The physical states of the reagents may vary widely. Thus liquid, gaseous, and aqueous ammonia together with solid and gaseous phosphorus pentoxide have been employed.[67, 107] It has also been claimed[68] that ammonium salts such as bicarbonate, acetate or chloride, may be substituted for ammonia, provided the mole ratio $NH_3:P_2O_5$ lies in the range 1·4–2·5:1.

By stirring excess of liquid ammonia with phosphorus oxide in an autoclave for 24 hr. at 40°–50°C., a glassy grey solid is obtained.[10] When this is heated at 100°–110°C. ammonia is evolved, yielding a hygroscopic amorphous grey solid believed to be an ammonium amidopolyimidopolyphosphate, i.e.:



$$NH_4O\text{—}\underset{O}{\underset{|}{\overset{O}{\overset{\|}{P}}}}\text{—}O\left[\text{—}\underset{ONH_4}{\underset{|}{\overset{O}{\overset{\|}{P}}}}\text{—}\overset{H}{\overset{|}{N}}\text{—}\underset{ONH_4}{\underset{|}{\overset{O}{\overset{\|}{P}}}}\text{—}O\text{—}\right]_n\underset{NH_2}{\underset{|}{\overset{O}{\overset{\|}{P}}}}\text{—}ONH_4$$

where *n* is four. The following mechanism has been suggested:



The composition of the ammonium salt is expressed by the ratios:

$$P:N_{total}:N_{ammoniacal} = 1:1{\cdot}5:1$$

In a similar experiment the products fused at 180°–220°C. and a glassy condensed product was formed above 400°C. under pressure from 12 to 50 kg./cm.$^2$; 25% of the nitrogen was not in the ammoniacal form.

In the reaction[107] between phosphorus pentoxide and aqueous ammonia, ammonia losses are counteracted by passing gaseous ammonia into the reaction mixture. The reaction may be carried out by suspending the phosphorus pentoxide in a non-aqueous solvent immiscible with water.[69] In general, mixtures of polyamidopolyimidopolyphosphates are produced which may be obtained as solids by evaporating the solutions under vacuum, by precipitation using non-aqueous solvents, or by spray drying.

Various authorities[70-2, 108] claim that it is advantageous to prepare phosphorus pentoxide *in situ* by burning phosphorus, largely because the gaseous material is then available at a conveniently high temperature. The significant variables for the vapour phase reaction appear to be the $NH_3/H_2O/P_2O_5$ ratio, the temperature of the phosphorus pentoxide vapour and the time interval between mixing the vapours and quenching the product.[67] The preferred ratios are as follows:

| | |
|---|---|
| $NH_3/P_2O_5$ | $0{\cdot}8 \sim 3{\cdot}0$ |
| $H_2O/NH_3$ | $0{\cdot}0 - 2{\cdot}0$ |

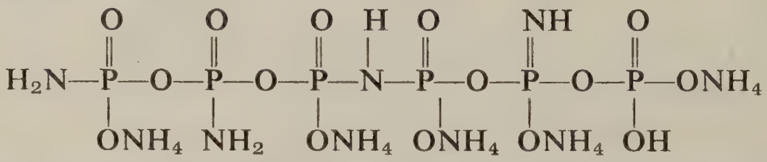
when compounds of general formula $(N'_wH_x)P_nO_yN_z$ result; N′ refers to the ammoniacal nitrogen only. The overall equation may be expressed:

$$(w+z)NH_3 + \frac{n}{2}P_2O_5 + \left(y-\frac{5n}{2}\right)H_2O \rightarrow N'_wH(3w+3z+2y-5n)P_nO_yN_z$$

where

$$y \geqslant \frac{5n}{2}, \qquad \frac{y+z}{n} \geqslant 4$$

A typical compound of empirical composition $9NH_3,3P_2O_5$ may thus have the following possible constitution:



$$H_2N{-}\underset{ONH_4}{\overset{O}{P}}{-}O{-}\underset{NH_2}{\overset{O}{P}}{-}O{-}\underset{ONH_4}{\overset{O}{P}}{-}\overset{H}{N}{-}\underset{ONH_4}{\overset{O}{P}}{-}O{-}\underset{ONH_4}{\overset{NH}{P}}{-}O{-}\underset{OH}{\overset{O}{P}}{-}ONH_4$$

assuming that no rings or P–P bonds and only quadruply linked phosphorus atoms are present.

## Physical Properties

Polyamidopolyimidopolyphosphoric acids and their ammonium and alkali metal salts are usually amorphous greyish-white powders. Although many are very hygroscopic and readily dissolve in water to produce viscous solutions, most of them contain a significant fraction which is insoluble or only slowly soluble in water. The solubility seems to be inversely proportional to the temperature of formation of a given polymer.

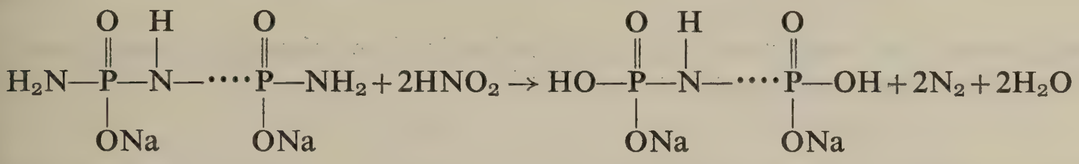
## Chemical Properties

Since the principal preparative technique consists in deaminating smaller molecules, there is a tendency for further elimination of ammonia to take place when the long-chain products themselves are heated *in vacuo* or treated chemically with reagents such as hydrogen chloride. In such a way, polyimidopolyphosphorylpolyamides, $P_nO_n(NH)_{n-1}(NH_2)_{n+2}$, eventually lose all their hydrogen to yield $(PON)_x$.[19]

If, however, these polymers are heated in moist air, they lose all their nitrogen and eventually become polyphosphates,[20] e.g.:

$$Na_nP_nO_{2n}(NH)_{n-1}(NH_2)_2 + n\,H_2O \rightarrow \underset{\text{Graham's salt}}{(NaPO_3)_n} + (n+1)NH_3$$

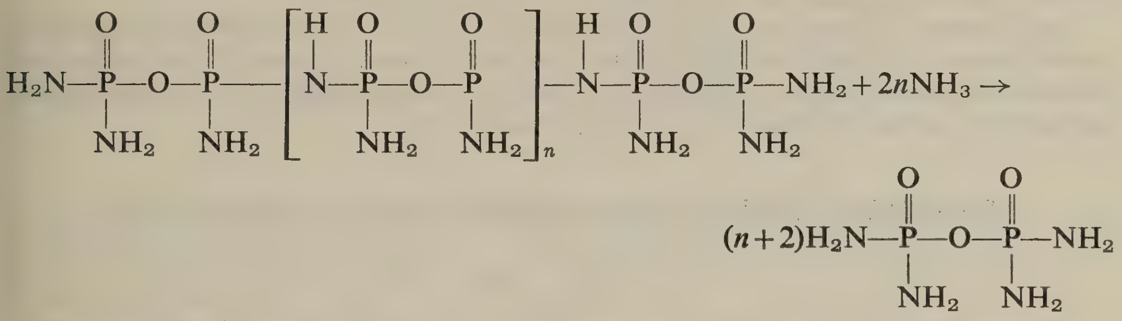
Amido groups, attached to long chains containing phosphorus, oxygen and nitrogen atoms, are selectively removed by treatment with freshly prepared nitrous acid[24]:



$$H_2N-\underset{ONa}{\overset{O}{\overset{\|}{P}}}-\overset{H}{N}-\cdots\underset{ONa}{\overset{O}{\overset{\|}{P}}}-NH_2 + 2HNO_2 \rightarrow HO-\underset{ONa}{\overset{O}{\overset{\|}{P}}}-\overset{H}{N}-\cdots\underset{ONa}{\overset{O}{\overset{\|}{P}}}-OH + 2N_2 + 2H_2O$$

whilst any acid groupings remaining are readily neutralized by treatment with gaseous ammonia[67] in a straightforward acid-base reaction.

To a limited extent deamination is a reversible process, since the solid polymer obtained by rapid addition of ammonia to pyrophosphoryl tetrachloride can be depolymerized by leaching it with liquid ammonia[25]:



$$H_2N-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}-O-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}-\left[\overset{H}{N}-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}-O-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}\right]_n-\overset{H}{N}-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}-O-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}-NH_2 + 2nNH_3 \rightarrow (n+2)H_2N-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}-O-\underset{NH_2}{\overset{O}{\overset{\|}{P}}}-NH_2$$

Because of their similarity to polyphosphates, polyamidopolyimidopolyphosphates have found application as additives to rinsing agents and detergents,[59] as water softeners, particularly in the pH range 7–9[68], and as anticorrosion agents.

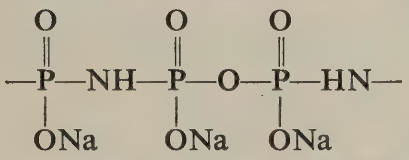
Many of these compounds, particularly the organo-substituted polymers,[60-5] are resins which are suitable for use as flameproofing materials.[37, 109-15]

Several polyamidopolyimidopolyphosphates coagulate albumen[68] and a few have been used as fertilizers,[67, 70-1] although their agronomic value is said to have been improved by hydrolyzing the products to ammonium polyphosphates.[73]

## POLYIMIDOPOLYOXOPHOSPHORIC ACIDS AND THEIR SALTS

If trisodium trimetaphosphimate tetrahydrate is slowly heated to 200°C. in a stream of moist air it decomposes to ammonia, sodium polyphosphates and sodium trimetaphosphate. However, rapid heating yields in addition an insoluble nitrogen-containing residue. This swells in water to a gelatinous mass, which on treatment with ethanol or methanol yields a white amorphous solid.

The N:P molar ratio of this material varies between 0·33:1 and 0·5:1, and with other analytical data suggests formulae between $[(NaPO_3)_2.NaPO_2NH]_n$ and $[(NaPO_3).(NaPO_2NH)]_n$. Similar bodies can be made by thermal condensation at 300°–350°C. of mixtures of sodium dihydrogen phosphate with sodium and ammonium imidodiphosphates. It therefore seems probable that such materials are polymeric sodium imido-oxypolyphosphates containing chains of the type:

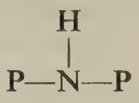


$$-\underset{ONa}{\overset{O}{\overset{\|}{P}}}-NH-\underset{ONa}{\overset{O}{\overset{\|}{P}}}-O-\underset{ONa}{\overset{O}{\overset{\|}{P}}}-HN-$$

In water they slowly hydrolyze to trimetaphosphate, di-imidotrimetaphosphate, and imidotrimetaphosphate, with smaller amounts of mono- and diamidophosphate. When heated in moist air they evolve ammonia, the final product being sodium trimetaphosphate.[137]

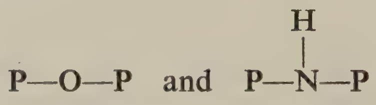
## THE CYCLIC NITROGEN-SUBSTITUTED OXYACIDS OF PHOSPHORUS

This classification is not confined to the metaphosphimic acids since this term usually refers to acids containing



$$P{-}\overset{\displaystyle H}{\overset{|}{N}}{-}P$$

bridges only. It also includes acids such as imidotrimetaphosphoric and di-imidotrimetaphosphoric acids which contain both



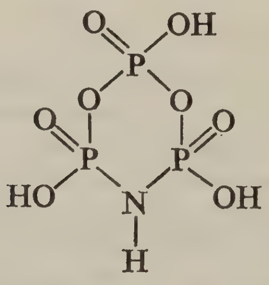
$$P{-}O{-}P \quad \text{and} \quad P{-}\overset{\displaystyle H}{\overset{|}{N}}{-}P$$

bridges.

Previous reports (Mellor, VIII, 716) suggest the possibility of dimetaphosphimic acids, but no evidence for four-membered ring acids has been obtained and the six-membered ring is most likely the first member of each series.

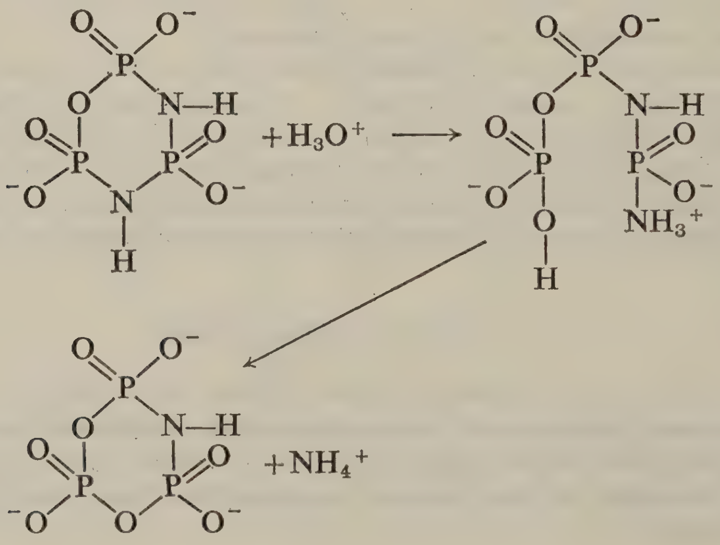
For a general discussion of the properties of cyclic P–N compounds, reference should be made to Section XVIII of this volume. However, most of the compounds considered here do not exhibit many features characteristic of phosphonitrilic derivatives, as they normally contain imido-nitrogen.

## MONOIMIDOTRIMETAPHOSPHORIC ACID AND ITS SALTS

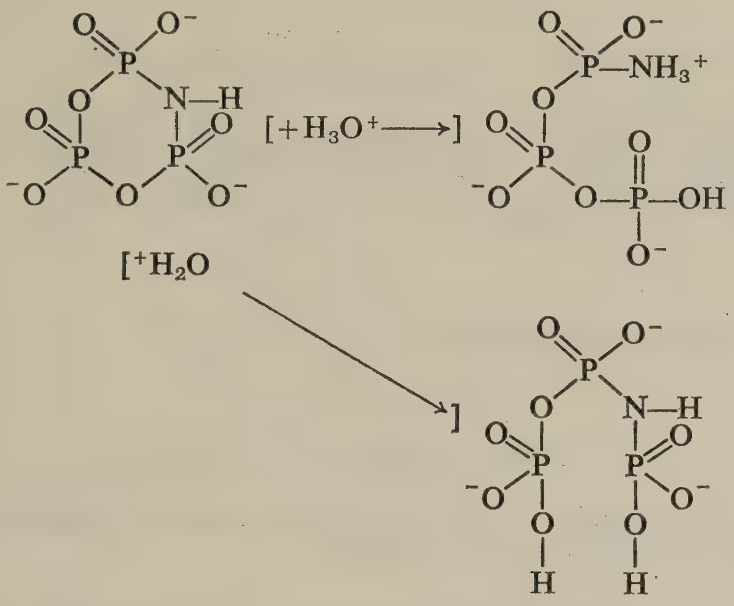


The monoimidotrimetaphosphate ion appears in the sequence of compounds arising from the hydrolysis of trimetaphosphimate.

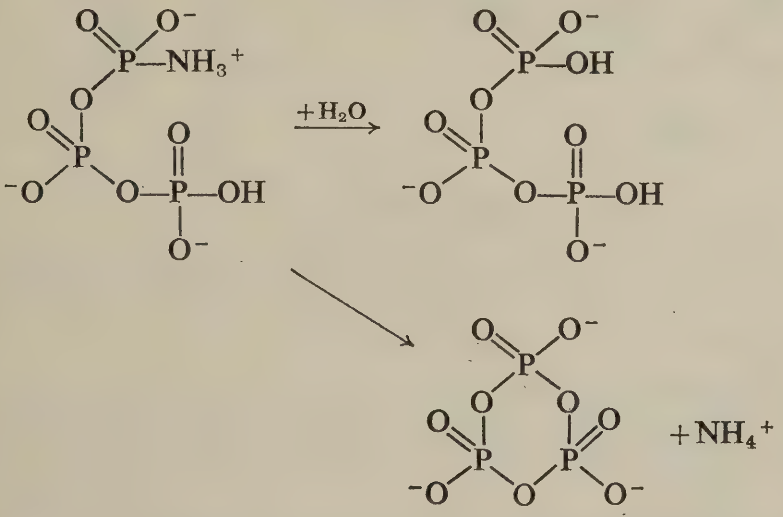
The mechanism is discussed under the chemical properties of trimetaphosphimic acid. Thus, di-imidotrimetaphosphate gives rise to monoimidotrimetaphosphate as indicated below[17,46]:



The process does not cease at this point but continues by stages to yield trimetaphosphate, imidotriphosphate or triphosphate as the pH and the rates of the respective reactions vary. The ring tends to break at one of two possible points depending on the pH, i.e.:

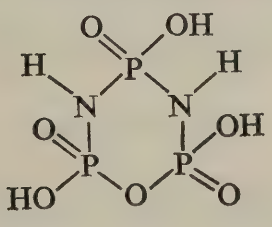


forming either amidotriphosphate or imidotriphosphate respectively. The amidotriphosphate may either decompose to triphosphate or, possibly, recyclize to yield trimetaphosphate[48, 105, 135]:



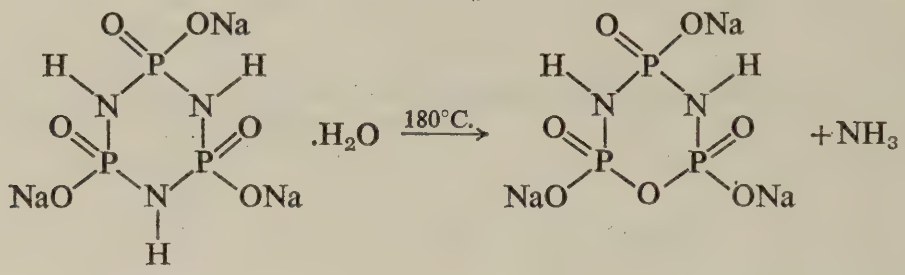
Quarter-life of $1{\cdot}4 \times 10^3$ and 9 to $12 \times 10^3$ min. has been measured[17] at pH 3·5 and 8·0 respectively. It will be noticed that the high pH is associated with a longer quarter-life, which is in harmony with the observation that concentrated aqueous ammonia attacks the imidotrimetaphosphate ring only slowly.[48]

## DI-IMIDOTRIMETAPHOSPHORIC ACID AND ITS SALTS

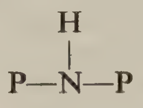


### Formation and Preparation

The formation of sodium di-imidotrimetaphosphate was suggested to account for the loss of ammonia observed when attempts were made to dehydrate sodium trimetaphosphimate monohydrate[74]:

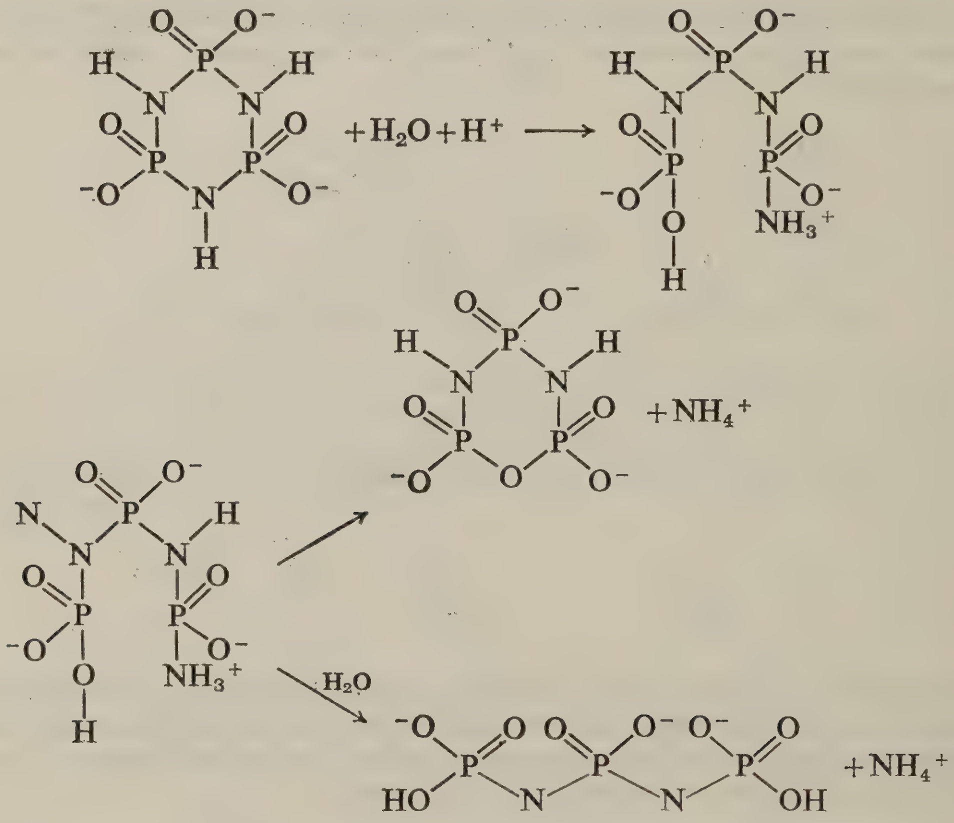


In solution, similar replacement of



$P{-}\overset{\overset{H}{|}}{N}{-}P$ bridges by P—O—P

takes place. The mechanism, which is discussed under the chemical properties of trimetaphosphimic acid, proceeds as follows:



The chain phosphates and imidophosphates are removed, precipitating the silver salt of the metaphosphimic acid and finally exchanging this salt with sodium chloride. The product was identical with that prepared by the method of de Fiquelmont.[45]

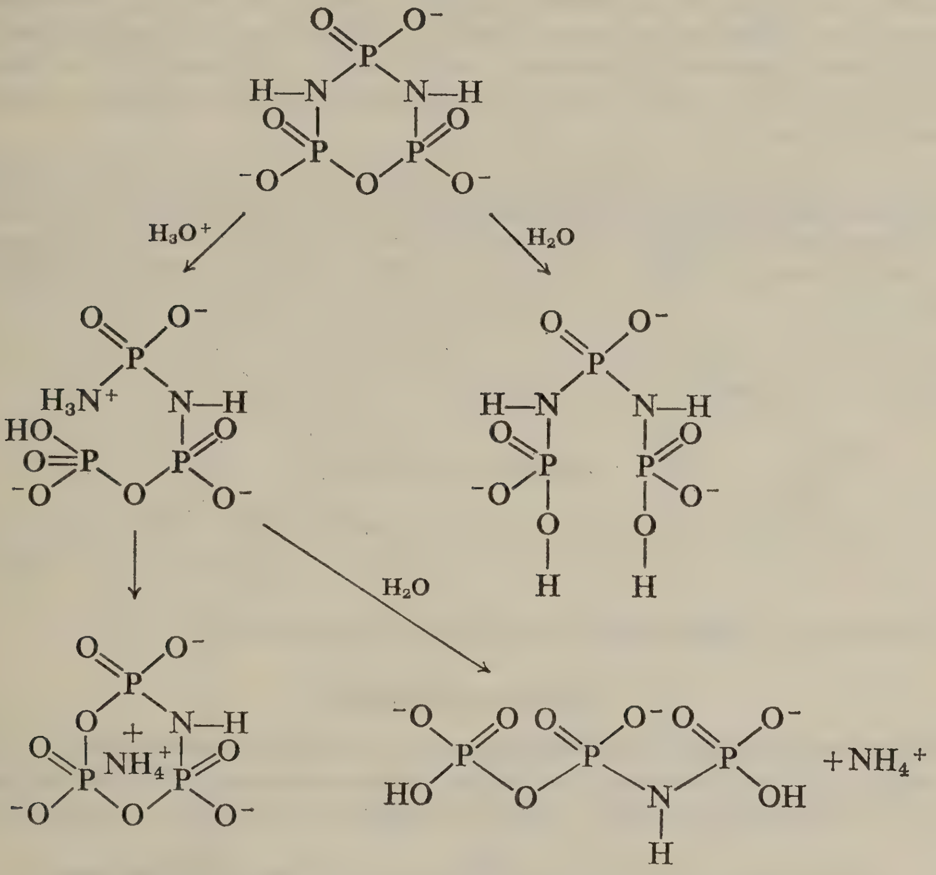
### Physical Properties

*X*-Ray powder diffraction photographs of the sodium salt were not particularly helpful,[74] since the lines were very weak, indicating largely amorphous character.

However, it has been possible to examine the infra-red spectra of the potassium, silver and thallium salts, including an addition compound of thallium di-imidotrimetaphosphate and thallium hydroxide. In all cases there was strong absorption in the 2900–3200 cm.$^{-1}$ region corresponding to >N–H stretching.

### Chemical Properties

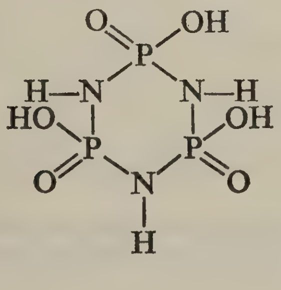
The di-imidotrimetaphosphate ion continues to hydrolyze following the same sort of mechanism by which it was produced, giving rise to imidotrimetaphosphate and to a lesser extent di-imidotriphosphate and imidotriphosphate,[46] as shown below[17]:



The quarter-life is as follows: at pH 3·5, 170 min., and at pH 8·0, 3–9 × $10^4$ min. Consequently at high pH values little hydrolysis may be expected to occur. In fact concentrated aqueous ammonia does not appear to attack the di-imidotrimetaphosphate ion at all.[48]

If sodium di-imidotrimetaphosphate is heated at 270°C. for some considerable time it eventually loses all its nitrogen and becomes anhydrous sodium trimetaphosphate.[74]

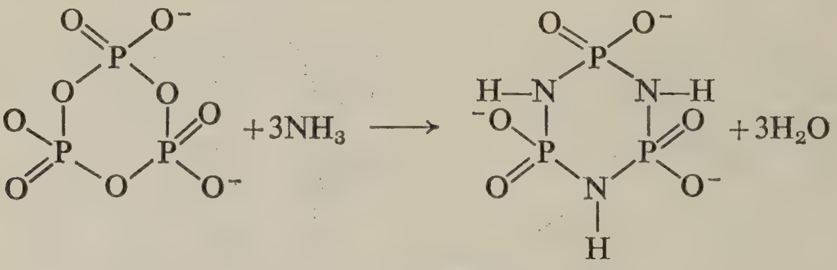
## TRIMETAPHOSPHIMIC ACID AND ITS SALTS



### Formation and Preparation

It is probably most convenient to prepare the trimetaphosphimate ion by hydrolyzing the corresponding phosphonitrilic chloride (Mellor, VIII, 717). Very slight deviations from the original experimental technique[45, 74, 138–9] have proved satisfactory. The hydrolysis of the phosphonitrilic trimer[116] has been studied under neutral conditions and the order in which the chlorine atoms are replaced by hydroxyl groups postulated. However, it is also possible to obtain the trimetaphosphimate ion from higher polymetaphosphimates.[58] Apart from the tetrametaphosphimate, which is rather stable at a pH of 3·6, all the polymetaphosphimates so far investigated appear to decompose, yielding trimetaphosphimate and orthophosphate at the first stage (for a discussion of the probable mechanism see page 810). Anhydrous trimetaphosphimic acid can be obtained from the potassium salt by treatment with perchloric acid, followed by evaporation of the solution at a temperature below 35°C. It forms needle-like crystals, m.p. 150°C. (decomp.). The dihydrate, $H_3[P_3O_6(NH)_3].2H_2O$, m.p. 110°C., is precipitated from aqueous solution by methanolic hexane.[139]

It has been claimed that P–O–P bridges may be replaced by $\mathrm{P{-}\overset{H}{\overset{|}{N}}{-}P}$ bridges by reacting a condensed phosphate with ammonia at elevated temperatures and pressures.[59] Thus the trimetaphosphate ion would yield trimetaphosphimate under these conditions,



but no evidence of this particular reaction has been published.

### Physical Properties

The infra-red spectra of the acid and several salts have been examined[21, 75] including a sample of the anhydrous tripotassium salt containing some deuterated material, i.e. $K_3(PO_2ND)_3$. The principal absorption regions are presented in Table XII.

*Table XII.—The Infra-red Absorption of Trimetaphosphimates*

| Frequency (cm.$^{-1}$) | Assignment |
|---|---|
| 3200–2900* | $>$N–H stretching |
| 1400–1220 | $\mathrm{P{-}\overset{H}{\overset{|}{N}}{-}P}$ group |
| 1300–1200<br>900–850 | $-\mathrm{P}\genfrac{}{}{0pt}{}{\diagup\!\!\diagup \mathrm{O}}{\diagdown \mathrm{O}^{(-)}}$ group |

* $>$N–D stretching occurs in the vicinity of 2390 cm.$^{-1}$

The Raman spectra of trimetaphosphimates have not been studied in detail. However, comparison of the spectra of sodium trimetaphosphimate and the trimetaphosphates of potassium and sodium (see Table XIII), shows that there are differences in frequency of between 50 and 100 cm.$^{-1}$ This has been attributed to the weaker P–N–P bonding compared with P–O–P bonding.[76]

*Table XIII.—Raman Spectra of Trimetaphosphimates and Trimetaphosphates*

| Potassium trimetaphosphate | Sodium trimetaphosphate | Sodium trimetaphosphimate |
|---|---|---|
| 651 | 634 (and 665) | 529 |
| 1111 | 1119 | 1014 |
| 1161 | 1158 | 1109 |
| 1244 | 1243 | 1164 |

The nuclear magnetic resonance spectrum of an aqueous solution of trisodium trimetaphosphimate has been examined in a magnetic field of 7140 gauss.[23] A chemical shift of +1 (±2) p.p.m. of the applied field with respect to 85% phosphoric acid was observed.

An *X*-ray study of trisodium trimetaphosphimate tetrahydrate, $Na_3(NHPO_2)_3$, $4H_2O$, shows that it crystallizes in space group $P2_1/n$ with $Z=4$, $a=16{\cdot}976$; $b=7{\cdot}834$; $c=8{\cdot}918$ A.; $\beta=97{\cdot}08°$. The cyclic anions have a chair shape, and the hydrogen atoms are predominantly linked to nitrogen atoms, as the chemistry would suggest.[140]

## Chemical Properties

Curves obtained by plotting the specific conductivity of the acid against the number of moles of added base (see Fig. 7)

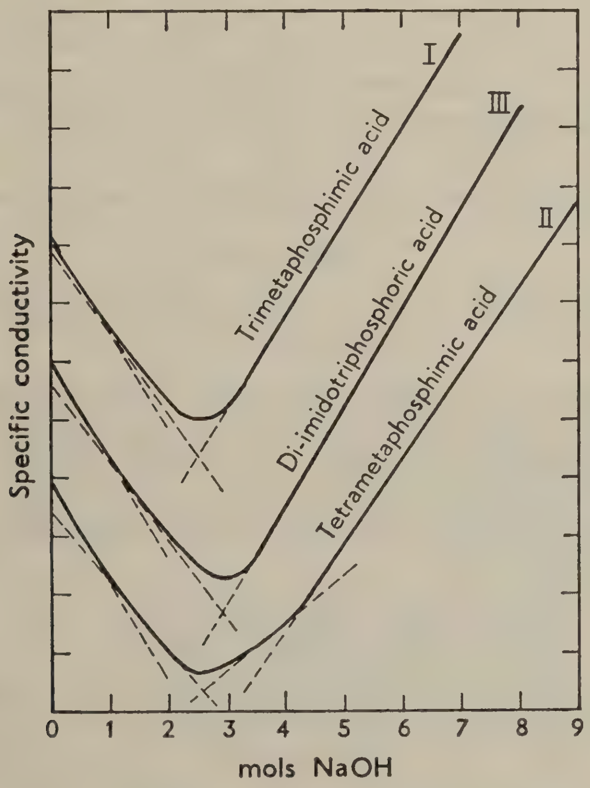


FIG. 7.—Variation in specific conductivity of dilute aqueous solutions of metaphosphimic acids and di-imidotriphosphoric acid during their neutralization with sodium hydroxide

show three inflexions, indicative of three distinct acid functions, the third of which is more feeble than the other two. Doubt is expressed on the identity[53] of the compound hexasilver trimetaphosphimate, $Ag_6P_3N_3O_6$, previously reported by Stokes (Mellor, VIII, 717).

The hydrolytic decomposition of the trimetaphosphimates is pH dependent.[17, 58] The quarter-life has been computed for a series of pH values (see Table XIV).

*Table XIV.—The Quarter-Life of Trimetaphosphate at Various pH Values*

| pH | Quarter-life (min.) |
|---|---|
| 1·0 | 8 |
| 3·5 | 25 |
| 8·0 | $1–2 \times 10^5$ |
| 11·0 | $>2 \times 10^5$ |

The hydrolysis of trimetaphosphimates at 60°C. under mildly acid conditions is considered by Quimby *et al.*[17] to take place as shown on p. 222.

This work was extended by later workers[116-8] using ion exchange and paper chromatographic techniques. Acid hydrolysis of trimeric ring imidophosphates in unbuffered solutions showed a rise in pH with time, Fig. 8, due to the liberation of ammonia and simultaneous formation of other anionic species as shown in the scheme above. These species may be formed by two degradation mechanisms: a complex ring mechanism (I in diagram) or a chain mechanism (II). As it is found that DITMP and ITMP (for abbreviations see diagram, p. 803) appear in the hydrolysis products, the first stage of the hydrolysis might be represented by a complex ring mechanism as follows:

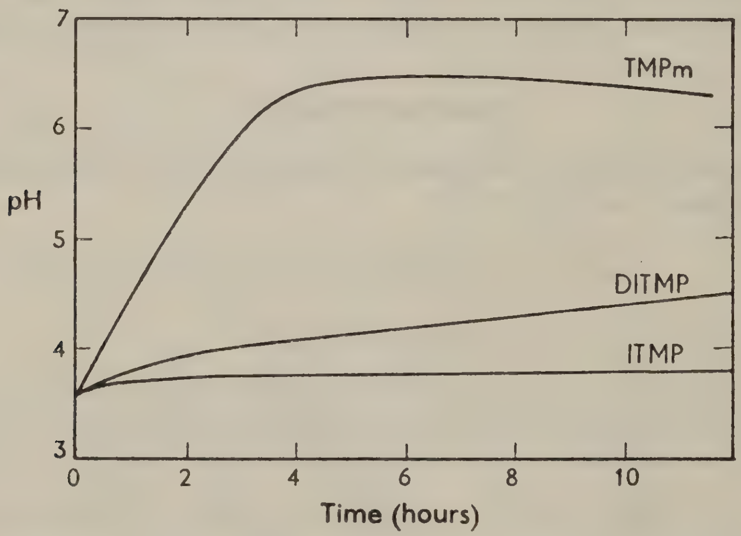

FIG. 8.—Rate of change of pH for the hydrolysis of trimeric ring imidophosphates at pH 3·6 and 60°

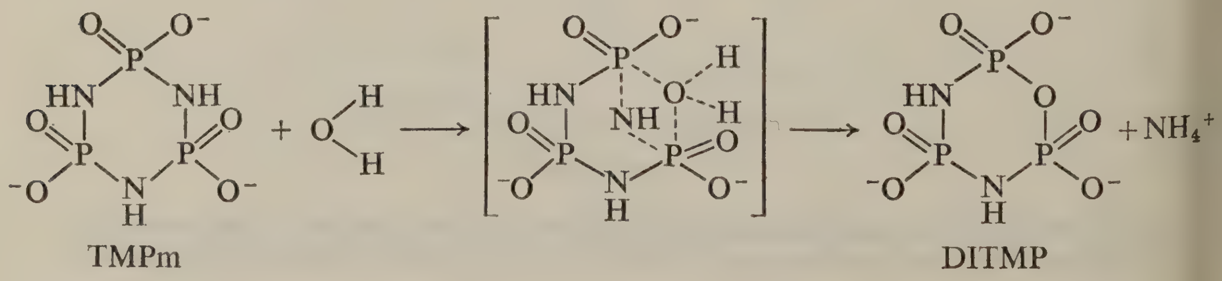
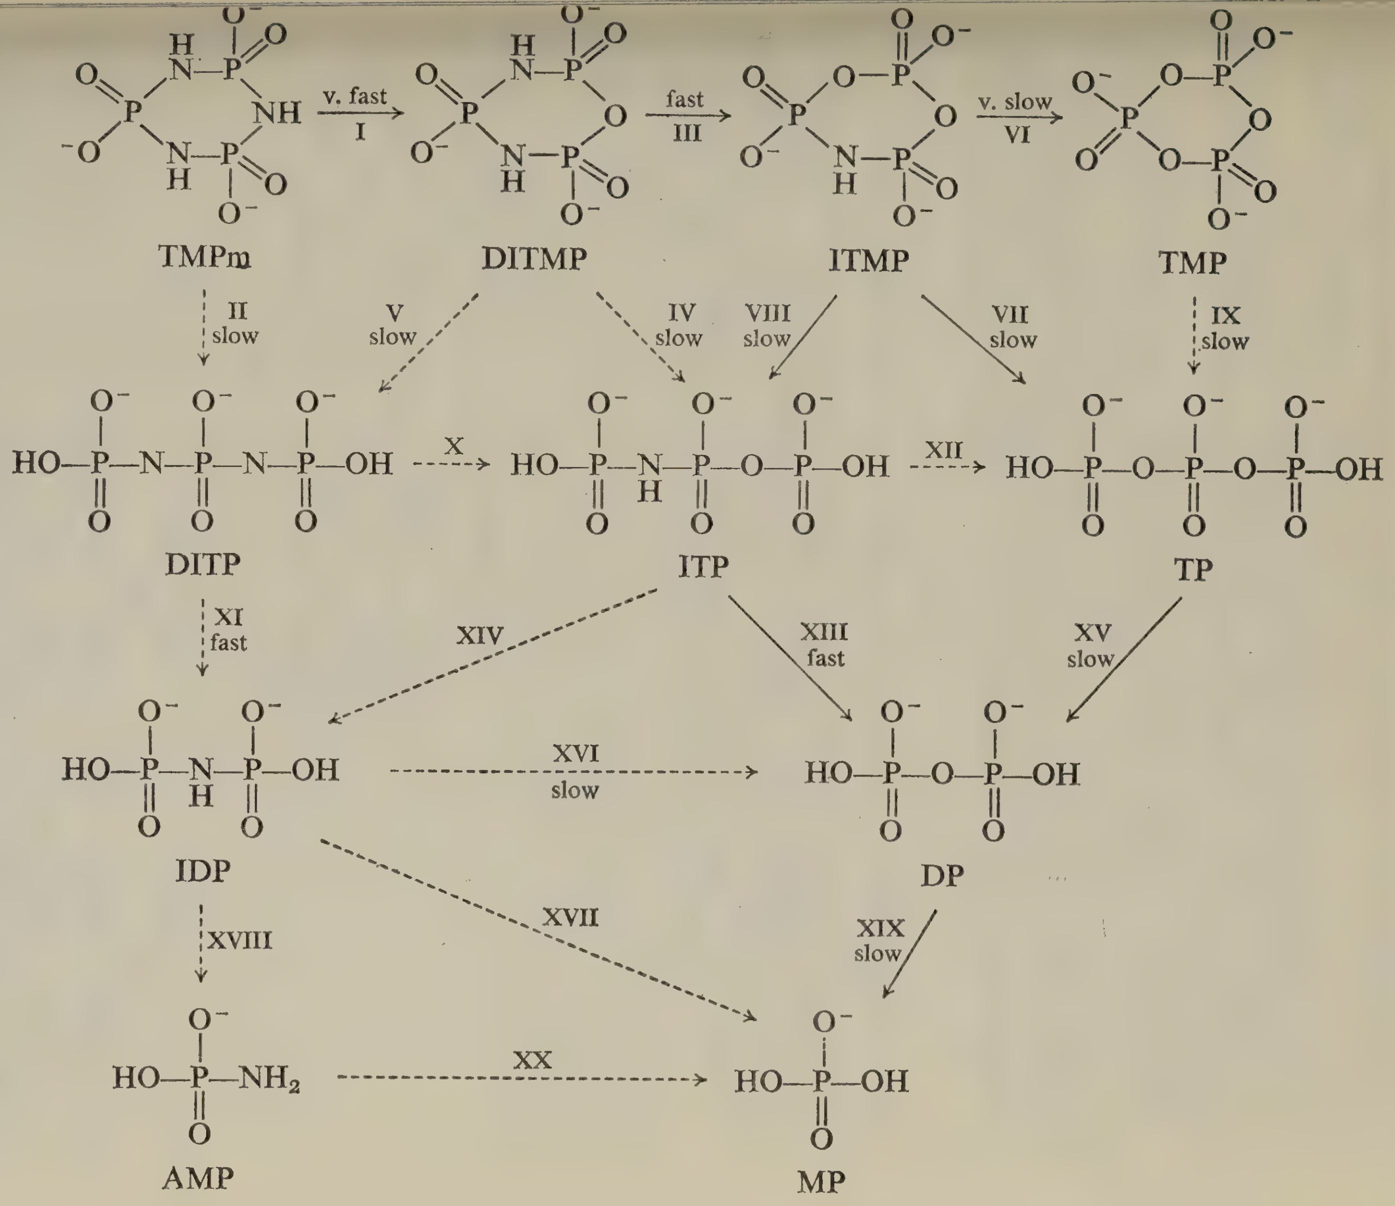


| Abbreviation | Name of acid species |
|---|---|
| TMPm | Trimetaphosphimate |
| DITMP | Di-imidotrimetaphosphate |
| ITMP | Imidotrimetaphosphate |
| TMP | Trimetaphosphate |
| DITP | Di-imidotriphosphate |
| ITP | Imidotriphosphate |
| TP | Triphosphate |
| IDP | Imidodiphosphate |
| DP | Pyrophosphate |
| MP | Orthophosphate |
| AMP | Monoamidophosphate |
| ADITP | Amido-di-imidotrimetaphosphate |
| AITP | Amido-imidotriphosphate |
| ATP | Amidotriphosphate |
| TeMPm | Tetrametaphosphimate |

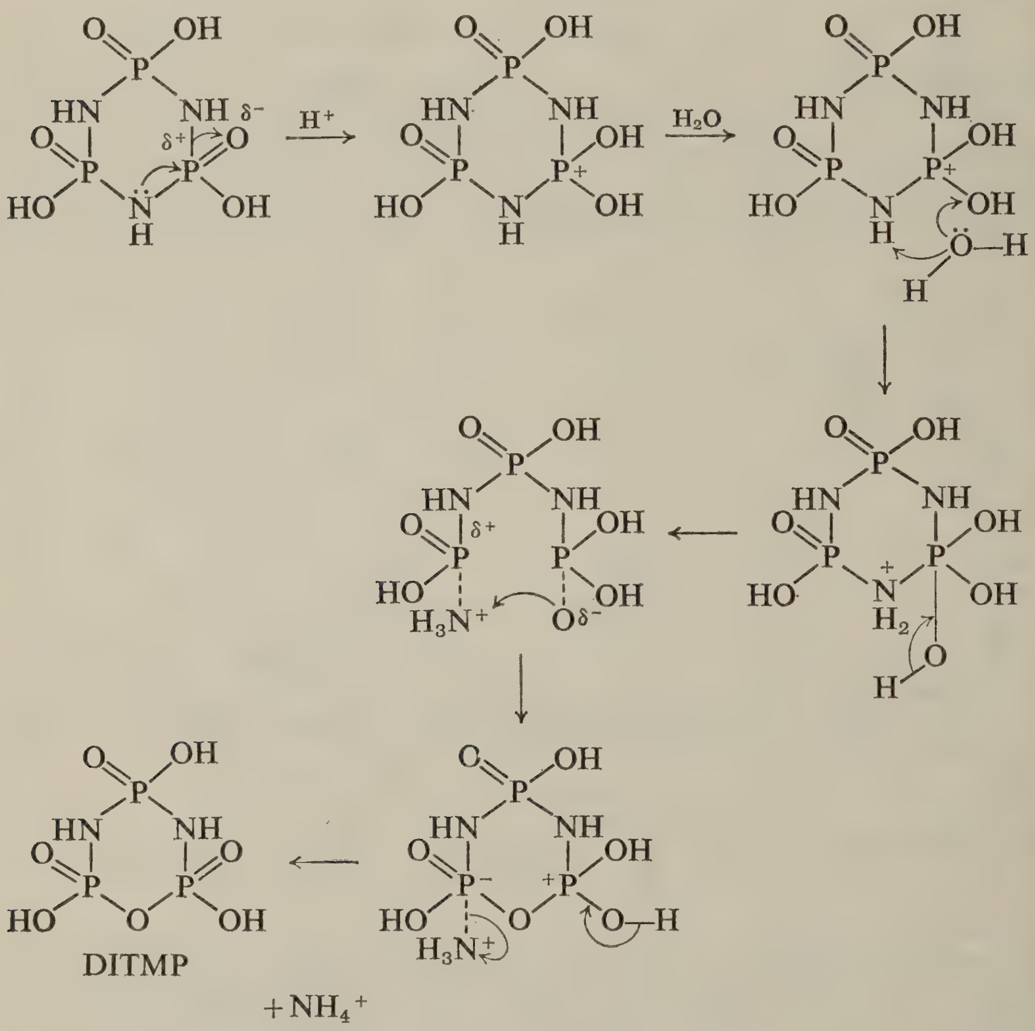


ITMP and TMP should be formed by a similar mechanism. However, as the amounts of TMP formed are very small and orthophosphate appears before TMP is detected, ITMP must hydrolyze by two paths. ITMP can break at the P–O or P–N linkage, the latter giving ITP which easily decomposes to ortho and pyrophosphate.

The argument against the complex ring mechanism is that despite the large size of the 3*d* orbitals of the phosphorus atom these atoms are too far apart for a P–O–P bond to form simultaneously with a P–N–P bond.

The argument against the chain mechanism is that chain imidophosphates are known to break down rapidly in acid solutions. As only DITMP and no orthophosphate is formed immediately and it is considered unlikely that condensation of amidophosphates would occur rapidly, the chain mechanism seems improbable.

A 'ruptured ring' mechanism is suggested incorporating ideas from both alternative mechanisms in which bond rupture and reformation may simultaneously occur.



DITMP

$+NH_4^+$

The steps are thought to occur almost simultaneously. Similar mechanisms are proposed for the hydrolysis of DITMP and ITMP, the rate decreasing in the order TMPm > DITMP > ITMP. An attack at a P–N–P linkage in a ring compound generally gives a ring compound containing a P–O–P link, whilst attack on a P–O–P ring gives polyphosphates.

Two techniques have been employed for measuring the hydrolysis rate:

(*a*) Hydrolysis in buffered solution in which acid was automatically added to maintain the pH at 3·6 permitted the calculation of the approximate hydrolysis rate.

(*b*) Analysis of the hydrolysis degradation products by ion exchange.

The results are presented in Table XV.

*Table XV.—Reaction Constants for the Hydrolysis of Imidophosphates*

| Species | Velocity constant at (min.$^{-1}$) | | Activation energy $E^*$ (kcal./mole) | Differences (kcal./mole) |
|---|---|---|---|---|
| | 60° ref. 117 | 65° ref. 118 | | |
| Trimetaphosphimate | $\sim 8\times 10^{-3}$ | $8{\cdot}91\times 10^{-3}$ | 19·5 | 1·45 |
| Di-imidophosphimate | $\sim 6\times 10^{-3}$ | $1{\cdot}02\times 10^{-3}$ | 20·95 | 1·55 |
| Imidophosphimate | $\sim 7\times 10^{-4}$ | $2{\cdot}30\times 10^{-5}$ | 22·5 | |

The results show that when one imido linkage in a six-membered ring is replaced by an oxygen the ring is stabilized by 1·45 kcal./mole. A further replacement stabilizes the ring by 1·5 kcal./mole. These results are consistent with the value of $E^*$ for sodium trimetaphosphate, 24 kcal./mole, representing a change of 1·5 kcal./mole for the replacement of the last imido linkage in imidotrimetaphosphate.

By heating trisodium trimetaphosphate in moist air at 180°C., it is possible to produce trisodium di-imidotrimetaphosphate.[74] Increasing the temperature to 270°C. results in the appearance of trisodium trimetaphosphate after several hours heating.[74, 141] These reactions do not seem to differ in essence from the hydrolyses discussed immediately above, although it has been suggested that they afford evidence that the degradation proceeds by alternate breaking and reclosure of rings, with loss of ammonia at each stage[141]:

$$\underset{\text{TMPm}}{[P_3O_6(NH)_3]^{3-}} \xrightarrow[-H^+]{+H_2O} \underset{\text{ADITP}}{[H_2NP_3O_7(NH)_2]^{4-}} \xrightarrow[+H^+]{-NH_3}$$

$$\underset{\text{DITMP}}{[P_3O_7(NH)_2]^{3-}} \xrightarrow[-H^+]{+H_2O} \underset{\text{AITP}}{[H_2NP_3O_8(NH)]^{4-}} \xrightarrow[+H^+]{-NH_3}$$

$$\underset{\text{ITMP}}{[P_3O_8(NH)]^{3-}} \xrightarrow[-H^+]{+H_2O} \underset{\text{ATP}}{[P_3O_9.NH_2]^{4-}} \xrightarrow[+H^+]{-NH_3} \underset{\text{TMP}}{[P_3O_9]^{3-}}$$

In view of the dubious existence of some of the intermediates suggested, further evidence for this route is desirable.

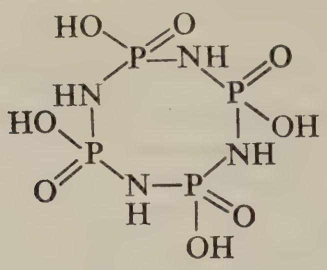
It has been claimed that by the action of various hypochlorites the hydrogen of the imido groups in metaphosphimates can be replaced by chlorine. Provided that the pH lies in the range 4–9 hypochlorous acid is suitable,[77] although metallic hypochlorites may be employed[78] and in certain cases[79] organic hypochlorites, e.g. butyl hypochlorite. The chlorimido derivatives which result are capable of forming addition compounds in much the same way as trimetaphosphimates themselves, e.g.:

$$3[K_3(PO_2NCl)_2.PO_2NH][2KCl][10H_2O]$$

In this particular instance only two imido groups in the ring have been chlorinated, but there appears to be no restriction and a fairly wide range of compounds of general formula $[MPO_2NH_{(n-a)/n}Cl_{a/n}]_n$ may be obtained. A typical example is trisodium trichlorimidotrimetaphosphimate, $Na_3(PO_2NCl)_3,2H_2O$, which crystallizes as parallelogram plates, extinguishing between crossed nicols at 40° to the long sides.

These compounds are readily soluble in water, hydrolyzing under alkaline conditions to release hypochlorite ions which render them suitable for bleaching, disinfecting, oxidizing and chlorinating purposes.

## TETRAMETAPHOSPHIMIC ACID AND ITS SALTS



### Formation and Preparation

The most convenient method[119-20,142] for preparing the tetrametaphosphimate ion is by hydrolyzing the corresponding phosphonitrilic chloride with ammonia or ammonium acetate, the latter giving the purer product. The sodium salt is difficult to isolate as it forms an oil. The simple amido derivatives of the phosphonitrilic chloride tetramer also decompose[45] to give tetrametaphosphimates:

$$P_4N_4Cl_6(NH_2)_2 + 8H_2O \rightarrow P_4N_4O_8H_6(NH_4)_2 + 6HCl$$
$$P_4N_4Cl_4(NH_2)_4 + 8H_2O \rightarrow P_4N_4O_8H_6(NH_4)_2 + 2NH_4Cl + 2HCl$$
$$P_4N_4Cl_6(NH_2)_2 + 10H_2O \rightarrow P_4N_4O_8H_8.2H_2O + 2NH_4Cl + 4HCl$$

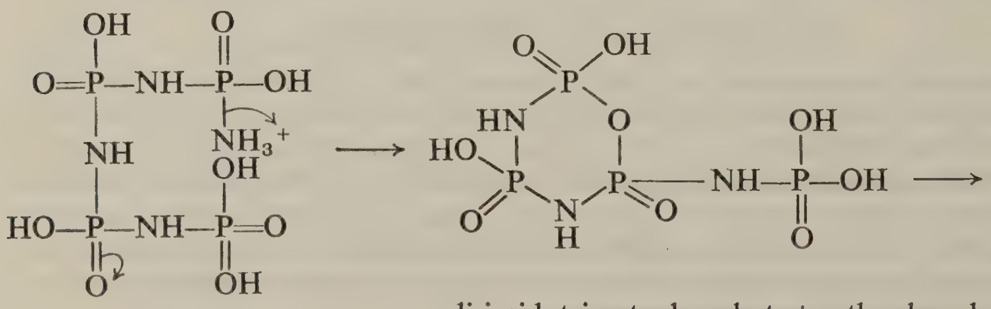
The tetrabasic acid shows an inflexion point at a pK of 3·25. For other properties, except hydrolysis, of this and other polymetaphosphimic acids see page 808.

### Properties

HYDROLYSIS

The hydrolytic decomposition of tetrametaphosphimates is pH-dependent. Only orthophosphates were found when solutions of tetrametaphosphimates were treated with acid at pH 1·0, but at pH 3·6 several species were observed. Ion exchange analyses of the products of hydrolysis of the ammonium salt in a buffer solution of pH 2·0 at 60°C. showed the simultaneous formation of large amounts of orthophosphate and six-membered ring compounds. Allowing for additional orthophosphate formed by hydrolysis, it seemed fairly certain that each tetrametaphosphimate ion formed one orthophosphate and one cyclic ion, probably trimetaphosphimate, which subsequently degraded by way of imidotrimetaphosphate and trimetaphosphate to form orthophosphate.

It is believed that these observations are best explained by a 'ruptured ring' mechanism, the first three major steps of the reaction bring: (1) protonation of a P atom, (2) approach of a water molecule and bonding to a P atom, (3) rupture of the P–N bond taking place as for trimetaphosphimate. The ring formation step would then be:



di-imidotrimetaphosphate + orthophosphate + $NH_4^+$

At pH 3·62 the reaction constant $k_1$ for ring degradation was calculated to be $3{\cdot}37 \times 10^{-4}$ min.$^{-1}$ at 65·0°C. and $1{\cdot}00$–$1{\cdot}01 \times 10^{-3}$ min.$^{-1}$ at 80·0°C. $E^*$ (TeMPm → DITMP) = 17·3 kcal./mole.

## POLYMETAPHOSPHIMIC ACIDS AND THEIR SALTS

The polymetaphosphimic acids, $(H.PO_2NH)_n$, form an homologous series of cyclic compounds of which trimetaphosphimic acid is formally the first member. However, as often happens in such cases, the behaviour of the trimeric acid is somewhat anomalous, and for this reason it has been treated separately here. Tetrametaphosphimic acid is a very stable compound, and to this extent it too is anomalous, although chemically in other respects it resembles the higher members of the series, in so far as they have been investigated. The separation of individual compounds in a pure state becomes progressively more difficult as the series is ascended.

### Formation and Preparation

Polymetaphosphimates are normally prepared by hydrolysis of the appropriate phosphonitrilic derivative (see page 563). The hydrolysis is most conveniently undertaken by dissolving phosphonitrilic chloride in ether and shaking this solution with water[45, 67]:

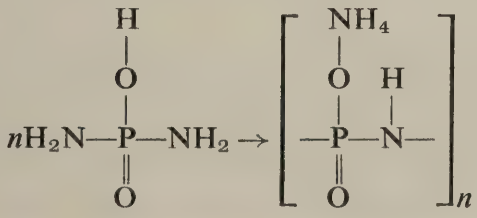
$$(PNCl_2)_n + 2n\ H_2O \rightarrow (PO_2NH)_n^{n-} + 2n\ Cl^- + 3n\ H^+$$

The rate of hydrolysis appears to increase with ring size.

Most alkali-metal salts are readily prepared by straightforward acid-base neutralization procedures, although when the free acid is titrated against standard sodium hydroxide solution the shape of the curve obtained depends to a certain extent on the duration of the experiment.[28] This effect suggests the existence of an equilibrium in which a possible tautomeric form is slowly established.

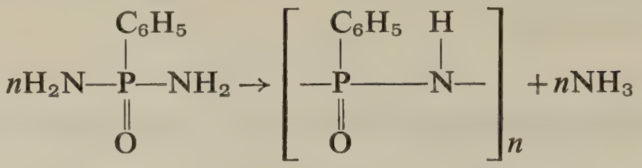
The acid salts can be obtained from the normal compounds by acidifying their solutions (Mellor, VIII, 718). Thus di- and tetra-sodium tetrametaphosphimates, $Na_2H_2(PO_2NH)_4,2H_2O$ and $Na_4(PO_2NH)_4,2H_2O$, have been isolated, although alkali-metal salts are often conveniently prepared by hydrolyzing phosphonitrilic compounds in dilute alkaline media. Diammonium tetrametaphosphimate may be prepared directly from tetrametaphosphimic acid in a rapid reaction with gaseous ammonia; by a much slower reaction the tetrammonium derivative, $(NH_4)_4(PO_2NH)_4$, $4H_2O$, is produced, but the last compound is more effectively prepared in concentrated ammoniacal solution.[45] The preparation of octasilver tetrametaphosphimate (Mellor, VIII, 718) and other silver tetrametaphosphimates containing more than four atoms of silver per molecule is not confirmed.[53]

Claims have been made that the ammonolysis of phosphorus pentoxide, prepared *in situ* from elemental phosphorus, gives rise to a mixture of hygroscopic materials containing between 10 and 30% of ammonium polymetaphosphimate,[71] but there is some doubt as to the nature of this material. However, amorphous hygroscopic ammonium polymetaphosphimate seems to be formed when diamidophosphoric acid is heated to between 100° and 110°C.[10]:



$$n\,H_2N{-}\underset{\underset{O}{\|}}{\overset{\overset{H}{|}}{\overset{O}{|}}{P}}{-}NH_2 \rightarrow \left[{-}\underset{\underset{O}{\|}}{\overset{\overset{NH_4}{|}}{\overset{O}{|}}{P}}{-}\overset{\overset{H}{|}}{N}{-}\right]_n$$

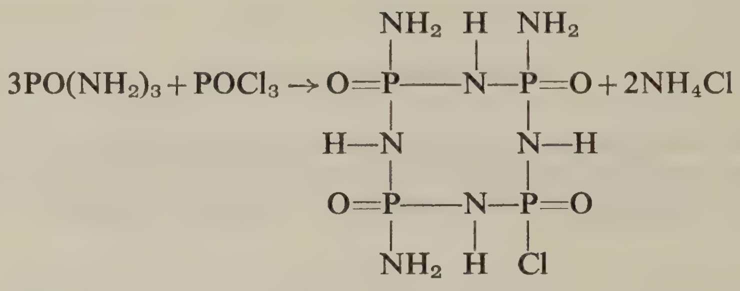
An analogous reaction has been reported[60]:



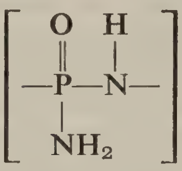
$$nH_2N{-}\underset{\underset{\displaystyle O}{\|}}{\overset{\overset{\displaystyle C_6H_5}{|}}{P}}{-}NH_2 \rightarrow \left[ {-}\underset{\underset{\displaystyle O}{\|}}{\overset{\overset{\displaystyle C_6H_5}{|}}{P}}{-\!-}\overset{\overset{\displaystyle H}{|}}{N}{-} \right]_n + nNH_3$$

It has been claimed that anhydrous metaphosphates react with ammonia at elevated temperatures and pressures so that a tetrametaphosphate would give rise to the corresponding tetrametaphosphimate.[59] However, bearing in mind the chemical properties of polymetaphosphimates,[58] such a reaction seems improbable.

It is conceivable that an eight-membered ring is formed as a result of the reaction between phosphoryl trichloride and phosphoryl triamide. The following interpretation has been suggested[57]:



When treated with ammonia, the solitary chlorine atom might be replaceable by an amido group to yield fully symmetrical tetrametaphosphimic tetramide, but only a polymer derived from this has been isolated, the structure of which seems uncertain. However, repeating units of the type:



$$\left[ {-}\underset{\underset{\displaystyle NH_2}{|}}{\overset{\overset{\displaystyle O}{\|}}{P}}{-}\overset{\overset{\displaystyle H}{|}}{N}{-} \right]$$

are no doubt present.

## Physical Properties

The infra-red spectra of several tetrametaphosphimates have been examined, including the diammonium, the tetrammonium (tetrahydrate), the disodium, the tetrasodium (hydrates), the dipotassium, the tetrapotassium, the tetrasilver, the tetrathallium, the dirubidium, the dicalcium (tetrahydrate), the dibarium (dihydrate), the dicopper (tetrahydrate), the dinickel (2·5 hydrate) and the dilead (hydrate) salts.[21, 75] No common physical properties are given for any of these compounds. The main absorption regions do not differ appreciably from those of the trimetaphosphimates (*q.v.*). The presence of water of crystallization, where it does not mask the absorption, tends to displace much of the absorption to slightly lower frequencies, possibly because of hydrogen bonding to anionic oxygen.

The structure of tetrametaphosphimic acid dihydrate has been studied by *X*-ray diffraction. The compound crystallizes in the orthorhombic system (space group $P2_12_12$) with $a = 13{\cdot}98$; $b = 8{\cdot}32$; $c = 5{\cdot}04$ Å. The evidence, although not firm, indicates that the nitrogen atoms of the ring are linked to hydrogen atoms. There are P–O bonds of two types, differing in length, which are consistent with a formulation of the compound as a hydronium salt, $2H_3O^+.[(NH)_4P_4O_8H_2]^{2-}$.

The anions have the tub configuration with approximate symmetry 4. The P–N bonds are all equal within experimental error, and are longer than is found in phosphonitrilic derivatives, again supporting the 'keto' (metaphosphimic) rather than the 'enol' (phosphonitrilic) structure.[143] Unit cell dimensions for the dihydrate[143] and the dipotassium and dirubidium salts[80] have been recorded (see Table XVI).

*Table XVI.—Orthorhombic Unit Cell Dimensions of Tetrametaphosphimates*

| Compound | *a*(A.) | *b*(A.) | *c*(A.) |
|---|---|---|---|
| Free acid dihydrate | 13·98 | 8·32 | 5·04 |
| Dipotassium salt | 13·89 | 8·07 | 5·03 |
| Dirubidium salt | 14·03 | 8·24 | 5·06 |

This structural analysis of tetrametaphosphimate therefore confirms previous conclusions from infra-red studies[21] that metaphosphimates exist in the $-PO(O^-)-NH-$ form, rather than the tautomeric phosphonitrilic form, $-PO^-(OH)=N-$. For this reason, metaphosphimates would not be expected to exhibit the unique chemical or structural properties of phosphonitrilic compounds, and the term 'phosphonitrilates' is inappropriate to them, but should be reserved for organic derivatives of the type $[(RO)_2P=N]_n$. Potentiometric titrations[121] of the pentametaphosphimate gave two inflexion points corresponding to p$K_1$ values of 2·70 and 6·70. The hexametaphosphimate gave three inflexion points corresponding to p$K_1 = 2·80$, p$K_2 = 6·88$ and p$K_3 = 9·40$.[123]

## Chemical Properties

Metaphosphimic acids behave as polybasic acids, the basicity depending on the number of phosphorus atoms in the ring. Thus tetrametaphosphimic acid has a basicity of four, but conductimetric titrations[53] indicate that the fourth acid function is weaker than the other three (see Fig. 7). In spite of this only two series of salts seem to exist in equilibrium in their aqueous solutions, those in which four hydrogen ions of the acid are replaced by metallic ions, and those in which only two hydrogen ions are replaced. The existence of salts containing eight metallic ions (Mellor, VIII, 718) was not confirmed. A titration curve is shown in Fig. 9, only one inflexion being observed.

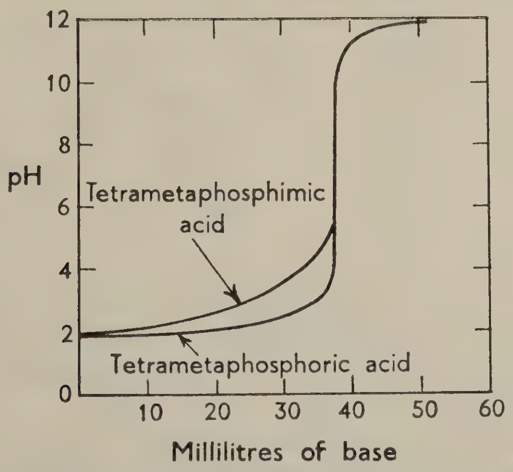


FIG. 9.—Titration curve of tetrametaphosphimic acid compared with that of tetrametaphosphoric acid. The end point of pH equal to about 7 corresponds to one equivalent of base per atomic weight of phosphorus

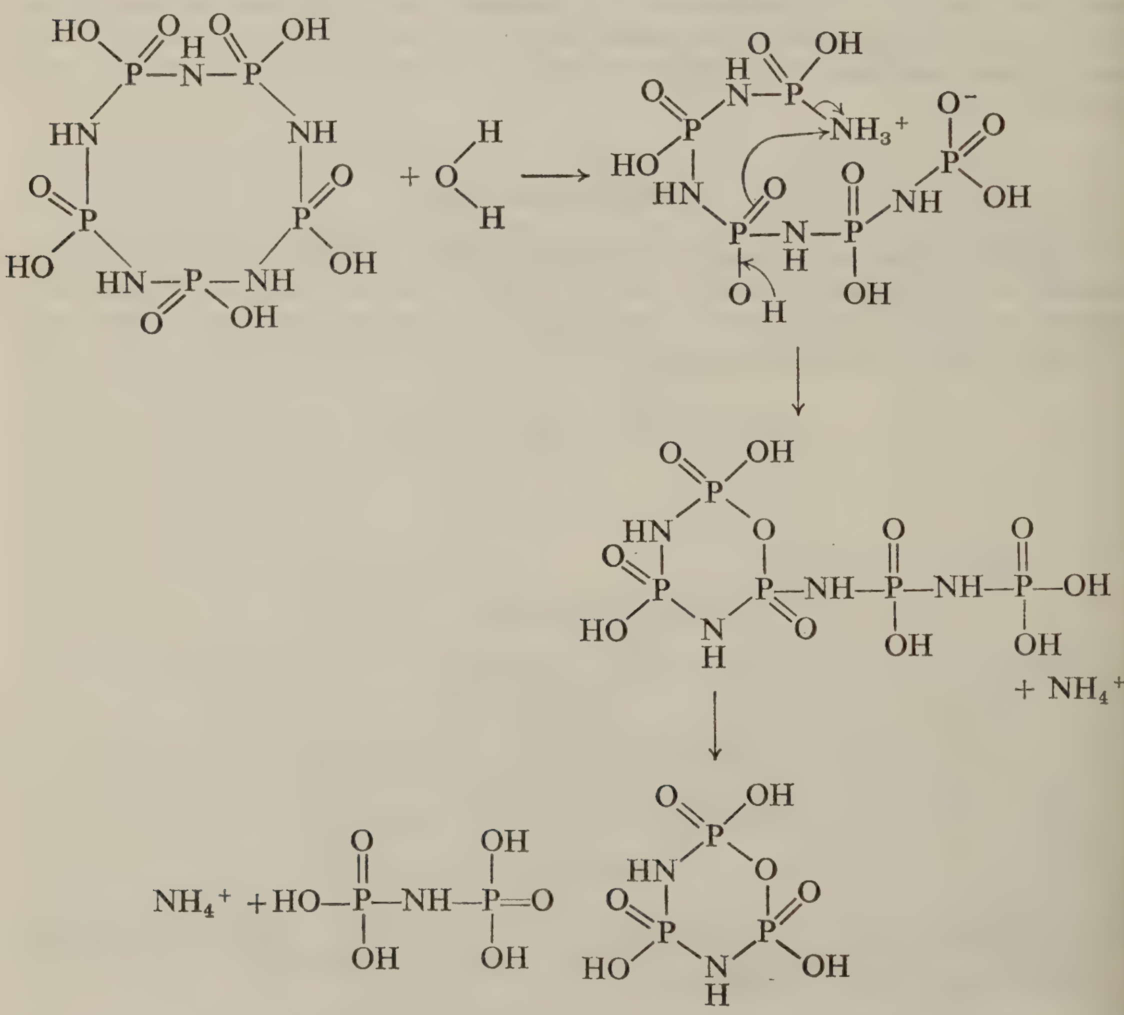
Polymetaphosphimates are decomposed by the action of heat. Tetrametaphosphimic acid dihydrate was heated under very low pressure (approximately 0·1 mm. mercury) with gradually increasing temperature in the presence of [*sic*] phosphorus pentoxide. At about 100°C. water of hydration was evolved, and in the region of 170°–300°C. a further reaction took place, with loss of ammonia. The product was hygroscopic and gave rise to imidodiphosphoric acid in the presence of moisture, suggesting that a polymeric imidodiphosphoric anhydride had been formed.[44] Above 300°C., further decomposition occurred to phosphorus pentoxide, nitrogen and phosphorus nitride, $(PN)_n$.

Under acidic conditions polymetaphosphimates hydrolyze. By analogy with trimetaphosphimates it would be anticipated that a mechanism involving the successive replacement of P–N(H)–P bridges by P–O–P bridges would operate.

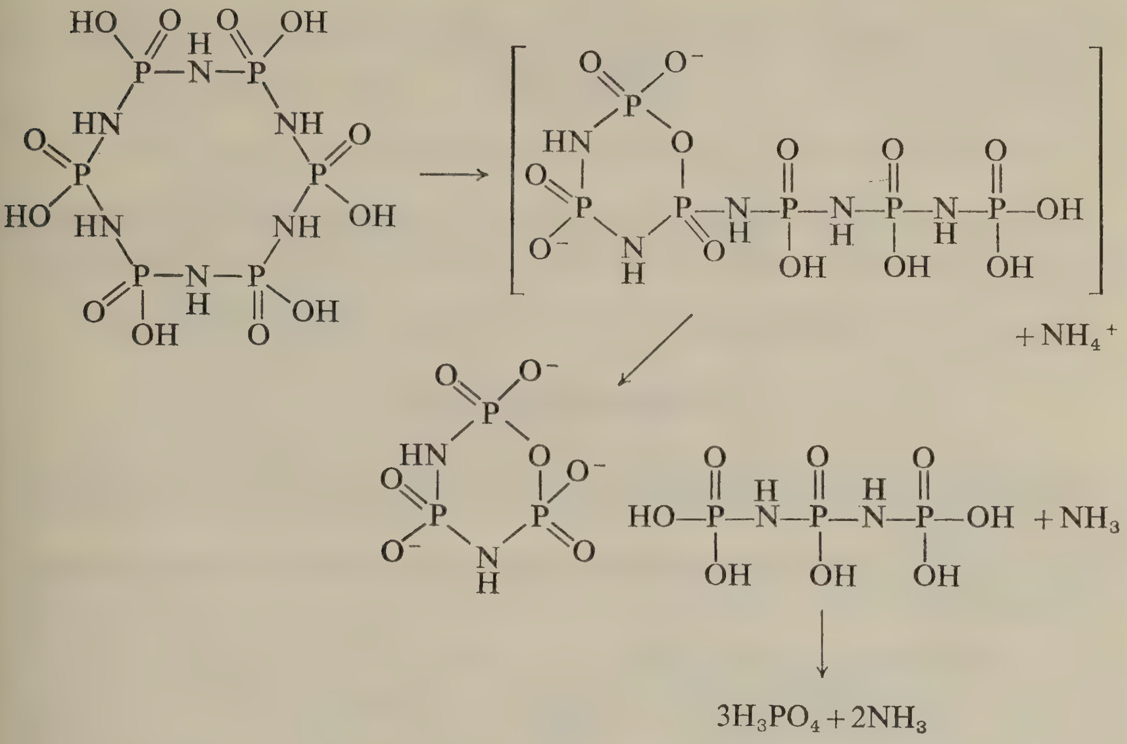
Nevertheless, as with tetrametaphosphimates, similar mechanisms for the hydrolysis of the pentametaphosphimate[121] at pH 3·6 and 60°C. to give trimetaphosphimate and di-imidotrimetaphosphate are thought to occur.

In the 'ruptured ring' mechanism it is again likely that the chain will reform into a six-membered ring, forming a polyimidotrimetaphosphate and eliminating imidodiphosphate. Under the reaction conditions the latter immediately hydrolyzes to ortho- and pyrophosphates:

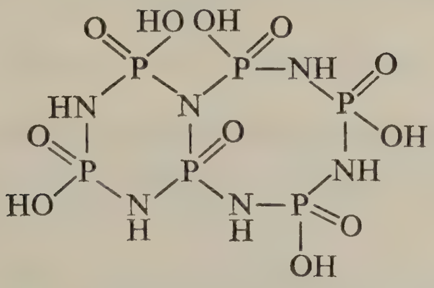


The small amounts of trimetaphosphimate which are also formed may be accounted for by bonding taking place between a nitrogen and a phosphorus atom on opposite sides of the ring. Examination of models shows that in pentametaphosphimate these atoms could indeed be in close proximity.

The hydrolysis of the hexametaphosphate[123] is thought to occur by two mechanisms, one giving di-imidotrimetaphosphate and orthophosphate by a 'ruptured ring' mechanism:



and the other giving trimetaphosphimate or tetrametaphosphimate and orthophosphate by intra-annular cyclization, e.g.:



There is no evidence that this process can take place more than once.

Quantitative hydrolysis of the heptametaphosphimate[122] suggests that the first step is the formation of a trimeric imidophosphate, together with small amounts of trimetaphosphimate which is probably formed by a mechanism like that already discussed.

There appears to be some conflict between the mechanism envisaged above and the claim[73] that ammonium polymetaphosphimate can be hydrolyzed to ammonium polymetaphosphate, which is resolved only if the latter salt is in fact the trimetaphosphate.

Polymetaphosphorochlorimidates may be prepared by treating metaphosphimates with hypochlorites, either as hypochlorous acid,[77] or metallic[78] or organic hypochlorites.[79] Derivatives of tetrapotassium and tetrasodium tetrametaphosphimates have been reported, as in Table XVII.

Polymetaphosphimates exhibit properties typical of polyanions of high molecular weight; for instance egg albumen is immediately coagulated by a polymetaphosphimate solution.[10]

*Table XVII.—Some Tetrametaphosphorochlorimidates*

| Formula of compound | Crystal habit | Optical extinction |
|---|---|---|
| $Na_4(PO_2NCl)_4.9H_2O$ | parallelogram plates | parallel long side |
| $Na_4(PO_2NCl)_4.14H_2O$ | parallelogram plates | 72° to long side |
| $Na_4(PO_2NCl)_4.25H_2O$ | acicular prisms | parallel long side |
| $K_4(PO_2NCl)_4.6H_2O$ | rhomboidal plates | with diagonals |

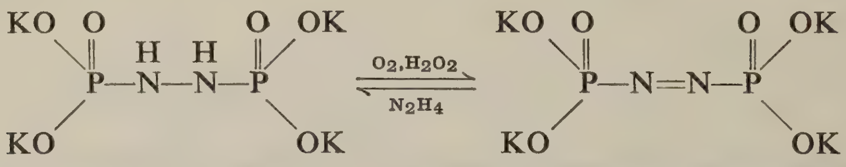
Like linear and cyclic condensed phosphates, solutions of polymetaphosphimates such as the ammonium salts have a slightly alkaline pH and show sequestering properties.

Mixtures of polymetaphosphimates have found application as fertilizers.[71]

## AZO-DIPHOSPHONATES

Alkaline hydrolysis[124] of the tetraphenyl ester of hydrazine diphosphonic acid with potassium hydroxide under nitrogen results in the formation of the tetrapotassium salt, $K_4N_2H_2P_2O_6$.

This salt can be oxidized by hydrogen peroxide or oxygen according to the following equation:



The salt of azo-diphosphonic acid thus formed is bright red in colour and decomposes at a temperature above 300°C. before reaching its melting point. The decomposition may be represented by the following equation:

$$K_2O_3P—N{=}N—PO_3K_2 \xrightarrow{300°} N_2 + K_2O_3P—PO_3K_2$$

Hydrolytic breakdown of the compound produces nitrogen and hydrazine:

$$2K_2O_3P—N{=}N—PO_3K_2 + 4H_2O \xrightarrow{[H^+]} N_2 + N_2H_4 + 4K_2HPO_4$$

## THE ANALYSIS OF NITROGEN-SUBSTITUTED OXYACIDS OF PHOSPHORUS

The value of classical methods of chemical analysis to investigate the chemistry of the nitrogen substituted oxyacids of phosphorus was amply demonstrated by Stokes (Mellor, VIII, 705 *et seq.*). Nevertheless, such methods have severe limitations, particularly when the compounds have similar chemical properties and structures, and more modern physical methods have been employed to good advantage.

*X*-Ray powder diffraction patterns have been examined by a large number of investigators and several details have been published.[12,18,22,29,31,33,35,39,42,45,57] To a limited extent nuclear magnetic resonance spectroscopy is a useful diagnostic tool.[22-3,48]

It is, however, the application of paper chromatography which has been of the greatest value in this field. The majority of recent investigators have employed this technique.[10,12,17,20,22,25 46,58,86] A solvent system which has proved particularly satisfactory[47] is prepared from *iso*propanol (20 parts), dimethylformamide (20 parts), methyl ethyl ketone (20 parts), 25% ammonia solution (1 part) and water (39 parts).

**Refs. p. 813**

From the $R_f$ values (see Table XVIII) the chain lengths ($n$) were estimated from an equation of the form:

$$\ln P_k = -an+b$$

*Table XVIII.—Paper Chromatography of Nitrogen-Substituted Oxyacids of Phosphorus*

| Ion | $R_f$ value | $P_k$ |
|---|---|---|
| orthophosphate | 0·40 | — |
| amidophosphate | 0·44 | — |
| diamidophosphate | 0·57 | 100 |
| phosphoryl triamide | 0·58 | — |
| pyrophosphate | 0·29 | — |
| imidodiphosphate | 0·32 | — |
| diamidoimidodiphosphate | 0·46 | 79·5 |
| diamido-imidotriphosphate | 0·37 | 63·7 |
| diamidotri-imidotetraphosphate | 0·30 | 50·9 |
| diamidotetrimidopentaphosphate | 0·24 | 39·7 |
| diamidopentimidohexaphosphate | 0·18 | 30·9 |
| trimetaphosphimate | 0·43 | — |

Thin layer chromatography, like paper chromatography, has been applied to the analysis of mixtures of phosphorus oxyacids, and a critical comparison of the two methods has been published.[144]

Ion exchange chromatography[58] has been applied successfully to determine the nature of the hydrolysis products of polymetaphosphimates. This technique involves eluting the resin with progressively increasing concentrations of electrolyte so that the ions are desorbed successively.

A microchemical procedure has been developed[81] in which *o*-tolidine, ammonium or silver salts of the appropriate acid are prepared and examined under the microscope. The results are compared with standard micrographs in order to identify the compounds, as opposed to separating them.

## SECTION XXIX

# PEROXOPHOSPHORIC ACIDS AND THE PEROXOPHOSPHATES

BY J. E. SUCH

## PEROXOPHOSPHORIC ACIDS

### Preparation

ALTHOUGH hydrogen peroxide solutions have not been observed to react with orthophosphoric acid, they do so with pyrophosphoric acid and higher linear polyphosphoric acids[31] to form the so-called peroxomonophosphoric acid, $H_3PO_5$, and other peroxopolyphosphoric acids, such as $H_4P_2O_8$, according to equations of the type[1]:

$$\text{(i)} \qquad H_4P_2O_7 + H_2O_2 = H_3PO_5 + H_3PO_4$$

$$\text{(ii)} \qquad H_4P_2O_7 + H_2O_2 = H_4P_2O_8 + H_2O$$

In aqueous solution, peroxomono- and peroxodi-phosphoric acids are said to exist in equilibrium according to equation (iii):

$$\text{(iii)} \qquad H_4P_2O_8 + H_2O \rightleftharpoons H_3PO_5 + H_3PO_4$$

the formation of products on the right-hand side being favoured by acid and on the left by alkaline conditions.[2-3]

The reaction between the volatile hexagonal (H) form of phosphoric oxide and solutions of hydrogen peroxide, of 30% by weight concentration and above, is extremely violent and can only be carried out successfully by slow addition of small portions of the oxide to well-cooled and vigorously stirred hydrogen peroxide solutions.[1]

However, the vigour of this reaction may be moderated in two ways:

(*a*) If the reactive (H) form of the anhydride is suspended in an inert organic solvent, such as acetonitrile,[4] hydrocarbons, fluorocarbons,[32] or even in orthophosphoric acid itself,[5] hydrogen peroxide of high concentration can then be introduced into the well-cooled and stirred system without excessive loss of active oxygen by decomposition either of hydrogen peroxide or of the peroxoacid itself.

In a typical experiment, using acetonitrile, the following procedure is described: 5·18 millimols. of phosphoric oxide is suspended in 1 mol. of acetonitrile and cooled in a freezing mixture. A solution of 12·34 millimols. of hydrogen peroxide and 3·84 millimols. of water in 1·05 ml. of acetonitrile is added slowly to the well-stirred cooled suspension of phosphoric oxide. Some escape of gas occurs, accompanied first by the odour of ozone and then by the characteristic peroxoacid odour associated with peroxomonosulphuric and peroxo-benzoic acids. After being kept for 24 hr. at room temperature, the solution contains 57% of the added active oxygen in the form of $H_3PO_5$ and 18·5% as hydrogen peroxide. It is believed that most of the peroxoacid formation and the loss of peroxide occur during the first hour of the reaction. After addition of dibenzyl sulphide to the acetonitrile solution, to remove active oxygen as dibenzyl sulphoxide, the residual acid shows equal titrations with alkali, up to the methyl orange indicator change point, and from this stage to the phenolphthalein indicator colour change. Although this property equally well indicates that the acid formed is either orthophosphoric or pyrophosphoric acid, it has been claimed[4] that the chemical properties of the original solution support the view that the main product of the initial reaction is $H_3PO_5$. When ether or *iso*amyl alcohol is substituted for acetonitrile as the inert organic solvent, the reaction between hydrogen peroxide and phosphoric oxide is not so complete, the product containing only 9% or 17% respectively of the added active oxygen as $H_3PO_5$.

Preparations using orthophosphoric acid as the suspension medium are claimed to give products containing much higher proportions of peroxomonophosphoric acid than those previously mentioned, but at the same time some peroxodiphosphoric acid is formed.[5] For example, the best yields are obtained when phosphoric oxide, hydrogen peroxide and water are in the mole ratio of 1 : 2 : 1, and provided good mixing and cooling are applied, high strength (85–95%) hydrogen peroxide can be safely used. If the reaction temperature is kept below 35°C., a typical product contains 71·2% of the added active oxygen in the form of $H_3PO_5$, 1·4% in the form of $H_4P_2O_8$ and 21·4% as $H_2O_2$. The excess of hydrogen peroxide may be removed from the solution by distillation *in vacuo*, at temperatures preferably below 50°C., to give substantially pure peroxomonophosphoric acid.

(*b*) The volatile (H) form of phosphoric oxide can be converted into one of the more complex and less reactive forms by heating it, for example, for 16 hr. at 500°C. under a reduced pressure of 10 mm. Hg. In contrast to the (H) form, the heated oxide reacts only very slowly with high-strength hydrogen peroxide (50–90% $H_2O_2$), complete solution requiring up to 20 hr. or more.[6] The proportion of peroxoacids formed is, however, much less than that obtained by the methods described under (*a*).

Phosphoric oxide did not react with anhydrous (100%) hydrogen peroxide in dry liquid ammonia, even at room temperature under pressure, and the products of reaction in chloroform suspension could not be separated. The reactants combine vigorously if mixed without a diluent, giving permonophosphoric acid and the lower polyphosphoric acids.[37]

The mechanism of the step-wise interaction between hydrogen peroxide and the various forms of phosphoric oxide has not yet been investigated as thoroughly as the aqueous hydration process.

Peroxodiphosphoric acid is obtained, together with pyrophosphoric acid, by the hydration of tetraphosphorus hendecaoxide (*q.v.*)[38]

$$P_4O_{11} + 4H_2O \rightarrow H_4P_2O_8 + H_4P_2O_7$$

Attempts have been made to separate pure permonophosphoric acid from orthophosphoric acid, using ion exchange resins. The separation was successfully achieved in acetonitrile solution (cf. [4]) on a Deacidite FF strong base resin column in its acetate form, by elution with an acetate buffer at pH 5. Concentration of the eluate *in vacuo*, and removal of metal ions by a cation exchange resin in its $H^+$ form, gave a solution containing acetic acid and 95% of the original peroxo-oxygen. Removal of the acetic acid and further concentration by vacuum distillation and freeze drying caused a further 25% loss of oxygen. The product, a colourless viscous liquid containing 80% permonophosphoric acid, slowly lost oxygen if allowed to stand at room temperature. Unstable amorphous lithium, sodium or potassium salts were obtained by neutralization with the appropriate hydroxide, and evaporation of the resulting solution *in vacuo*.[39]

## Properties

*Peroxomonophosphoric acid*, $H_3PO_5$, a strong oxidizing agent, liberates iodine from acidified potassium iodide solution and oxidizes manganous salts, in the cold, to permanganate. Although stable in concentrated aqueous and acetonitrile solutions, it is said to hydrolyze in dilute solution to form orthophosphoric acid and hydrogen peroxide,[7–8] according to equation (iv):

(iv) $$H_3PO_5 + H_2O \rightleftharpoons H_3PO_4 + H_2O_2$$

The kinetics of this decomposition have been studied in aqueous alkaline media, ethylenediaminetetraacetic acid being added to suppress homogeneous catalysis by trace metal ions. The bimolecular decomposition had a maximum rate near pH 12·5, corresponding closely to the third dissociation constant of the acid, which the authors determined as $pK_{3a} = 12{\cdot}8 \pm 0{\cdot}2$. It is therefore suggested that under these conditions decomposition occurs by nucleophilic attack of the species $PO_5^{3-}$ on the phosphorus atom of a second $HPO_5^{2-}$ ion.[33]

This was confirmed in a study of the decomposition of $H_3PO_5$ by alkali containing $^{18}O$ at 20°C. In acid solutions, however, a different mechanism obtains.[40] The hydrolysis is of first order in peroxo acid, and also depends (but not linearly) on pH. Rate constants, activation parameters and other data suggest a mechanism involving nucleophilic attack of water on a protonated species:

$$H_3PO_5 + H^+ \rightleftharpoons H_4PO_5^+$$
$$H_4PO_5^+ + H_2O \rightarrow H_3PO_4 + H_2O_2 + H^+$$

The rate of hydrolysis is accelerated tenfold by 0·1 M. fluoride ion, probably by a bimolecular nucleophilic displacement mechanism.[41]

A study of possible isotope exchange between radioactive phosphate and peroxomonophosphoric acid, prepared by the method of reference 4, was prevented by difficulties encountered in the separation of the two species, during which complete decomposition of the peroxo-ion occurred.[9]

After neutralization, solutions of peroxomonophosphoric acid give a dark precipitate with silver nitrate, which rapidly turns white and in a few hours becomes yellow, owing to the formation of silver orthophosphate, which is accompanied by the evolution of ozonized oxygen. Precipitates formed in alkaline solution by silver, iron, nickel and manganous salts rapidly change to orthophosphates, again with evolution of ozonized oxygen.[1]

*Peroxodiphosphoric acid*, $H_4P_2O_8$, on the other hand is more stable in dilute solution, possibly because it has first to hydrolyze to peroxomonophosphoric acid by the reaction given in equation (iii), and liberates iodine only slowly from an iodide solution, the rate depending sensitively on the acidity of the system.[30] A later kinetic study of this reaction has indeed shown that the reaction takes three main paths:

$$H_3P_2O_8^- + I^- \rightarrow HPO_4^{2-} + H_2PO_4^- + I^+$$
$$H_3P_2O_8^- + H_2O \rightarrow H_2PO_4^- + H_2PO_5^- + H^+$$
$$H_2P_2O_8^{2-} + I^- \rightarrow 2HPO_4^{2-} + I^+$$

These are followed by fast reactions which give the final products.[42]

Accurate volumetric determination of the peroxodiphosphate ion in acid solution by the addition of excess of ferrous sulphate followed by back-titration with potassium chromate solution has been described[30] and direct potentiometric titration of acid peroxodiphosphate solutions with ferrous ammonium sulphate is also possible.[30] In the oxidation of tris(1,10-phenanthroline)iron(II), the rate-determining step is the dissociation of the Fe(II) complex ion.[43]

The manganous ion can be oxidized quantitatively to manganese dioxide, slowly at room temperature and rapidly at 100°C., by excess of peroxodiphosphate[3]; the permanganate ion is thought to be an intermediate in the reaction mechanism. Incomplete oxidation of thallous, chromic and cobaltous ions and selenic acid occurs under the same conditions, but the oxidation of the thallous and chromic ions was found to be quantitative in the presence of known amounts of manganous ion.[3] The oxidation-reduction potentials of $P_2O_8^{4-}$ and $PO_5^{3-}$ solutions have been measured, using smooth and platinized platinum electrodes against the standard calomel electrode. The substances which determined the oxidation-reduction potential of $P_2O_8^{4-}$ were its decomposition products, especially $PO_5^{3-}$. The potential for $PO_5^{3-}$ depended linearly on the logarithm of the concentration of $PO_5^{3-}$. Hydrogen peroxide caused a lowering of the potential.[44]

It has been reported[10] that the peroxodiphosphate ion decomposes more slowly in $H_2{}^{18}O$ than percarbonate or perborate ions, and that the origin of the oxygen formed depends on the pH of the solution. For example, at pH 5·2, 81% of the oxygen formed was derived from the peroxodiphosphate ion, whilst at pH 12·8 all was derived from water. At room temperature no $^{18}O$ was exchanged between $H_2{}^{18}O$ and potassium peroxodiphosphate in 8 hr.

Acid hydrolysis of the peroxodiphosphoric acid,[11] or other peroxopolyphosphoric acid components of the reaction products obtained, for example, by the reaction between hydrogen peroxide and phosphoric oxide suspended in phosphoric acid[5] for a short period at temperatures not exceeding 60°C., considerably increases the proportion of peroxomonophosphoric present.

The hydrolysis of peroxomono- and peroxodi-phosphates has been reported to be similar to that of pyrophosphates.[45] A study of the hydrolysis over a pH range 0–7·6 and a range of ionic strengths 1·6-3·8 showed, however, that the kinetics were complex, and could be explained only if the variously protonated ions of peroxodiphosphate each had a specific velocity constant for its hydrolysis. Because of the complexity of the system, the nature of the transition state complex could not be deduced from these kinetic data, and hence the authors could not distinguish between the possibilities:

$$(1a) \qquad H_nP_2O_8^{(n-4)-} + H^+ \rightleftharpoons H_{n+1}P_2O_8^{(n-3)-}$$

$$(1b) \qquad H_{n+1}P_2O_8^{(n-3)-} + H_2O \rightarrow \text{products}$$

$$(2) \qquad H_nP_2O_8^{(n-4)-} + H_3O^+ \rightarrow \text{products}^{46}$$

The addition of thiocyanates increases the oxidizing power of peroxophosphates in electrolytic cells by the fixation of pseudocyanogen on the anode, which prevents active centres from catalyzing the formation of gaseous oxygen. The effect decreases with decreasing pH and is less for peroxophosphates than for persulphates, but greater than for perborates.[12]

## PEROXOPHOSPHATES

### Preparation and Properties

Several general methods are available for the preparation of peroxophosphates:

(*a*) neutralization of solutions of the peroxoacids with bases,
(*b*) anodic oxidation of suitable electrolytes,
(*c*) precipitation and double decomposition reactions.

(*a*) Solutions of the alkali metal, ammonium, magnesium or calcium salts of peroxomonophosphoric acid can be obtained in a comparatively pure state by neutralization, with the appropriate bases, of a concentrated solution of the acid prepared as described in references 5 and 11. On evaporation *in vacuo* at low temperature, or on the addition of water-miscible solvents, such solutions yield the crystalline salts.[11]

(*b*) Alkali metal and ammonium salts of peroxophosphoric acids can also be prepared by the anodic oxidation of phosphates; the yields obtained by the methods reported earlier[1] can be improved by adding small amounts of chromates and fluorides to the electrolyte, or by keeping the temperature low and using an anode current density not exceeding 0·020 amp./cm.[2, 13–5] Crude ammonium perphosphate made by this process may contain chromate, which is difficult to remove by recrystallization. However, metathesis with sodium perchlorate gives sodium permonophosphate which is more readily purified.[42]

As the formation of peroxophosphoric acid when fluorine is bubbled through orthophosphoric acid has been reported,[16] it was suggested that fluorine might be an intermediate in the mechanism of anodic oxidation in the presence of fluorides,[13] for example as illustrated by equations (v) and (vi):

$$\text{(v)} \qquad 2K_2HPO_4 + F_2 = K_4P_2O_8 + 2HF$$

$$\text{(vi)} \qquad K_4P_2O_8 + H_2O = K_2HPO_5 + K_2HPO_4$$

The formation of the peroxomonophosphate is minimized by performing the electrolysis under alkaline conditions; for example the electrolysis, at 10°C., of a solution containing 302 g. of potassium dihydrogen orthophosphate, 198 g. of potassium hydroxide, 120 g. of potassium fluoride and 0·355 g. of potassium chromate per litre, using a platinum dish as anode, a rotating platinum rod as cathode and a current density of 0·023 amp./cm.$^2$, gives up to 85% conversion to potassium peroxodiphosphate, which may be obtained by a single crystallization from the aqueous solution in purities up to 90% $K_4P_2O_8$[13, 17] and practically pure by three-fold recrystallization.

The yield of peroxophosphates is not enhanced by carrying out the electrolysis under specific conditions in the presence of a glow-discharge,[14] as is that of hydrogen peroxide from potassium hydrogen phosphate.[9] Optimum concentrations, pH and temperatures have been given for $H_4P_2O_8$ production. The current yield is good and increases with increasing over-voltage of the anode metal. Yields are diminished by addition of fluorides.[47]

(*c*) When soluble salts of barium, zinc or lead are added to aqueous solutions of potassium peroxodiphosphates, the following compounds are precipitated[13]:

$Ba_2P_2O_8,4H_2O$, a white micro-crystalline solid, slightly soluble in water, easily soluble in nitric or hydrochloric acid.
$Zn_2P_2O_8,4H_2O$, a white micro-crystalline precipitate, fairly soluble in water.
$Pb_2P_2O_8$, a heavy white precipitate, insoluble in water.

No precipitate is formed when magnesium sulphate solution or magnesia mixture is added to aqueous potassium peroxodiphosphate, and this observation affords a method of separating phosphate from peroxophosphate[13] in solution.

A colourless silver salt, $Ag_4P_2O_8$, is precipitated when potassium peroxodiphosphate reacts with silver nitrate in saturated ammonium nitrate at −14°C.,[18] but it quickly decomposes on standing according to reaction (vii):

$$\text{(vii)} \qquad 3Ag_4P_2O_8 + 3H_2O = 4Ag_3PO_4 + 2H_3PO_4 + 3O$$

By double decomposition with salts of perchloric acid, neutral and acid sodium and ammonium peroxodiphosphates can be prepared from the potassium salt[19] according to reactions of the type illustrated in equations (viii) and (ix):

$$\text{(viii)} \qquad K_4P_2O_8 + 4NaClO_4 = Na_4P_2O_8 + 4KClO_4$$

$$\text{(ix)} \qquad K_4P_2O_8 + 2HClO_4 + 2NaClO_4 = Na_2H_2P_2O_8 + 4KClO_4$$

the products being separated by fractional crystallization.

Tertiary butyl dialkyl esters of permonophosphoric acid have been made by the action of *tert.* butyl peroxide on dialkyl phosphorochloridates:

$$(RO)_2POCl + Me_3COOH = (RO)_2P(O)OOCMe_3 + HCl$$

They are moderately stable solids, but the corresponding aryl esters deflagrated on isolation.[34]

Thermal decomposition of the alkyl esters gives 55–80% yields of tetraalkyl pyrophosphates[48]:

$$(RO)_2POOOCMe_3 \rightarrow ((RO)_2PO)_2O \quad \text{etc.}$$

Although the preparation of peroxomonophosphates has been reported,[49] little has been recorded of their properties; more is known about the formation and behaviour of peroxodiphosphates, for example:

*Neutral potassium peroxodiphosphate*, $K_4P_2O_8$, is very soluble in water, but crystals can be separated by slow concentration over sulphuric acid of electrolytes resulting from anodic oxidation of the orthophosphate. Stored in well-stoppered bottles the crystalline salt is stable.[13,17] The oxidation of freshly reduced solutions of leuco-malachite green and leuco-indigo by potassium peroxodiphosphate occurs slowly at room temperature, but instantly in the presence of a trace of silver nitrate,[13] the catalytic effect of which is possibly due to the decomposition reaction (equation vii).

*Acid potassium peroxodiphosphate* has been prepared[19] by the dropwise addition of an aqueous solution of perchloric acid to a well-stirred neutral potassium peroxodiphosphate solution, both solutions being ice-cold:

$$K_4P_2O_8+2HClO_4 = 2KClO_4+K_2H_2P_2O_8$$

After removal of the relatively insoluble potassium perchlorate, the acid perdiphosphate is precipitated by the addition of methanol. Crystallization from a water–methanol solvent gives phosphate-free, colourless needles, readily soluble in water with a composition corresponding to $K_2H_2P_2O_8$. Being free from chromate and phosphate, it is a useful source for the preparation of the neutral salt for spectroscopic standards.[19]

The primary and tertiary salts have not been reported.

*Neutral sodium peroxodiphosphate* is more readily prepared by double decomposition, according to equation (iv), than by direct anodic oxidation of sodium orthophosphate.[19] After separation of the less soluble potassium chlorate, recrystallization of the crude product from water yields pure $Na_4P_2O_8,20H_2O$ in the form of colourless hexagonal plates moderately soluble in water, the solution being weakly alkaline. On exposure to air at room temperature the crystals rapidly effloresce to the hexahydrate $Na_4P_2O_8,6H_2O$. Tensimetric measurements[19] show the existence of $Na_4P_2O_8,18H_2O$, and also indicate that the hexahydrate exists in two forms, one of which changes into a second unstable form between 30° and 40°C. The transition is accelerated by the presence of the unstable phase and rapid decomposition thus ensues.

*Acid sodium peroxodiphosphate* is prepared from the neutral potassium salt by double decomposition under ice-cold conditions, according to equation (ix), the perchloric acid being added first, followed by the sodium perchlorate solution. After purification by recrystallization, colourless prisms, moderately soluble in water, with the composition $Na_2H_2P_2O_8,2H_2O$ are formed.[19]

*Neutral ammonium peroxodiphosphate* is obtained in good yield by electrolysis,[13,15] but is not easily separated from solution in the solid state, since the ammonium ion is liable to undergo oxidation by the $P_2O_8^{4-}$ ion to form ammonium phosphate and ammonium nitrate.[13] However, the double decomposition technique using ammonium perchlorate, when carried out under well-controlled, ice-cold conditions, gives colourless crystals with the composition $(NH_4)_2P_2O_8,2H_2O$.

*Acid ammonium peroxodiphosphate* is obtained[19] as described for the corresponding sodium salt, using ammonium instead of sodium perchlorate. The compound $(NH_4)_2H_2P_2O_8$ crystallizes as colourless needles readily soluble in water and having an acid reaction.

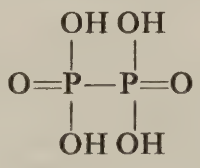
The peroxophosphates of rubidium and cæsium are more easily prepared by anodic oxidation than those of potassium, even without fluorides or chromates being present.[13,15] Lithium peroxodiphosphate, $Li_4P_2O_8,4H_2O$, derived from the potassium salt by a double decomposition reaction with lithium perchlorate,[30] is thought on the basis of nuclear magnetic resonance evidence to have a symmetric structure.[3] Potentiometric and conductimetric titrations also revealed that the corresponding acid possesses one strongly dissociated hydrogen atom per phosphorus atom, which suggests the presence of the –P–O–O–P– group in the molecule.[3]

## Ionization Constants and Structures

The pH titration curves of tetramethylammonium peroxodiphosphate against hydrochloric acid at 25°C., a typical example of which is shown in Fig. 1, have been obtained at a series of ionic strengths, and give figures for the third and fourth ionization constants[20] which on extrapolation to infinite dilution yield the values: $K_3 = 6{\cdot}6 \pm 0{\cdot}3 \times 10^{-6}$; $K_4 = 2{\cdot}1 \pm 0{\cdot}1 \times 10^{-8}$.

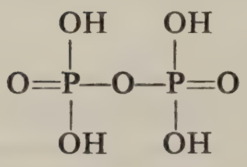
Approximate values for the first and second ionization constants, deduced from the trends observed in other tetrabasic acids of similar structure (see Fig. 2) are: $K_1 \simeq 2$; $K_2 \simeq 3 \times 10^{-1}$.

The three related phosphorus acids referred to in Fig. 2 may be represented by the following structures:



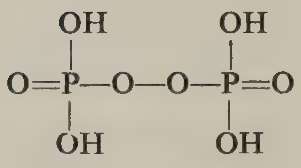
$$\mathrm{O{=}\underset{OH}{\overset{OH}{P}}{-}\underset{OH}{\overset{OH}{P}}{=}O}$$

hypophosphoric acid



$$\mathrm{O{=}\underset{OH}{\overset{OH}{P}}{-}O{-}\underset{OH}{\overset{OH}{P}}{=}O}$$

pyrophosphoric acid



$$\mathrm{O{=}\underset{OH}{\overset{OH}{P}}{-}O{-}O{-}\underset{OH}{\overset{OH}{P}}{=}O}$$

peroxodiphosphoric acid

the first two of which have been established by physical methods, whilst that of the peroxoacid is generally accepted. It has been suggested[20] that the increasing acid strength, in the order hypo-, pyro- and peroxo-acids, may be attributed to the increasing electro-negativity of the additional oxygen atoms attached to the phosphorus along the series; this facilitates the removal of hydrogen ions, by decreasing the electron density at the hydrogen atoms. It may also be supposed that inductive effects, due to intramolecular charges, decrease as the central P atoms become further separated.

The values of the formation constants of complex ions of peroxodiphosphoric acid with cations, e.g. $Li^+$, $K^+$, $Mg^{2+}$, compared with the constants of the complex ions of these metals with pyrophosphoric acid, support the structural configuration proposed above for the peroxoacid.[20] The Raman and infra-red spectra of potassium, sodium and ammonium peroxodiphosphates are also in conformity with a structure of this type, in which the two phosphorus atoms are in a *trans* configuration to one another.[35]

A polarographic method has been described for the determination of peroxo-, mono- or di-phosphates, separately or together.[36]

Although not definitely established, it is considered likely from their chemical and physical properties[20] and by analogy with the peroxosulphates, that the various peroxophosphate ions reported have the structures illustrated below (Fig. 3). Others,

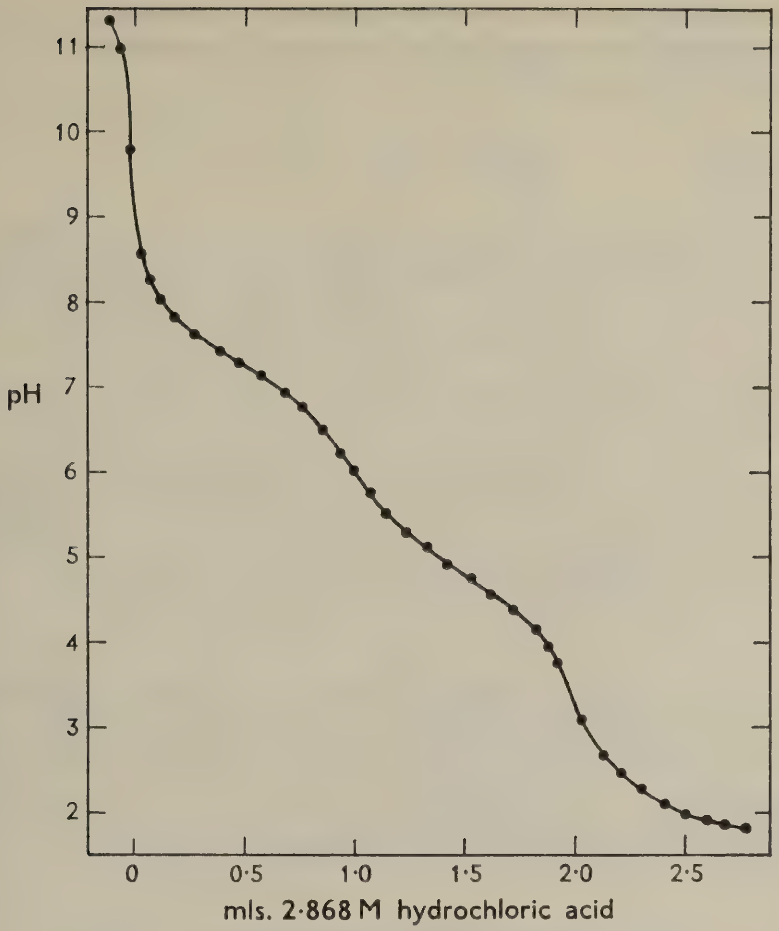


FIG. 1.—Titration curve for the peroxodiphosphate ion

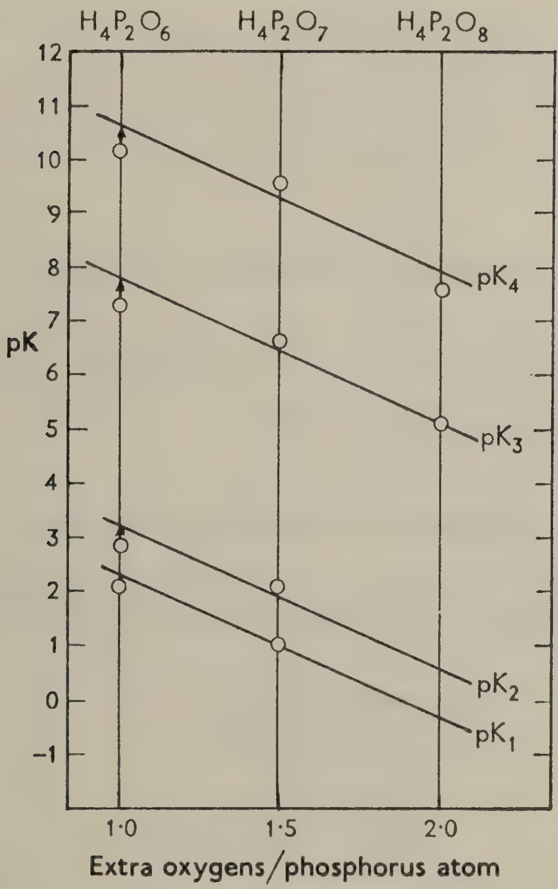

FIG. 2.—The effect of structure on the acidity of three related phosphorus acids

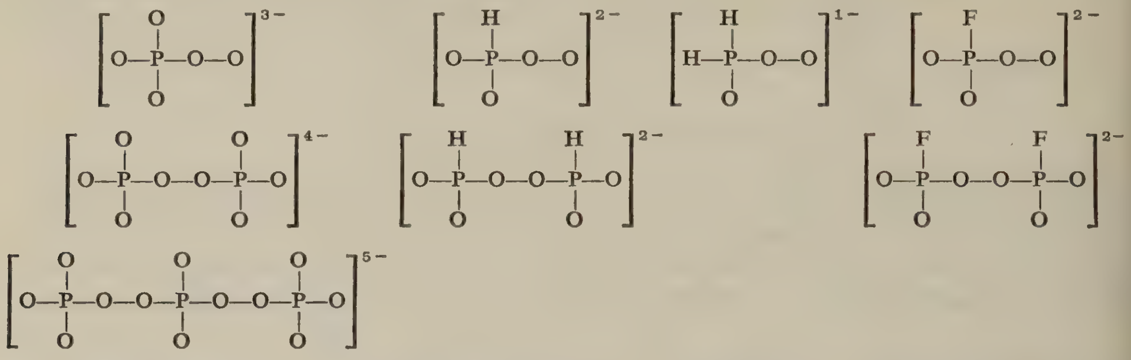
more complex, or (less probably) with phosphorus in a lower valency state, can be visualized, for example the hypothetical peroxopolyphosphoric and the peroxohypophosphorous ions formulated in Fig. 3.



Peroxomono-, di- and (tri-) phosphate ions

Peroxomono- and diphosphite ions

Peroxomono-hypophosphite ion

Peroxomono-fluoromono-phosphate and peroxodifluoro-diphosphate ions

FIG. 3.—Probable structures of the peroxophosphate ions

## Uses

The practical application of peroxophosphates has received little study so far, but they have been suggested as detoxicants for hydrogenation catalysts which have been poisoned by sulphur compounds, such as cysteine, $\beta$-thionaphthol, thiophen[24-5] or carbon disulphide,[26] or by phosphorus compounds such as dimethylphenylphosphine.[27] Desorptive washing of the poisoned platinum catalyst by the peroxophosphate solution restores its activity to the original value.

## PEROXOPHOSPHITES

When sodium hypophosphite or phosphite is oxidized in dilute aqueous solution with oxygen containing a little ozone or fluorine, the presence, in solution, of compounds which have oxidizing properties resembling those of the peroxophosphates has been reported.[21] Peroxomono- and peroxodiphosphorous acids have been suggested as intermediates in the chain mechanism proposed for this autoxidation reaction.

## PEROXOFLUOROPHOSPHATES

Anodic oxidation of alkali metal or ammonium salts of monofluorophosphoric acid, or of the acid itself, is believed to form peroxofluorophosphoric acids or salts analogous to the peroxophosphoric acids already described.[22-3] These compounds are also discussed in Section XXX.

## PHOSPHATE PEROXOHYDRATES

A number of neutral or alkaline phosphates form compounds with hydrogen peroxide, in which the $H_2O_2$ molecule takes the place of water of hydration[15, 28-9, 50] for example:

$Na_3PO_4,2H_2O_2$
$Na_2HPO_4,2H_2O_2$
$K_4P_2O_7,3H_2O_2$
$Na_4P_2O_7,2H_2O_2$
$Na_4P_2O_7,2H_2O_2,8H_2O$
$Na_5P_3O_{10},2H_2O_2,H_2O$

On solution in water these compounds quickly yield hydrogen peroxide and do not therefore oxidize iodides as rapidly as the salts of the true peroxophosphoric acids themselves. They are generally prepared by mixing concentrated hydrogen peroxide with the respective anhydrous salts.

### SECTION XXX

# THIOPHOSPHOROUS AND THIOPHOSPHORIC ACIDS AND THEIR SALTS

BY (MRS.) C. A. CLARK

## THIO-ORTHOPHOSPHORIC ACIDS

ALTHOUGH many salts of the phosphorus thio-acids have been prepared (Mellor, VIII, 1061–71), the acids themselves have not been studied extensively. This may be due to the belief that they all decompose spontaneously in solution.[1-3] Dithiophosphoric acid, $H_3PO_2S_2$, and monothiophosphoric acid, $H_3PO_3S$, were discovered in an attempt to prepare tetrathiophosphoric acid, $H_3PS_4$, from barium tetrathiophosphate, $Ba_3(PS_4)_2,12H_2O$, by treatment with acid.[4] Any tetrathiophosphoric acid formed is hydrolyzed at once:

$$H_3PS_4+H_2O = H_3POS_3+H_2S$$

The trithio-acid is also unstable in solution:

$$H_3POS_3+H_2O = H_3PO_2S_2+H_2S$$

Dithiophosphoric acid is more stable and can be detected in solution. It is more slowly hydrolyzed to the relatively stable monothiophosphoric acid.

### Preparation and Properties of Free Thiophosphoric Acids

Monothiophosphoric acid (phosphorothioic acid, $H_3PO_3S$) is best prepared from barium dithiophosphate and sulphuric acid. By using this salt the amount of hydrolysis of the monothiophosphoric acid ultimately formed is greatly reduced. A 5% solution of the acid can be obtained; this decomposes very slowly on standing, evolving hydrogen sulphide and, if air is present, depositing sulphur. The pure acid may be obtained by ion-exchange removal of pyridine from its pyridinium salt, and freeze-drying of the eluate.[5] The monohydrate, $H_3PO_3S,H_2O$, is the final product.

The acid decomposes very slowly below room temperature; less than 10% of a 3·6% solution in water decomposes after 8 weeks at −2°C. If water is distilled under vacuum from a 5% solution at 0°C. an oily liquid containing *ca.* 84% $H_3PO_3S$, sp. gr. 1·7, remains. On further cooling it solidifies at −60° to a glass. If the liquid is warmed to 50°, hydrogen sulphide is vigorously evolved. The acid solution cannot be made more concentrated than 84% under these conditions.

Monothiophosphoric acid reduces ferricyanide in a mole-for-mole ratio, forming a phosphorothioate dimer. The kinetics of the reduction are of second order with respect to the reactants over the pH range 5·8–7·8 (ionic strength $\mu = 0{\cdot}035$–$0{\cdot}06$, temperature 15°–40°) and the rate constant shows a minimum at pH 6·2. Free radical intermediates were demonstrated. From a potentiometric titration of trisodium thiophosphate against N. hydrochloric acid at 23°, three apparent dissociation constants were evaluated: $pK_1 < 2$, $pK_2 = 5{\cdot}75$, $pK_3 = 10{\cdot}4$.[68]

Monothiophosphoric acid is also the end-product of the hydrolysis of thiophosphoryl fluoride, $PSF_3$, which is believed to occur in stages:

$$PSF_3 \rightarrow HPOSF_2 \rightarrow H_2PO_2SF \rightarrow H_3PO_3S$$

Dithiophosphoric acid (phosphorodithioic acid, $H_3PO_2S_2$) may be prepared by acidifying barium tetrathiophosphate, $Ba_3(PS_4)_2$, or barium dithiophosphate, the former being preferable.[4] If the dithio-salt is used, considerable hydrolysis of the dithiophosphoric acid formed occurs during the preparation. Even when barium tetrathiophosphate is used the preparation must be carried out in saturated hydrogen sulphide solution at 0°C. to suppress hydrolysis. Rapid neutralization of the acid solution with sodium hydroxide solution gives a sodium salt, the crystal form and *X*-ray diagram of which are characteristic of sodium dithiophosphate. A 2·3% solution of dithiophosphoric acid hydrolyzes completely to monothiophosphoric acid in 10 hr. at 0°C.[4]

Tetrathiophosphoric acid (phosphorotetrathioic acid, $H_3PS_4$) is prepared by treating sodium tetrathiophosphate with hydrochloric acid and pouring the vigorously stirred mixture into acetone at −70°C. Yields as high as 96% were claimed.[6−7]

The rate of hydrolysis of monothiophosphoric acid has been studied in detail; a plot of the observed rate constant *vs.* pH gives a bell-shaped curve with a rate maximum of $1{\cdot}64\times10^{-4}$ sec.$^{-1}$ at 52·8°C. and pH 3·0. Another rate maximum is observed at pH 8.[8] The rate constants for hydrolysis of the acid at 52·8° in a solution of 1 M. ionic strength are $2{\cdot}43\times10^{-5}$ sec.$^{-1}$ for the neutral acid, $16{\cdot}7\times10^{-5}$ sec.$^{-1}$ for the monoanion, $3{\cdot}81\times10^{-5}$ sec.$^{-1}$ for the dianion and $1{\cdot}56\times10^{-5}$ sec.$^{-1}$ the trianion.[9]

Monothiophosphoric acid is oxidized by iodine in solution. The reaction course is probably[10]:

$$2[H_2PO_3S]^- + I_2 \rightleftharpoons [HPO_3S\text{–}SPO_3H]^{2-} + 2I^- + 2H^+$$

No physical measurements appear to have been made on trithiophosphoric acid, which is rapidly hydrolyzed in solution. Tetrathiophosphoric acid is even more unstable, and has been reported to have a half-life of about 20 min. at 20°C.[11] In both cases the final product of hydrolysis is monothiophosphoric acid.

The sulphur content of the thiophosphoric acids may be determined by treatment with excess of iodine in alkaline solution and back-titration of the acidified solution with thiosulphate. Phosphorus can be determined as ammonium phosphomolybdate by the Lorenz method.[4]

## THIOPHOSPHATES

There are two basic routes for the preparation of salts of the thiophosphoric acids. One uses a starting material, such as a thiophosphoryl halide or phosphorus sulphide, which already contains P–S bonds, and the other involves the formation of P–S bonds in the course of the preparation.

### Monothiophosphates

Trisodium monothiophosphate dodecahydrate (trisodium phosphoromonothioate, $Na_3PO_3S,12H_2O$) has been prepared by refluxing thiophosphoryl chloride, $PSCl_3$, with aqueous sodium hydroxide.[12−3] When the mixture is cooled in ice the solid thiophosphate separates out and can be filtered off and reprecipitated from aqueous solution with methanol. Thiophosphoryl fluoride can also be used as starting material.[14] The anhydrous salt is obtained when the hydrated salt is suspended in anhydrous methanol; after an hour the crystals are filtered off and heated at 100°C. for 1 hr.[12] Sodium monothiophosphate has also been prepared by heating a finely powdered 1 : 1 mixture of sodium metaphosphate and anhydrous sodium sulphide to 750°C. in an atmosphere of nitrogen, or *in vacuo*[15]:

$$NaPO_3 + Na_2S = Na_3PO_3S$$

*X*-ray studies show that the product of this reaction is identical with that obtained from alkaline hydrolysis of thiophosphoryl chloride.[15] The product is only 87% pure since water in the metaphosphate takes part in the reaction:

$$H_2O + Na_2S + NaPO_3 = Na_3PO_4 + H_2S$$

Sodium hydroxide and sodium carbonate in the sulphide also yield phosphate:

$$2NaOH + Na_2S + 2NaPO_3 = 2Na_3PO_4 + H_2S$$
$$Na_2CO_3 + NaPO_3 = Na_3PO_4 + CO_2$$

The impurities may be precipitated from a solution of the crude thiophosphate by careful addition of magnesium sulphate solution, avoiding an excess of the reagent, which redissolves the precipitate. Good yields of sodium monothiophosphate can also be obtained by the action of sodium trithiocarbonate on metaphosphates, particularly sodium trimetaphosphate.[61] Trisodium monothiophosphate dodecahydrate can be recrystallized from aqueous alcohol.[15]

The solubility of the hydrate in water is given in Table I.[12]

*Table I.—Solubility of Trisodium Monothiophosphate Dodecahydrate in Water*

| Temperature °C. | Solubility g./l. |
|---|---|
| 4 | 21·2 |
| 18 | 79·2 |
| 28 | 132·7 |
| 38 | 241·5 |

The crystals of trisodium monothiophosphate dodecahydrate are rhombic, with parameters $a = 12{\cdot}58$ A., $\alpha = 42{\cdot}3°$. [16] There does not appear to be any mixed crystal formation between the thiophosphate and the corresponding phosphate, $Na_3PO_4,12H_2O$; the *X*-ray diffraction pattern of each component appears to be unaffected by the presence of the other.

The positions and intensities of the bands in the infra-red spectrum of the dodecahydrate are given in Table II.[17]

*Table II.—Infra-red Absorption Frequencies (cm.$^{-1}$) of Trisodium Monothiophosphate Dodecahydrate*

| | | | |
|---|---|---|---|
| 3430 | s | 1068 | s |
| 1642 | m–w | 988 | vw |
| 1252 | w | 952 | m–s |
| 1157 | m–s | 860 | m–s |
| ~1125 | m–s | | |

The infra-red spectra of trisodium monothiophosphate and its dodecahydrate are given in Figs. 1 and 2.[18]

At room temperature the solid hydrate smells slightly of hydrogen sulphide, indicating slow decomposition; at 60°C. decomposition is rapid.[12] Investigation of the thermal behaviour of the salt using the techniques of thermogravimetry and differential thermal analysis shows that an endothermic change occurs at *ca.* 48°C. corresponding to the transformation[18]:

$$Na_3PO_3S,12H_2O = Na_3PO_3S,9H_2O + 3H_2O$$

At 64°C. the nonahydrate dissolves in its own water of crystallization, at the same time undergoing partial hydrolysis. The subsequent dehydration to the anhydrous salt is reversible and if the anhydrous salt is kept in a current of nitrogen saturated with water vapour at *ca.* 20°C., it takes up water rapidly to form the nonahydrate which then slowly changes to the dodecahydrate.[18]

Anhydrous trisodium monothiophosphate is very stable at room temperature, and does not decompose when heated to 100°C. in air. It does not absorb moisture from the air at relative humidities below 31%.[12] The salt is stable in oxygen up to 296°C. At this temperature the P–S bond is broken in a highly exothermic reaction involving the formation of phosphate, pyrophosphate, sulphur dioxide, sulphate and elemental sulphur.[18] If the anhydrous salt is heated *in vacuo* there is no evolution of sulphur dioxide, but slow liberation of sulphur begins at *ca.* 300°C., decomposition being complete only at 800°C. The residue contains sodium sulphide and compounds containing phosphorus in a low oxidation state.[18]

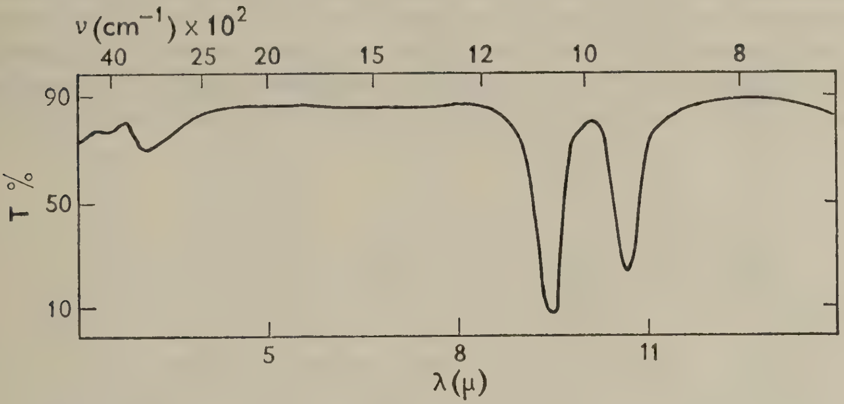

FIG. 1.—Infra-red spectrum of anhydrous trisodium monothiophosphate

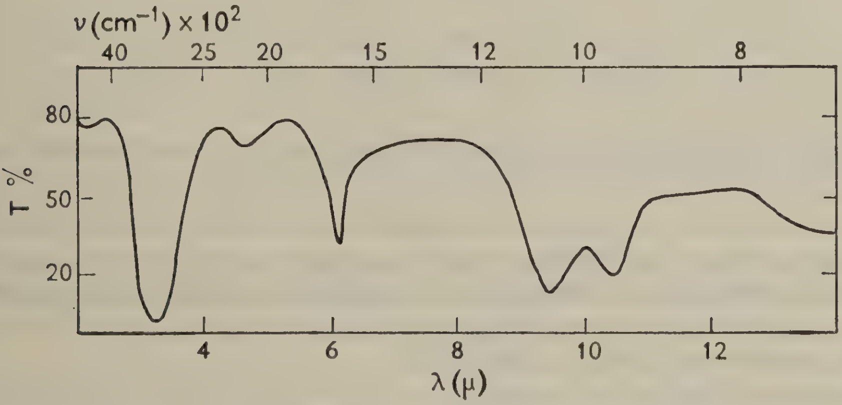

FIG. 2.—Infra-red spectrum of trisodium monothiophosphate dodecahydrate

Aqueous solutions of trisodium monothiophosphate decompose very slowly at room temperature[61]; addition of sodium carbonate stabilizes the solution. Acidification of the solution gives the disodium salt, which is rapidly hydrolyzed to monothiophosphoric acid,[18] and finally to phosphoric acid.[19] The rate constant for hydrolysis of trisodium monothiophosphate in 1 M. sodium hydroxide at 50°C. has been determined as $2{\cdot}5 \times 10^{-4}$ min.$^{-1}$; silicone grease catalyzes the reaction, increasing the rate constant to $2{\cdot}1 \times 10^{-3}$ min.$^{-1}$.[20] Acid titration of a solution of trisodium monothiophosphate with a glass electrode gives two well defined waves at 25°, with p*K* values roughly 10·2 and 5·6.[21]

If a lead salt is added to a solution of trisodium monothiophosphate a white precipitate forms, which on warming rapidly turns black through formation of lead sulphide. This reaction may be used to determined the purity of crude trisodium monothiophosphate; the sulphur content may be determined by titration with alkaline iodine solution[15]:

$$Na_3PO_3S+4I_2+10NaOH = Na_3PO_4+8NaI+Na_2SO_4+5H_2O$$

An attempt has been made to prepare a trisodium salt, $NaS.PO(ONa)_2$, as a compound distinct from $NaO.PS(ONa)_2$, starting with trimethyl phosphoromonothionate, $PS(OCH_3)_3$.[22] Monosodium dimethyl and disodium monomethyl monothiophosphates were isolated and characterized, but no salt differing from trisodium monothiophosphate was identified.

If concentrated hydrochloric acid is dropped into an aqueous solution of trisodium monothiophosphate at 10°C., and the mixture is then cooled to 0°C. and treated with alcohol, an oil appears. This oil crystallizes on being stirred with acetone and cooled in an ice–salt mixture. The composition $Na_2HPO_3S,5H_2O$ was attributed[4,18] to these crystals which were very hygroscopic. Their infra-red spectrum is given in Fig. 3.

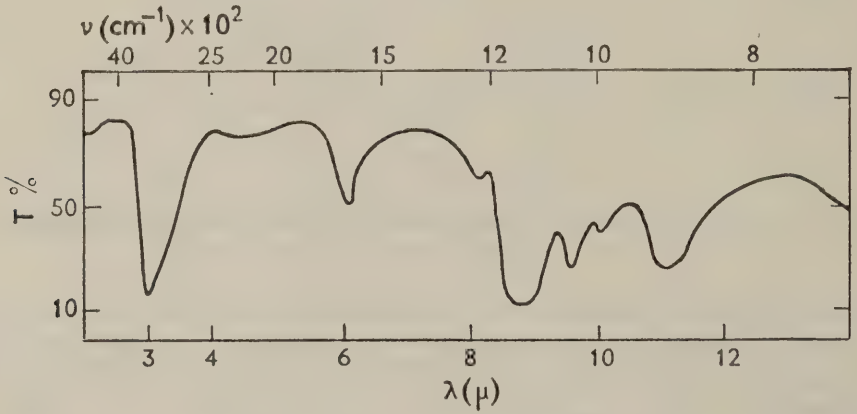

FIG. 3.—Infra-red spectrum of disodium monothiophosphate pentahydrate

A fairly pure sample of anhydrous disodium monothiophosphate has been obtained by dehydrating the hydrate over phosphoric acid in a desiccator.[23] The infra-red band positions and intensities for the hydrated disodium monothiophosphate in potassium bromide discs, and the Raman band positions and intensities for an aqueous solution are given in Table III.[23]

In an improved method of preparation of disodium monothiophosphate the treatment with alcohol was accompanied by scratching, and the salt was precipitated in the reaction solution.[24] This product was shown to be the hydrate, $Na_2HPO_3S$, $6{\cdot}5H_2O$. It was stable in air for a short period, but yielded the phosphate in 1–2 days. Hydrogen sulphide is evolved when this salt is heated to 40°C., and at 50°C. a clear melt is obtained.[24]

Trisodium monothiophosphate can be detected by liberation of iodine after paper chromatographic separation in quantities as small as 0·6 μg. (using perchloric/periodic acid medium) and 0·2 μg. (using iodine/sodium azide medium).[25] Paper-chromatographic spots developed with an aqueous solution of sodium fluoresceinate and silver nitrate appear green in visible light and dark under ultra-violet light.[26]

Potassium monothiophosphate has been prepared by hydrolyzing thiophosphoryl chloride with potassium hydroxide solution under reflux and cooling the product in an ice bath. The salt is purified by repeated crystallization from methanol. It is difficult to remove all traces of potassium chloride, possibly because it is slightly soluble in a methanol–water mixture.[12] The potassium salt forms no hydrate.

Wedge-shaped crystals of the monopotassium salt, $KH_2PO_3S$, are precipitated by methanol–ether from an aqueous solution prepared by neutralizing monothiophosphoric acid to pH 4·5 with potassium hydroxide, while at pH 9 the dipotassium salt, $K_2HPO_3S$, can be isolated.[62]

When thiophosphoryl chloride is refluxed with concentrated aqueous ammonia only phosphate and ammonium chloride are obtained as the reaction products.

*Table III.—Infra-red and Raman Absorption Frequencies (cm.$^{-1}$) for Disodium Monothiophosphate*

However, if ammonia is slowly added to ice-cold thiophosphoryl chloride with vigorous stirring and the mixture then treated with alcohol and cooled in an ice-salt mixture, a precipitate of diammonium monothiophosphate, $(NH_4)_2HPO_3S$, mixed with ammonium chloride, is obtained.[18] The salt is purified by recrystallization. It decomposes on heating, probably forming first diammonium monothiopyrophosphate and then ammonium metaphosphate.[18] The salt may be completely dehydrated over sulphuric acid in a desiccator.[23] The infra-red bands for anhydrous diammonium monothiophosphate are given in Table IV.[23]

*Table IV.—Infra-red Absorption Frequencies (cm.$^{-1}$) for Anhydrous Diammonium Monothiophosphate*

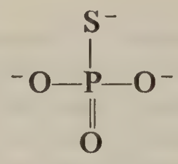
Rubidium monothiophosphate, $RbH_2PO_3S$, and cæsium monothiophosphate, $CsH_2PO_3S$ (platelets) are obtained by reaction of the respective chlorides with concentrated aqueous $Na_3PO_3S$ at pH 4.[62]

Attempts have been made to prepare neutral salts of the alkaline-earth metals by precipitation with a solution of a sodium monothiophosphate.[4] Addition of a barium or strontium salt to trisodium monothiophosphate in solution yields the mixed salt $NaBaPO_3S,8H_2O$ or $NaSrPO_3S,8H_2O$, whichever reagent is in excess. A calcium salt gives with trisodium monothiophosphate a slimy precipitate which resembles an orthophosphate. The precipitate appears to be a mixture of hydrated tricalcium monothiophosphate and sodium calcium monothiophosphate octahydrate, $NaCaPO_3S,8H_2O$. The tricalcium salt cannot be separated from this, but if the reaction is carried out by slowly dropping calcium chloride solution into a vigorously stirred solution of trisodium monothiophosphate, rectangular crystals of sodium calcium monothiophosphate octahydrate form in the solution.[4] Refluxing of calcium acetate hemihydrate with diethyl phosphite and sulphur in a mixture of ethyl alcohol and acetic anhydride gave a salt which analysis suggested was monocalcium monothiophosphate, $Ca(H_2PO_3S)_2$.[27]

The heavy-metal monothiophosphates are all unstable, and decompose quickly into the corresponding sulphides. The white precipitate formed when a cadmium salt is added to a solution of a monothiophosphate rapidly turns yellow.[4] The lead salt, which is also white, turns black.[4] Attempts to prepare silver monothiophosphate gave only a black precipitate of silver sulphide,[4,18] In this respect these thiophosphates show some resemblance to the heavy-metal thiosulphates, which decompose to give sulphides and sulphuric acid. Unstable thallium salts, $Tl_3PO_3S$ (pale yellow rhombic crystals) and $TlH_2PO_3S$ (pale brown crystals), have also been prepared by metathesis from $Na_3PO_3S$ and thallium nitrate.[62] When an excess of monothiophosphate ion is added to sodium acetate solution containing Co(II) ions the solution turns deep blue; under the same conditions Ni(II) ions form a greenish-white precipitate, Fe(III) gives a dark brown precipitate, and Mn(II), Al(III) and Zn(II) ions yield white precipitates.[28] The colour of a solution of Cr(III) ions is not affected by monothiophosphate ion, and it has been suggested that this difference might be of some analytical use.[28] On the basis of the products resulting from the reaction of monothiophosphates with alkyl halides, it has been suggested[67] that the ion exists mainly in the mesomeric form



$$^{-}O\text{—}\overset{\displaystyle S^{-}\atop|}{\underset{\|\atop\displaystyle O}{P}}\text{—}O^{-}$$

## Dithiophosphates

Trisodium dithiophosphate (trisodium phosphorodithioate, $Na_3PO_2S_2$) may be prepared from barium tetrathiophosphate, $Ba_3(PS_4)_2,12H_2O$, by treatment with acid.[4] The tetrathiophosphoric acid first formed is immediately hydrolyzed *via* trithiophosphoric acid to dithiophosphoric acid. The acid solution is neutralized with solid sodium hydroxide and a few grams of sodium sulphide are added, together with alcohol. The precipitate formed is dissolved in water and reprecipitated with alcohol to give a product which contains 10% of sodium monothiophosphate. The salt obtained is trisodium dithiophosphate undecahydrate, $Na_3PO_2S_2,11H_2O$, which has an orthorhombic structure, *Pnma* or *Pnz₁a*, with $a = 12{\cdot}51$ A., $b = 13{\cdot}94$ A., $c = 9{\cdot}48$ A., and is isomorphic with the trithiophosphate, $Na_3POS_3,11H_2O$.[16] Anhydrous trisodium dithiophosphate can be obtained by treating the undecahydrate with anhydrous methanol.[62] The $^{31}P$ nuclear magnetic resonance chemical shift for trisodium dithiophosphate in 3% sodium sulphide solution is $-61$ to $-62$ p.p.m., relative to 85% phosphoric acid.[11,14]

Trisodium dithiophosphate reacts with alkyl halides with the elimination of sodium halides, giving alkyl dithiophosphates.[29]

The spots of trisodium dithiophosphate obtained by paper chromatography may be developed with a mixture of sodium fluoresceinate and silver nitrate in aqueous solution giving a green colour, appearing dark under ultra-violet light.[26]

If a suspension of magnesium oxide in ice-cold water is treated with powdered tetraphosphorus decasulphide a precipitate of magnesium dithiophosphate,

$Mg_3(PO_2S_2)_2$, is obtained.[30] By treating this salt with the appropriate base dithiophosphates of sodium, potassium, ammonium, calcium and barium are obtained.[30] Octahedral crystals of triammonium dithiophosphate dihydrate, $(NH_4)_3PO_2S_2,2H_2O$, can be obtained by the action of aqueous ammonia on tetraphosphorus decasulphide at 40°–50°C., or by keeping triammonium trithiophosphate under concentrated aqueous ammonia for 3 days.[62]

Tribarium dithiophosphate, $Ba_3(PO_2S_2)_2$, is said to be formed when barium tetrathiophosphate is dissolved in ice-cooled hydrogen sulphide water.[4] The formation of dithiophosphoric acid, $H_3PO_2S_2$, when sodium acid sulphate is added to the solution, is evidence for the presence of the barium salt.[4]

Zinc dithiophosphate, $Zn_3(PO_2S_2)_2$, has been prepared by treating a solution of phosphorus pentasulphide in ammonia with ammoniacal zinc sulphate solution.[31] It may also be obtained by treating magnesium dithiophosphate with zinc oxide.[30]

Dithiophosphates of thallium and lead have been prepared from magnesium dithiophosphate.[30] Rodlets and needles of $TlH_2PO_2S_2$ can be obtained by using sodium or ammonium dithiophosphate. The manganese, mercury(II), thorium and lanthanum salts decompose fairly rapidly during drying.[30] The salts of bismuth, copper(II), mercury(I), nickel, cobalt, cadmium, silver and iron(II) decompose at once, even when the preparation is carried out in a mixture of alcohol and ice-cold water. Aluminium, zirconium and molybdenum dithiophosphates could not be prepared by this method.[30]

Palladous ions form very insoluble salts with dithiophosphates.[32] These salts are formed in the cold in acid or alkaline solution, and are decomposed only when boiled with mixtures of concentrated acids. These salts have been suggested as a possible means of separating palladium from other heavy metals.[32]

## Trithiophosphates

These are the least known of the thio-orthophosphates. No new method of prepreparing the salts seems to have been devised, and it is difficult to make physical measurements on the acid, which is rapidly hydrolyzed in solution.

*X*-Ray photographs of trisodium trithiophosphate undecahydrate showed it to have the orthorhombic structure, space group *Pnma* or $Pnz_1a$, although the crystals measured were not well formed.[16] The unit cell measurements are $a = 12{\cdot}60$ A., $b = 14{\cdot}02$ A., $c = 9{\cdot}33$ A., very little different from those of trisodium dithiophosphate undecahydrate. Powder photographs confirmed that the two salts are isomorphic.[16]

The $^{31}P$ nuclear magnetic resonance chemical shift for trisodium trithiophosphate in 3% sodium sulphide solution is $-86{\cdot}5$ p.p.m., relative to 85% phosphoric acid.[11,14]

A yellow spot, appearing dark under ultra-violet light, is observed when a paper chromatogram containing sodium trithiophosphate is developed with an aqueous solution of sodium fluoresceinate and silver nitrate.[26]

Triammonium trithiophosphate is obtained by the action of excess of concentrated aqueous ammonia on tetraphosphorus decasulphide at 0°–20°C. It forms fine needles or blunt prisms, which decompose in air and are hydrolyzed by aqueous ammonia to triammonium dithiophosphate. A flocculent yellow precipitate of the thallium salt, $Tl_3POS_3$, is obtained by adding a freshly prepared cold solution of sodium or ammonium trithiophosphate to excess of thallium nitrate solution.[62]

## Tetrathiophosphates

In spite of the instability of the parent acid, several salts of tetrathiophosphoric acid have been prepared and characterized.

Trisodium tetrathiophosphate octahydrate, $Na_3PS_4,8H_2O$, occurs in two crystalline forms, both monoclinic, space groups $P2_1/c$ and $P2_1/a$; the unit-cell constants are $a = 14{\cdot}7$ A., $b = 7{\cdot}09$ A., $c = 14{\cdot}15$ A., $\beta = 92°$, and $a = 13{\cdot}62$ A., $b = 12{\cdot}83$ A., $c = 8{\cdot}69$ A., $\beta = 104°$, respectively.[16] Crystals of the first form were always found to be twinned.[16] The salt is very soluble in water and hydrolyzes in solution, although it is fairly stable in air.[33]

The $^{31}$P nuclear magnetic resonance chemical shift for trisodium tetrathiophosphate in 3% sodium sulphide solution is −87·5 p.p.m.[11,14]

If the appropriate proportions of sodium sulphide, sodium hydrosulphide and tetraphosphorus decasulphide are heated together, an acid salt, disodium tetrathiophosphate, $Na_2HPS_4$, may be obtained.[34] Unless the mixture is heated only up to the point at which it has just fused, the salt decomposes with evolution of hydrogen sulphide. The existence of the salt was confirmed by treatment with absolute alcohol, when no mercaptan was formed; this showed that no free tetraphosphorus decasulphide was present.[34]

A tripotassium salt with behaviour similar to that of the corresponding sodium salt has been prepared by carefully fusing potassium sulphide pentahydrate with tetraphosphorus decasulphide in a porcelain dish.[33] On cooling the filtered solution small tetragonal rods separate. The salt dissolves readily in water with hydrolysis. Like the sodium compound, the salt is fairly stable in air and can be kept in a desiccator over sulphuric acid for many weeks, during which it loses part of its water of crystallization, but appears to be otherwise unchanged.[33] More water is lost on heating at 90°C. A crystal study shows that the salt belongs to the orthorhombic system, with the space group $D_{2h}^{16}$–*Pnma*, with *a*, $9{\cdot}10 \pm 0{\cdot}01$; *b*, $10{\cdot}51 \pm 0{\cdot}01$; and *c*, $9{\cdot}01 \pm 0{\cdot}01$ A., and density 2·13 (calc.).[65]

An ammonium tetrathiophosphate has been prepared by dissolving three times the theoretical amount, relative to ammonium sulphide, of tetraphosphorus decasulphide in a solution of aqueous ammonia saturated with ammonia and hydrogen sulphide.[33] After slow warming the solution is filtered and when kept thick prismatic crystals are formed. These crystals are very stable in air and can be dried without losing ammonia.[33]

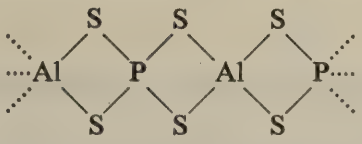
If a suspension of barium hydroxide in water is saturated with hydrogen sulphide, then gently warmed, any residue filtered off, and the cooled solution treated with trisodium tetrathiophosphate, a white curdy precipitate, said to be barium tetrathiophosphate, $Ba_3(PS_4)_2$, is immediately formed.[33] The precipitate, which become voluminous on shaking, is composed of fine microscopic needles which gradually turn yellow in air.

Boron tetrathiophosphate, $BPS_4$, has been prepared by heating boron and phosphorus, boron phosphide, or diboron trisulphide, $B_2S_3$, and phosphorus, with sulphur[35]:

$$\begin{aligned} B+P+4S &= BPS_4 \\ BP+4S &= BPS_4 \\ B_2S_3+2P+5S &= 2BPS_4 \end{aligned}$$

It could not be obtained by heating diboron trisulphide with tetraphosphorus decaoxide. Two modifications were observed, one when the preparation was carried out at 450°–500°C. and the other from a preparation at 650°–700°C. The low-temperature modification forms hygroscopic, colourless, orthorhombic crystals which rapidly decompose in air, giving off hydrogen sulphide. The lattice dimensions are $a = 5{\cdot}60 \pm 0{\cdot}06$ A., $b = 5{\cdot}25 \pm 0{\cdot}06$ A., $c = 9{\cdot}04 \pm 0{\cdot}06$ A., density $d_{20°} = 1{\cdot}98$ g./cm.$^3$ A chain structure has been proposed for these crystals.[35] This modification hydrolyzes to give boron phosphate, and no monothiophosphate could be detected. The high-temperature modification forms brown plates which are more stable in air than those of the low-temperature modification. The lattice dimensions are $a = 10{\cdot}38$ A., $b = 6{\cdot}05$ A., $c = 6{\cdot}69$ A., $\beta = 75°$. The colourless modification is transformed into the brown modification when heated at 650°C. Both modifications decompose on heating *in vacuo* above 750°C., and both explode when heated with air at 1000°C.[35]

Aluminium tetrathiophosphate, $AlPS_4$, could not be prepared by a similar method. It can be obtained as colourless needles and plates, however, when aluminium phosphide is heated at 650°C. in an atmosphere of sulphur.[36] The crystals are hygroscopic and decompose on exposure to air with evolution of hydrogen sulphide. The structure has been shown to be:



with Al–S distance of 2·1 A. in the *a* and *b* directions, P–S distances 2·1 A. in the *a* direction and 2·0 A. in the *b* direction, and Al–P distance 2·8 A.[36]

An *X*-ray study of crystals of copper(II) tetrathiophosphate, $Cu_3PS_4$, shows that they have a structure identical with that of enargite, $Cu_3AsS_4$.[37] The crystals are rhombic, space group $C_{2v}^7$, with two molecules in the unit cell, and contain $PS_4$ tetrahedra. The unit cell parameters are: $a = 6{\cdot}46 \pm 0{\cdot}02$ A., $b = 7{\cdot}43 \pm 0{\cdot}02$ A., $c = 6{\cdot}18 \pm 0{\cdot}2$ A.[37]

A zinc tetrathiophosphate has been prepared by fusion of tetraphosphorus decasulphide and zinc sulphide in an atmosphere of nitrogen at 315°–425°C.[31]

## THIOPHOSPHITES

A substance with a composition corresponding to ammonium monothiophosphite, $(NH_4)_2HPO_2S$, has been detected and isolated by ion-exchange chromatography. It is a white microcrystalline salt, which yields hydrogen sulphide and ammonium phosphite with acid, reduces silver nitrate to metallic silver, and reacts strongly with concentrated nitric acid or bromine water.[64]

It has been reported that hydrates of trisodium trithiophosphite (trisodium phosphorothioite) may be prepared by reaction of lower sulphides of phosphorus with sodium sulphide.[33] Sodium sulphide and tetraphosphorus heptasulphide react rapidly, cooling being necessary. The mixture changes to a thick liquid which is filtered through a warm-water filter and then cooled. On standing the thiophosphite separates in low yield as flat, rectangular, shiny crystals. If tetraphosphorus trisulphide is mixed with sodium sulphide a different hydrate is obtained.[33] The sodium sulphide melts on being warmed, and dissolves the tetraphosphorus trisulphide. A little water is added, and the thick liquid is filtered as before. Fine needles separate on standing; these have substantially the same properties as the product obtained from tetraphosphorus heptasulphide.[33]

The salt is readily soluble in water, apparently decomposing. Hydrogen sulphide is evolved when the solution is acidified, and it rapidly reduces permanganate. The crystals are stable in air.[33] On the basis of a vibration band at 1045 cm.$^{-1}$, said to be due to a P–O vibration, it has been suggested that this supposed thiophosphite salt is a mixture of phosphates.[38]

Ammonium trithiophosphite is reported to be a product of the reaction of tetraphosphorus heptasulphide with liquid ammonia.[39] It is insoluble in liquid ammonia at −33°C., and decomposes slowly in air above −25°C. *In vacuo* it is stable up to 100°C., when mixtures of thiophosphates of varying nitrogen content are formed. At 250°C. the salt decomposes to ammonia, hydrogen sulphide and polymeric PNS. In a stream of ammonia gas at 750°C. polymeric triphosphorus pentanitride, $(P_3N_5)_x$, is formed.

If a concentrated solution of barium sulphide is digested with tetraphosphorus heptasulphide, the solution filtered and a little alcohol added, a precipitate of barium trithiophosphite is formed.[33] This consists of fine, white, microscopic, rhombic prisms. The salt is fairly stable in air and can be kept for some weeks without decomposing. Hydrogen sulphide is evolved on treatment with acid, but even after boiling out all the hydrogen sulphide the solution has strong reducing properties.[33]

Paper-chromatographic studies of the hydrolysis products of tetraphosphorus heptasulphide detected an ion with a P:S ratio of 1:1 and fairly good reducing properties. The colour developed with silver nitrate solution in sulphuric acid

**Refs. p. 841**

resembles that developed by phosphite. The ion is probably monothiophosphite, $PO_2S^{3-}$; the $R_f$ value quoted is 0·75, compared with 0·60 for phosphate ion, $PO_4^{3-}$.[38,40]

## OTHER THIO-ACIDS OF PHOSPHORUS

Not many of the lower sulphur-containing acids of phosphorus are known. New ions were detected in the products of hydrolysis of tetraphosphorus heptasulphide.[38] Three unknown compounds with $R_f$ values 0·33 (P:S = 1:2), 0·64 and 0·75 (P:S = 1:1) were observed, the compound with $R_f$ value 0·75 having a lower reducing power than the other two. By analogy with phosphite and hypophosphite ions, the presence of dithiohypophosphite, $H_2PS_2^{2-}$ ($R_f$ value 0·33), monothiohypophosphite, $H_2POS^{2-}$ ($R_f$ value 0·64) and thiophosphite, $HPO_2S^{2-}$ ($R_f$ value 0·75) is suggested.[38]

A compound, $CuPS_2$, is obtained when copper, phosphorus and sulphur, or cupric sulphide and diphosphorus trisulphide, are heated together in a sealed tube under vacuum at 800°C. for 24 hr.[41] It is a yellow, amorphous powder, fairly stable in air, and does not appear to decompose when treated with cold de-aerated water. If heated in a sealed tube under vacuum, it melts over a temperature range of 890°–990°C., but solidifies completely at 910°C. The crystal form is a superstructure of the wurtzite type, with $a = 3·652$ A., $c = 6·085$ A., density 3·55 g./c.c. and P–S distance 2·252 A.[41] At 600°–1000°C. the compound dissociates according to the equation[41]:

$$4CuPS_2 = 2CuPS + Cu_2S + P_2S_5$$

The nature of the bonds between the atoms has not yet been determined.

## THIOPOLYPHOSPHATES

### THIODIPHOSPHATES (THIOPYROPHOSPHATES)

Di-, tri- and tetra-sodium thiodiphosphates have been prepared by reaction of suitable amounts of sodium sulphide and/or hydrosulphide with tetraphosphorus decasulphide[34]:

$$\begin{aligned} 2NaHS + P_2S_5 &= Na_2H_2P_2S_7 \\ NaHS + Na_2S + P_2S_5 &= Na_3HP_2S_7 \\ 2Na_2S + P_2S_5 &= Na_4P_2S_7 \end{aligned}$$

The reactants are ground together and heated until they fuse; if the heating is carried beyond this point hydrogen sulphide is lost from the mixture. Low yields of thiodiphosphate also result from the interaction of disodium phosphite and sulphur in an inert atmosphere.[56]

Hydrogen sulphide is evolved and sulphur deposited when sodium thiodiphosphates are brought into contact with water. Addition of alcohol is accompanied by evolution of a little hydrogen sulphide and acetaldehyde. No mercaptan is formed, showing that the product contains no tetraphosphorus decasulphide and is therefore a definite compound.[34]

Unlike pyrophosphate, ammonium thiodiphosphate gives no precipitate with magnesium, aluminium, manganese, iron, cobalt or nickel salts. Silver salts give a yellow precipitate, which slowly turns red-brown.[56]

### THIOTETRAPHOSPHATES

Hexasodium monothiotetraphosphate, $Na_6P_4O_{12}S$, is prepared by heating a finely-divided mixture of sodium sulphide and sodium metaphosphate in 1 : 4 ratio at 150°C.[42-3] The mixture solidifies to give a dark yellowish-green powder, which dissolves in water to give a milky precipitate of sulphur.[44] A glassy, colourless mass with composition $Na_6P_4O_{10}S_3$ is formed when sodium sulphide is heated to incandescence with tetraphosphorus decaoxide in a ratio of 1 : 2.[42-3] Hexasodium tridecathiotetraphosphate, $Na_6P_4S_{13}$, may be prepared by heating sodium sulphide and tetraphosphorus decasulphide[42-3]

$$3Na_2S + 2P_2S_5 = Na_6P_4S_{13}$$

Compounds with S : O ratios between these extremes may be prepared by fusing the stoicheiometric quantities of sodium tetraphosphate and sulphur or tetraphosphorus decasulphide. These compounds are all extremely soluble in water, and can be used as water-softeners.[42-3]

### OTHER THIOPOLYPHOSPHATES

Oxidation of sodium monothiophosphate with iodine in acid potassium iodide solution[10,59] or manganese dioxide in concentrated hydrochloric acid solution[60] yields a solution of disulphanediphosphonic acid. After neutralization with potassium hydroxide solution, and concentration at 30°C. under a water pump, sodium chloride crystallizes out leaving the salt dipotassium disulphanediphosphonate, $K_2H_2P_2S_2O_6$, in solution. This salt separates on concentration under vacuum in 35% yield, referred to the original weight of trisodium monothiophosphate used. It crystallizes from water as colourless, dense crystals containing no water of crystallization.[10] The salt has a solubility in water of 4·5 g./100 cm.$^3$ $H_2O$; the solution has a pH of *ca.* 5 at 20°C. The two hydrogen atoms may be titrated with alkali using phenolphthalein as indicator. The weakly alkaline solution obtained slowly decomposes to phosphate, hydrogen sulphide and sulphur.[10] Treatment of the salt with perchloric acid gives free disulphanediphosphonic acid.[10,59] Its *X*-ray powder diagram differs from that of the corresponding tetrathionate.[10]

Dipotassium disulphanediphosphonate decomposes when heated to 180°–230°C. yielding potassium metaphosphate and a gas, possibly hydrogen disulphide.[10]

A strongly acid solution of the salt is unaffected by iodine, but weakly acid and pure solutions decolorize iodine. The salt decomposes in the presence of concentrated nitric acid, and sulphur is deposited. A white lead salt is precipitated when lead acetate solution is added to a solution of dipotassium disulphanediphosphonate in water. When warmed this salt decomposes rapidly to lead sulphide. No precipitate is formed with barium chloride solution, but a silver nitrate solution reacts to give black silver sulphide.[10]

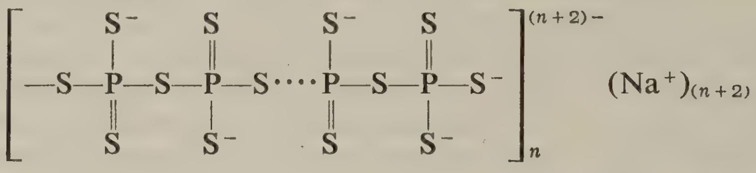
A reddish precipitate is formed when solutions of manganese chloride and dipotassium disulphanediphosphonate are mixed.[10] The precipitate has been assigned the formula $Mn(MnOH)_2P_2S_2O_6,3H_2O$, since three molecules of water are readily lost. More water is lost by heating at 100°C. over phosphorus pentoxide, and some decomposition occurs. The salt always contains some manganous phosphate, formed by hydrolysis during its preparation.[10] A barium salt is obtained from the sodium salt by addition of barium chloride solution at pH 4·5 and 0°C., and a colourless ammonium salt by addition of ammonium chloride followed by methanol. Iodine oxidation of the ammonium salt in acetic acid–ethanol solution gives polymeric $(NH_4PO_2S_2)_x$.[60]

Strontium polyphosphates containing various proportions of sulphur are obtained by dissolving sodium tetrathiophosphate in a strontium hydroxide suspension. On addition of alcohol a white crystalline powder is precipitated.[33]

Monothiophosphoric acid in ethereal solution reacts with sulphur dichloride to give trisulphanediphosphonic acid, $(HO)_2OPS{-}S{-}SPO(OH)_2$, and with sulphur monochloride to give tetrasulphanediphosphonic acid, $(HO)_2OPS{-}S{-}S{-}SPO(OH)_2$, in the form of oily dietherates.[45] The ether may be removed at 0°C. *in vacuo*; the compounds are not stable in air. They decompose in water, but precipitates of the barium salts $Ba_2O_6P_2S_3$ and $Ba_2O_6P_2S_4$, respectively, may be obtained by treating freshly prepared solutions of the acids with a suspension of barium hydroxide. Further polymers in the homologous series $(HO)_2OPS_xPO(OH)_2$ ($x = 1$–$8$) have been obtained by this method.[58]

Tetrathio-orthophosphoric acid reacts with the sulphur chlorides to give light-yellow plastic products which may be represented as $(PS_{5.5})_{2x}$ and $(PS_7)_x$.[45,57] The compounds are stable at room temperature *in vacuo*, are insoluble in organic solvents and water, but are decomposed by alkalis. They decompose on heating at *ca.* 220°C.

Sodium, silver and thallium thiometaphosphates, $(MPS_3)_x$, where $M = Na$, Ag or Tl, are prepared as yellow-brown glasses, by heating tetraphosphorus decaoxide with the appropriate metal sulphide.[46] The sodium thiometaphosphate is extremely hygroscopic. On dissolving in water it releases hydrogen sulphide and forms an acid solution. Addition of barium hydroxide to this solution leads to the formation of a precipitate of tribarium dithio-orthophosphate hexahydrate, $Ba_3(PO_2S_2)_2,6H_2O$. The compound reacts with liquid ammonia at –33°C. to give crystals of composition $NaNH_4(PS_3NH_2)$. The structure was shown to be that of a high molecular-weight polythiophosphate[46]:



$$\left[ -S-\overset{\overset{\large S^-}{|}}{\underset{\underset{\large S}{\|}}{P}}-S-\overset{\overset{\large S}{\|}}{\underset{\underset{\large S^-}{|}}{P}}-S\cdots\overset{\overset{\large S^-}{|}}{\underset{\underset{\large S}{\|}}{P}}-S-\overset{\overset{\large S}{\|}}{\underset{\underset{\large S^-}{|}}{P}}-S^- \right]_n^{(n+2)-} \quad (Na^+)_{(n+2)}$$

The silver and thallium compounds are stable in water and dilute acid, and do not dissolve in organic solvents. This inertness suggests that they are high molecular-weight polymers, almost completely covalently bonded.[46] A compound of trimetaphosphate composition, $Na_3P_3O_8S,6H_2O$, has been obtained by heating sodium hypophosphite with sulphur in a nitrogen atmosphere.[56]

## AMIDOTHIOPHOSPHATES

### THIOPHOSPHORIC TRIAMIDE

Thiophosphoric triamide (phosphorothioic triamide), $PS(NH_2)_3$, may be prepared by refluxing thiophosphoryl trichloride and ammonia in chloroform solution in the presence of ethylamine.[47] It is a colourless, crystalline solid, easily soluble in water. The compound is stable in dry air, but ammonia is evolved on contact with moist air; after a few weeks exposure the end-product is diammonium monothiophosphate, $(NH_4)_2HPO_3S$.

The infra-red absorption bands for solid thiophosphoric triamide are given in Table V.[48]

*Table V.—Infra-red Absorption Frequencies* (*cm.*$^{-1}$) *for Solid Thiophosphoric Triamide in Potassium Bromide*

| | |
|---|---|
| 3330 | 860 |
| 3240 | 715 |
| 1565 | 600 |
| 995, 1010, 1030, 1065 | 460 |
| 895, 930 | |

In aqueous solution, on the other hand, thiophosphoryl chloride and ammonia react exothermically, giving $NH_4(POS(NH_2)_2)$ and $(NH_4)_2(PO_2SNH_2)$.[63]

The $^{31}P$ nuclear magnetic resonance chemical shift for thiophosphoric triamide in dimethyl formamide solution is –59·4 p.p.m., relative to 85% phosphoric acid.[49]

The corresponding hydrazido compound, $PS(N_2H_4)_3$, could not be obtained by treating thiophosphoryl chloride with anhydrous hydrazine; hydrogen sulphide, phosphine and red-yellow polymers were obtained.[50] It has, however, been prepared from thiophosphoryl fluoride and hydrazine under pressure. Its infra-red spectrum has been discussed and partially assigned, the P–S and P–N valence vibrations being qualitatively in accord with the expected values.[69]

Diamidothiophosphoric fluoride, $PS(NH_2)_2F$, is formed when dry ammonia reacts with thiophosphoryl trifluoride, $PSF_3$.[51]

Sodium diamidothiophosphate is formed when the triamide is warmed with dilute sodium hydroxide[47]:

$$PS(NH_2)_3 + NaOH = NaOPS(NH_2)_2 + NH_3$$

Attempts to obtain the free acid were unsuccessful. If this salt is warmed with dilute acid, hydrogen sulphide is evolved. Ammonia is evolved when the compound is heated to 100°C. in a high vacuum and water-soluble compounds are formed. Impure triphosphorus decanitride is obtained as the final product of heating at 800°C. The preparation, and infra-red and Raman spectra of hydrated sodium, calcium, strontium, and barium diamidothiophosphates have been described. The salts can be obtained analytically pure.[66]

Disodium amidothiophosphate, $Na_2PO_2S(NH_2)$, is the product of saponification of diphenyl amidothiophosphate, $(C_6H_5O)_2PSNH_2$.[50] Chromatography shows that the salt is homogeneous. The reaction of hydrazine hydrate with diphenyl chlorothiophosphate, $(C_6H_5O)_2PSCl$, in ethanol yields diphenyl hydrazidothiophosphate, $(C_6H_5O)_2PSN_2H_4$. This compound may be saponified with sodium hydroxide to give disodium hydrazidothiophosphate, $Na_2PO_2SN_2H_4$.[50]

Complex amidothiophosphorus compounds are also obtained from the reaction of tetraphosphorus pentasulphide with liquid ammonia.[52] A canary-yellow hygroscopic solid, said to be $(NH_4)_3[P_4S_5(NH_2)_3]$, is formed when tetraphosphorus pentasulphide is dissolved in liquid ammonia, the solution filtered and evaporated, and the residue kept *in vacuo* for 20 hr. The compound decomposes at room temperature giving off small quantities of ammonia. It is hydrolyzed by moist air and on heating *in vacuo* at 70°C. becomes an intense golden yellow. The product has been assigned the formula $(NH_4)_2[P_4S_5(NH_2)_2]$.[52]

When tetraphosphorus pentasulphide in liquid ammonia is treated with hexamminochromium(III) nitrate a yellow-brown salt which has been given the formula $[Cr(NH_3)_6][P_4S_5(NH_2)_3]$ is formed. The nickel compound, $[Ni(NH_3)_4]_3[P_4S_5NH_2)_3]_2$, is obtained from the liquid ammonia solution of tetraphosphorus pentasulphide and tetramminonickel(I) thiocyanate.[52]

A variety of compounds containing phosphorus, nitrogen and sulphur have also been produced by reaction of tetraphosphorus heptasulphide with liquid ammonia.[39] At $-33$°C. compounds were formed which were assigned the formulæ $(NH_4)_3PS_3$ and $(NH_4)PS_3NH_2$. $(NH_4)_3PS$ is insoluble in liquid ammonia at this temperature, but $(NH_4)_3PS_3NH_2$ remains dissolved at temperatures above $-78$°C. It may also be obtained from phosphorus pentoxide and liquid ammonia at $-78$°C. These compounds are both readily hydrolyzed. $(NH_4)_3PS_3$ decomposes slowly above $-25$°C. and when heated *in vacuo* at 100°C. gives mixtures of different amidothiophosphates.[39] Ammonia, hydrogen sulphide and polymeric $(PNS)_x$ are the final products of heating to 250°C. Polymeric triphosphorus pentanitride is obtained when either $(NH_4)_3PS_3$ or $(NH_4)PS_3NH_2$ is heated in a stream of ammonia at 750°C. At room temperature $(NH_4)PS_3NH_2$ reacts with ammonia in a sealed tube to give $(NH_4)_3PS_3NH$. Tetramminonickel(I) thiocyanate forms the light-blue compound $Ni(NH_3)_6PS_3NH_2$ when treated with $(NH_4)PS_3NH_2$.[39]

Compounds which have been given the formulæ $(NH_4)_3P_3S_3(NH)_3$ and $(NH_4)P_2SN$ are also formed when tetraphosphorus heptasulphide reacts with liquid ammonia. Both are soluble at $-78$°C. Dark-brown, insoluble $[Ni(NH_3)_4][(NH_4)P_3S_3(NH)_3]$ is obtained when $(NH_4)_3P_3S_3(NH)_3$ is treated with tetramminonickel(I) thiocyanate.[39]

The amidoselenophosphate, $(NH_4)[P_4Se_3(NH_2)_2]$, was prepared by reaction of tetraphosphorus triselenide, $P_4Se_3$, with liquid ammonia at $-33$°.[53] At 20°C. this compound decomposes to $(NH_4)_2[P_4Se_3NH]$ which yields $NH_4[P_4Se_3NH_2]$ at 90°C., and finally tetraphosphorus triselenide at 200°C. Tetraphosphorus pentaselenide reacts with gaseous ammonia at 20°C. giving $(NH_4)_2[PSe_3NH_4]$. If the solution remaining after filtration of the product is cooled to $-70$°C. the compounds $(NH_4)_3(PSe_4)$ and $(NH_4)_2[PSe_2(NH_2)NH]$ separate.[53]

## HALOTHIOPHOSPHATES

The hydrolysis of thiophosphoryl trifluoride is believed to occur in stages[54]:

$$PSF_3 \rightarrow HPOSF_2 \rightarrow H_2PO_2SF \rightarrow H_2PO_3S$$

The difluorothiophosphate ion was first isolated as its nitron salt, $[C_{20}H_{16}N_4H^+][PSOF_2^-]$, by the addition of nitron acetate to thiophosphoryl trifluoride.[54] It has since been prepared by the hydrolysis of thiophosphoryl chlorodifluoride[70]; by the interaction of ammonium diamidothiophosphate and hydrogen fluoride[71]; by the reaction of tetraphosphorus hexaoxytetrasulphide and sodium fluoride in acetonitrile[72]; or by the reaction of tetraphenylphosphonium diazidothiophosphate with hydrogen fluoride.[72]

Free difluorothiophosphoric acid is unstable,[54, 73] decomposes on distillation, and slowly hydrolyzes in the cold to monofluorothiophosphate. Sodium, potassium[73] ammonium,[71] quaternary ammonium, phosphonium and arsonium[70, 72–3] salts have been isolated, but no inorganic cations were found to give precipitates in neutral solution.[71] The ammonium salt forms colourless, birefringent, optically negative biaxial leaflets, m.p. 110°, $d_4^{20}$ 1·83 g./c.c. It is very soluble in water and the commoner polar organic solvents, but insoluble in benzene, chloroform and petroleum ether. Nuclear magnetic resonance data have been recorded (see Table VI). The infra-red spectrum shows that this, like other similar anions, has the $O{=}PSX_2$ structure.[70]

Diammonium fluorothiophosphate has been similarly prepared by the action of hydrogen fluoride on a thioamidophosphate. It forms colourless needles, optically positive and biaxial, $d = 1{\cdot}60$ g./c.c., very soluble in water, but insoluble in the commoner organic solvents. The free acid is more stable than $HPSOF_2$, showing no hydrolysis after several hours at room temperature. It is, however, hydrolyzed in boiling water to thiophosphate and phosphate. Aqueous bromine oxidizes the anion to fluorophosphate and phosphate. Lead(II) gives a white precipitate with fluorothiophosphates, and silver(I) a white precipitate which slowly darkens. Other common inorganic cations give no precipitate. The nuclear magnetic resonance spectrum has been recorded (Table VI).[71]

Tetraphenyl-phosphonium or -arsonium chlorofluorothiophosphates have been prepared by the hydrolysis of thiophosphoryl dichlorofluoride in the presence of the appropriate quaternary chloride. However the hydrolysis of thiophosphoryl dibromofluoride gave impure products from which only the difluorothiophosphate could be isolated. These salts as well as the dichlorothiophosphate (*q.v.*) were all soluble in methanol, ethanol or acetone, although with some decomposition.[70]

*Table VI.—Nuclear Magnetic Resonance Data for Halothiophosphates*

(a) Reference to $CCl_3F$.
(b) Reference to 85% $H_3PO_4$.

If water is added to thiophosphoryl trichloride in acetone, dichlorothiophosphoric acid is formed in 99% yield, and can be precipitated as the sparingly soluble nitron salt, $[C_{20}H_{16}N_4H^+][PSOCl_2^-]$[55], or as the tetraphenyl-phosphonium or -arsonium salt.[70] When thiophosphoryl trichloride is titrated with alkali in an acetone–water mixture the steps of the hydrolysis:

$$\mathrm{PSCl_3 \rightarrow HPOSCl_2 \rightarrow H_2PO_2SCl \rightarrow H_3PO_3S}$$

can be demonstrated. Monochlorothiophosphoric acid has a measurable lifetime.[55]

Tetraphosphorus decasulphide reacts with certain metal halides and pseudohalides in media such as water, acetonitrile or 1,2-dimethoxyethane, to give three types of anion:

$$\underset{\mathrm{I}}{[\mathrm{S_2PX_2}^-]}\quad \underset{\mathrm{II}}{[\mathrm{S_2P(X)SP(X)S_2}^{2-}]}\quad \underset{\mathrm{III}}{[\mathrm{S_2P(X)S_2P(X)S_2}^{2-}]}$$

$$(\mathrm{X = F, N_3, CN})$$

The type isolated depends on the salt and solvent used and the isolation procedure. Thus sodium fluoride or azide in water gives primarily compounds of type II, while in acetonitrile type I is mainly formed. Sodium cyanide in acetonitrile gives the anion $[\mathrm{PS_2CN(CSNH_2)}^-]$.[74] Similar treatment of tetraphosphorus hexaoxytetrasulphide gives the anions $[\mathrm{PS_2F_2}^-]$, $[\mathrm{PSOF_2}^-]$, $[\mathrm{PS_2(CN)_2}^-]$ and $[\mathrm{PS_2(N_3)_2}^-]$. $[\mathrm{PSOF_2}^-]$ and $[\mathrm{PSOF(N_3)}^-]$ have been prepared by the action of hydrogen fluoride on $[\mathrm{PS_2(N_3)_2}^-]$.[72]

The dihalodithiophosphates appear to be remarkably stable in acidic or basic solutions. Indeed, the hydronium salts $\mathrm{H_3O^+[PS_2(N_3)_2{}^-]}$ and $\mathrm{H_3O^+[PS_2F_2{}^-]}$ can be distilled *in vacuo* without appreciable decomposition, while the former is stable at room temperature for several months. Cæsium difluorodithiophosphate decomposes at 325 to 375°C., evolving thiophosphoryl fluoride and phosphorus trifluoride. $\mathrm{Pr_4N^+[S_2PCN(CSNH_2)^-]}$ yields mainly hydrogen cyanide, while $\mathrm{Pr_4N^+[PS_2(N_3)_2]}$ evolves nitrogen at about 100°C.[74]

Diamidothiophosphoryl fluoride, $\mathrm{PS(NH_2)_2F}$, has been obtained by reaction of thiophosphoryl trifluoride with dry ammonia gas.[51]

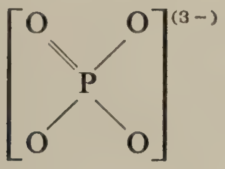
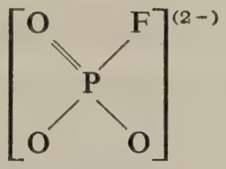
## SECTION XXXI

# FLUOROPHOSPHORIC ACIDS AND THE FLUOROPHOSPHATES

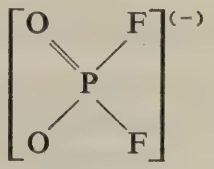
### BY D. A. PALGRAVE

THE fluorophosphates, sometimes called phosphorofluoridates, may be considered as being derived from the orthophosphate ion by replacement of the oxygen atoms by fluorine:

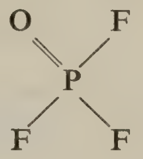


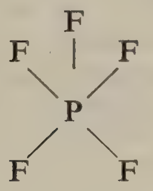


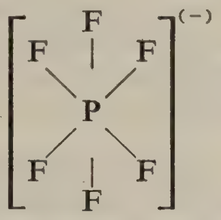
monofluoro-phosphate



difluoro-phosphate



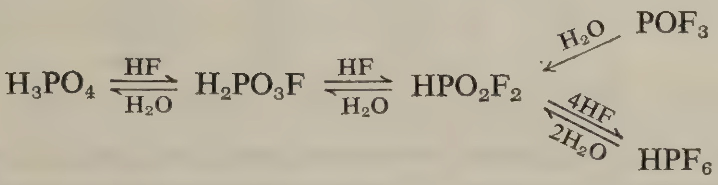




hexafluorophosphate

No fluorophosphates as such have been found in the earth's crust. When fluorine and phosphorus occur together in minerals they usually do so as fluoroapatites, in a lattice containing discrete fluoride and phosphate ions. However Carnot,[1] studying the fluorine content of fossils, suggested that fluorophosphates may take part in the geochemical fluorine cycle. Subsequent investigations[2] of the possible mechanism of fluoroapatite synthesis indicate that in the reaction between calcium pyrophosphate and calcium fluoride, calcium monofluorophosphate may be regarded as an intermediate. Furthermore the presence of randomly distributed $PO_3F^{2-}$ ions would account for the excesses of fluorine and the abnormal densities observed in non-stoicheiometric fluoroapatites. This would also be consistent with the group formula reported[3] for francolite, $[Ca(F,Cl,OH)](Ca,C)_4[(P,C).(O,OH,F)_4]_3$.

Fluorophosphoric acids were first synthesized in 1927 by Lange, who has since contributed very fully toward a general understanding of their chemistry.[4] The following sequence of equilibria has been established[15]:—



$$H_3PO_4 \underset{H_2O}{\overset{HF}{\rightleftharpoons}} H_2PO_3F \underset{H_2O}{\overset{HF}{\rightleftharpoons}} HPO_2F_2 \quad \overset{\xleftarrow{H_2O}\ POF_3}{\underset{\underset{2H_2O}{\overset{4HF}{\rightleftharpoons}}\ HPF_6}{}}$$

and in terms of this a great deal of the behaviour of these acids may be interpreted. The monofluorophosphate ion is quite stable and bears a striking resemblance to the sulphate ion in both physical and chemical properties. The difluorophosphate ion is relatively unstable, and this may account for the dearth of information in the literature. A slight similarity to the perchlorate ion has been suggested.[5] The most stable member of the series is the hexafluorophosphate ion, which in its physical properties has much in common with the chloride ion, and a little in common with the perchlorate ion.

Esters of mono- and di-fluorophosphoric acids have been investigated.[4] Many of the monofluorophosphates are highly toxic materials, being capable of inhibiting the enzyme acetylcholinesterase. This has suggested their possible use as war gases.[52] An account of the chemistry of these compounds may be found in the section dealing with organo-phosphorus derivatives.

## MONOFLUOROPHOSPHORIC ACID

Monofluorophosphoric acid may be formed by the general method of treating a salt with a stronger acid, and this was how an aqueous solution was first obtained[6] although the acid slowly hydrolyzed into orthophosphoric and hydrofluoric acids:

$$Ag_2PO_3F + 2HCl \rightarrow H_2PO_3F + 2AgCl$$

or

$$\underset{\text{(aqueous suspension)}}{Ag_2PO_3F} + \underset{\text{gas}}{H_2S} \rightarrow H_2PO_3F + Ag_2S$$

$$H_2PO_3F + H_2O \rightleftharpoons H_3PO_4 + HF.$$

The last equilibrium has been studied in detail.[8-9] If the mixture is boiled the reaction proceeds quantitatively from left to right. However, at room temperature, provided that the medium is sufficiently acidic, monofluorophosphoric acid can be formed. By applying the law of mass action to the equilibrium, the 'constant'

$$K = \frac{[H_2PO_3F][H_2O]}{[H_3PO_4][HF]}$$

was found to vary with the amount of water added to the reaction mixture of concentrated phosphoric acid and 41% hydrofluoric acid.

*Table I.—Equilibrium Data in the* $H_2O$–$H_3PO_4$–HF–$H_2PO_3F$ *System*

| Initial concentrations (molar) | | | Final concentrations (molar) | | | | |
|---|---|---|---|---|---|---|---|
| $H_2O$ | $H_3PO_4$ | HF | $H_2O$ | $H_3PO_4$ | $H_2PO_3F$ | HF | $K$ |
| 0·279 | 1 | 0·189 | 0·442 | 0·838 | 0·162 | 0·027 | 3·17 |
| 1·015 | 1 | 0·189 | 1·129 | 0·887 | 0·113 | 0·076 | 1·89 |
| 1·642 | 1 | 0·190 | 1·712 | 0·930 | 0·070 | 0·120 | 1·07 |
| 1·928 | 1 | 0·191 | 1·985 | 0·943 | 0·057 | 0·134 | 0·90 |
| 2·442 | 1 | 0·190 | 2·478 | 0·965 | 0·035 | 0·154 | 0·59 |
| 3·039 | 1 | 0·188 | 2·991 | 0·976 | 0·024 | 0·160 | 0·45 |
| 3·507 | 1 | 0·191 | 3·527 | 0·980 | 0·020 | 0·171 | 0·41 |
| 3·900 | 1 | 0·192 | 3·196 | 0·983 | 0·017 | 0·175 | 0·38 |
| 3·957 | 1 | 0·188 | 3·970 | 0·987 | 0·013 | 0·174 | 0·31 |
| 6·608 | 1 | 0·186 | 6·617 | 0·991 | 0·009 | 0·176 | 0·35 |
| 13·939 | 1 | 0·182 | 13·943 | 0·996 | 0·004 | 0·178 | 0·31 |

From the results in Table I it can be seen that as the proportion of water added to the mixture is increased, the value of $K$ gradually assumes a constant level. When only a small quantity of water is present large yields of monofluorophosphoric acid are obtained. A more complex process than that represented by the equation above seems to be taking place. No simple satisfactory explanation has been advanced and it has recently been suggested[11,16] that the problem could best be resolved using modern physical techniques. By increasing the concentration of both hydrofluoric acid and water the value of $K$ reaches 3·47, then levels off in the region of 0·8–0·9. Thus, if concentrated phosphoric acid is mixed with about 3·5 times its weight of 41% hydrofluoric acid, one-third of the phosphate is converted to fluorophosphate. Monopotassium phosphate can be fluorinated to the same extent by adding a large excess of aqueous hydrofluoric acid ($K = 0{\cdot}71$). The presence in the mixture of a 'strong' acid, e.g. perchloric acid, can increase the value of $K$ to 23·7.

The reaction between anhydrous phosphoric and hydrofluoric acids yields mainly monofluorophosphoric acid, but the formation of other fluorophosphoric acids is possible.

If phosphorus pentoxide is dissolved in 40% hydrofluoric acid solution several products are formed, the final mixture consisting of an aqueous solution of monofluorophosphoric, orthophosphoric and hydrofluoric acids. High yields of monofluorophosphoric acid can be obtained by arranging for the value of $x$ in the following equation to be zero:

$$P_2O_5 + (2-x)HF + (1-x)H_2O \rightarrow xHPO_2F_2 + (2-x)H_2PO_3F$$

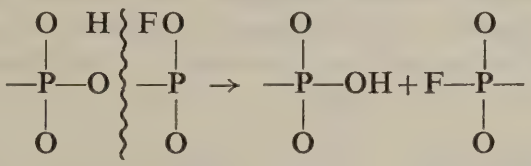
This is brought about by the use of 69% hydrofluoric acid,[12] and a reaction temperature of 150°C. The maximum value of $x$ is unity, when a stoicheiometric mixture of mono- and di-fluorophosphoric acids, is obtained. These can be separated by vacuum distillation.[13]

The reaction:

$$HPO_3 + HF \rightarrow H_2PO_3F$$

has been observed to proceed to completion,[7,14] albeit slowly owing to the viscous nature of the metaphosphoric acid.

The mechanism of the two reactions suitable for the preparation of monofluorophosphoric acid is still obscure,[4] although it seems likely that in each case hydrofluorolysis of P–O–P bridges is a fundamental step:



$$-\overset{O}{\underset{O}{P}}-\overset{H}{O}\,\Big\}\,\overset{F}{}-\overset{O}{\underset{O}{P}} \rightarrow -\overset{O}{\underset{O}{P}}-OH + F-\overset{O}{\underset{O}{P}}-$$

Such a process would explain why orthophosphoric acid comes to be detected in the final products.

Monofluorophosphoric acid is also produced by the hydrolysis of phosphoryl trifluoride.[5]

## Physical Properties

At room temperature monofluorophosphoric acid is a colourless oily liquid ($d_4^{25}$ 1·818) similar to sulphuric acid in appearance.[15] When cooled the acid becomes very viscous at −20°C., eventually setting rigid at −70°C. without signs of crystallization.[7]

Nuclear magnetic resonance spectra have been examined by several workers,[16–18] and provide evidence of a tetrahedral configuration for the $PO_3F^{2-}$ ion, with one of the oxygen atoms of the orthophosphate ion replaced by fluorine, as expected from general stereochemical considerations.

The fluorine resonance in monofluorophosphoric acid is shown in Table II but the phosphorus resonance is obscured by other phosphorus compounds present.[17]

*Table II.—Nuclear Magnetic Resonance Spectrum of Monofluorophosphoric Acid*

| Resonance | Line structure | Applied field (gauss) | Splitting (gauss) | Chemical shift* |
|---|---|---|---|---|
| Fluorine | (1–1) | 6365 | 0·238 | $-0{\cdot}25\times10^{-5}$ |
| | | 4180 | 0·241 | |
| | | 170 | $0{\cdot}240\pm0{\cdot}001$ | |

* Referred to trifluoroacetic acid.

## Chemical Properties

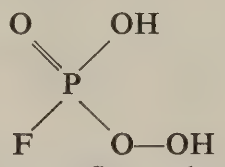
The anhydrous acid can be heated to 185°C. under reduced pressure with only slight decomposition.[7] Provided that no moisture is present glass is not attacked, but the ease of hydrolysis, at low pH values, to orthophosphoric acid and hydrofluoric acid makes glass unsuitable for use either as a storage or a reaction vessel under aqueous conditions.

Aqueous monofluorophosphoric acid behaves as a dibasic acid, although one hydrogen is much more readily ionized than the other. The titration curve[19] is very similar to that of orthophosphoric acid, the two neutral points occurring at pH 3·5 and 8·5 respectively, corresponding to the first and second ionization constants of 0·28 and $1{\cdot}58\times10^{-5}$. Conductance measurements suggest that the difference between the ionization constants is greater, and even that the acid may be monobasic. This behaviour is attributed to the formation of intramolecular hydrogen bonds, –F····H–O–. The equivalent conductance is 413·8 $\text{ohm}^{-1}$ $\text{equiv.}^{-1}$ $\text{cm.}^{-1}$ [130]

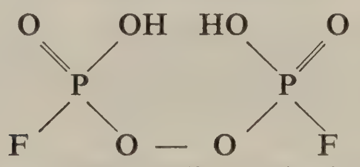
The anhydrous acid and very concentrated aqueous solutions attack most common metals and their alloys, including stainless steel. However silver, platinum and aluminium are not affected; neither are polyethylene, polystyrene and polymeric fluorocarbons. Rubbers, apart from butyl rubber, are not suitable for handling the concentrated acid, although dilute solutions have little or no effect on them. The dilute acid attacks aluminium and titanium[96]; the coating produced on the latter metal facilitates subsequent cold deformation operations. Aqueous solutions of the acid are readily absorbed by cellulose, generating extensive swelling.[15]

Monofluorophosphates may readily be prepared from aqueous solutions of the acid.[7]

Electrolytic oxidation results[28] in the formation of mono- and di-peroxyfluorophosphoric acids in yields of up to 2%:



monoperoxymonofluorophosphoric acid



diperoxydifluorodiphosphoric acid

Monofluorophosphoric acid has been mentioned in several patents describing various organic operations. It can function catalytically when olefines are polymerized,[21] *iso*paraffins are alkylated,[22] and when oils are refined[12] under non-oxidizing conditions. Various derivatives of monofluorophosphoric acid have been utilized as alkylation catalysts, including an addition compound with boron trifluoride $H_2PO_3,BF_3$ [94] and compounds from aluminium chloride[95] in which one or more of the chlorine atoms are replaced by acid monofluorophosphate groups, e.g. $AlCl_2(HPO_3F)$, $AlCl(HPO_3F)_2$. A further group of patents describes applications depending on the reactions of the acid with siliceous matter, e.g. the removal of residual sand from metals cast in sand moulds,[23] the improvement of permeability in certain geological operations[24-5,101-2] and the improvement of the physical properties of asphalt by blowing with air saturated with monofluorophosphoric acid,[26] or alternatively by heating the asphalt with the acid and subsequently blowing with air.[100] Metal cleaning and fungicidal properties have also been suggested.[15]

## MONOFLUOROPHOSPHATES

Monofluorophosphates were first obtained by Lange[5] by fusion of phosphorus pentoxide with ammonium fluoride:

$$P_2O_5 + 3NH_4F \rightarrow NH_4PO_2F_2 + (NH_4)_2PO_3F$$

At the reaction temperature (*ca.* 135°C.) the monofluorophosphate loses ammonia:

$$(NH_4)_2PO_3F \rightarrow NH_3 + NH_4HPO_3F$$

and consequently the alcoholic extract from the fusion mixture is treated with ammoniacal alcohol until the solution is neutral, when diammonium monofluorophosphate is precipitated. These reactions have been discussed.[27-30] The mechanism of the fusion reaction would seem to resemble the hydrofluorolysis postulated to explain the reaction between hydrofluoric acid and phosphorus pentoxide, which gives rise to monofluorophosphoric acid.

Monofluorophosphates are prepared by the neutralization of the acid by a base, e.g.[7]:

$$PbO + H_2PO_3F \rightarrow PbPO_3F + H_2O$$

or by a suitable double decomposition technique. The choice of method depends on the solubility of the desired salt. Since the solubilities of monofluorophosphates are very similar to those of the corresponding sulphates it is possible to select a suitable reaction fairly easily; e.g.:

$$CaCl_2 + Na_2PO_3F + 2H_2O \rightarrow CaPO_3F.2H_2O\downarrow + 2NaCl^{31}$$
$$2KOH + (NH_4)_2PO_3F \rightarrow K_2PO_3F + 2NH_3 + 2H_2O^{27-8}$$
$$Ag_2PO_3F + 2NaCl \rightarrow Na_2PO_3F + 2AgCl^{6,111}$$

If the sulphate is sparingly soluble the monofluorophosphate can be filtered off. If the sulphate is soluble then the use of either the ammonium salt or the silver salt is advisable, since ammonia can be removed from an aqueous solution by blowing air through it, whilst the silver chloride is readily removed by filtration. To obtain solid monofluorophosphates the solutions are evaporated to dryness *in vacuo* at room temperature.

The foregoing are illustrations of general methods of preparing salts. However one method, the hydrolysis of difluorophosphates, is less general:—

$$KPO_2F_2 + 2KOH \rightarrow K_2PO_3F + KF + H_2O^{6}$$

Perhaps the most useful technique is that of Hill and Audrieth[32-3] in which an anhydrous alkali-metal metaphosphate is fused with an alkali-metal fluoride and then quenched:

$$Na_3P_3O_9 + 3NaF \rightarrow 3Na_2PO_3F$$
$$(KPO_3)_n + nKF \rightarrow nK_2PO_3F$$

The phase diagram for mixtures of potassium metaphosphate and potassium fluoride is given in Fig. 1. The crystallization surface of the $K^+,Na^+ \| F^-,PO_3^-$ ternary reciprocal system has also been studied. Only sodium and potassium monofluorophosphates, and their double salts with the corresponding fluorides, were observed.[131] Traces of pyrophosphates or other condensed phosphates may be eliminated by treating an aqueous solution of the alkali metal monofluorophosphate with silver monofluorophosphate. It seems likely that the mechanism is analogous to that of the reaction between metaphosphoric acid and hydrogen fluoride. Hill[34] has suggested that metaphosphates in such high temperature systems can be regarded as Lewis acids, capable of reacting with an electron donor such as the fluoride ion.

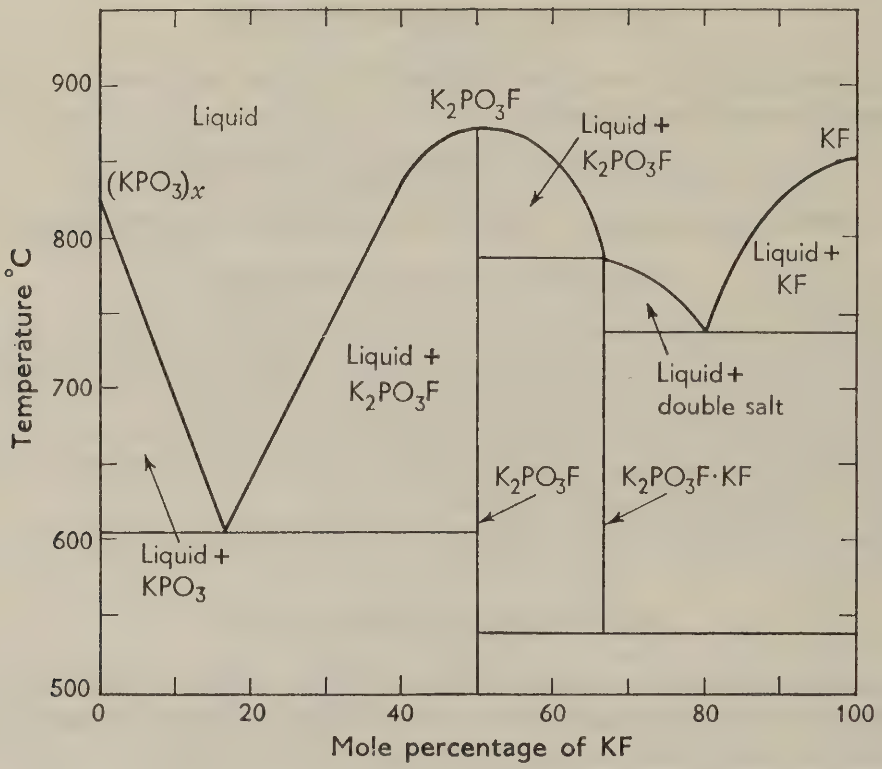


FIG. 1—The potassium metaphosphate–potassium fluoride system

Other studies of the interaction between fluorides and polyphosphates of various kinds have been made.[132-5] Although only monofluorophosphates have been detected, there is evidence for P–F compounds of other kinds, possibly polyphosphate in character.

## Physical Properties

Many workers have drawn attention to the remarkable crystallographic similarity between the monofluorophosphates and the sulphates.[35-41] This is undoubtedly due to the isosteric and isoelectronic nature of the two ions. Several examples of isomorphism have been reported by these investigators. $CuPO_3F,5H_2O$, $CoPO_3F,6H_2O$ and $NiPO_3F,7H_2O$ are isomorphous with $CuSO_4,5H_2O$, $CoSO_4,6H_2O$ and $NiSO_4,7H_2O$, respectively.[36] Similarly in another study $NiPO_3F,6H_2O$, $3CdPO_3F,8H_2O$, $CdPO_3F,H_2O$, $MnPO_3F,2H_2O$, $MnPO_3F,H_2O$, $Cr_2(PO_3F)_3,18H_2O$, $Cr_2(PO_3F)_3,15H_2O$ and $Cr_2(PO_3F)_3,6H_2O$ where shown to be stable at 50°. Each of these (except the dihydrated manganese salt) has an equivalent sulphate hydrate.[136] Magnetic susceptibility measurements have been recorded for these latter salts.[137] Many double salts of the alum and schoenite type have been prepared. Some are mixed monofluorophosphates and others mixed monofluorophosphate-sulphates[36,40]

| | |
|---|---|
| $NiPO_3F,(NH_4)_2PO_3F,6H_2O$; | $CoPO_3F,(NH_4)_2PO_3F,6H_2O$; |
| $(NH_4)_2PO_3F,Al_2(PO_3F)_2,24H_2O$; | $NiSO_4,(NH_4)_2PO_3F,6H_2O$; |
| $CuSO_4,(NH_4)_2PO_3F,6H_2O$; | $CoSO_4,(NH_4)_2PO_3F,6H_2O$; |
| $ZnSO_4,(NH_4)_2PO_3F,6H_2O$; | $MnSO_4,(NH_4)_2PO_3F,6H_2O$; |

The sulphate and monofluorophosphate of potassium are so similar that mixed crystals are formed in all proportions.[36] Calcium monofluorophosphate, like calcium sulphate, forms a monoclinic dihydrate which decomposes to a hemihydrate on heating.[31]

This similarity to the sulphates extends to the solubilities in water, the salts of the alkali metals being readily soluble and those of the alkaline earths being only sparingly soluble.[6] Some values are given in Table III and shown graphically in Fig. 2.

*Table III.—Solubilities of Monofluorophosphates and Sulphates in Water at* 20°C. (expressed in moles/litre)

| Cation | Monofluorophosphates | Sulphates |
|---|---|---|
| Calcium | $6{\cdot}3\times10^{-2}$ | $1{\cdot}5\times10^{-2}$ |
| Strontium | $5{\cdot}5\times10^{-2}$ | $6\times10^{-4}$ |
| Barium | $6\times10^{-4}$ | $1\times10^{-5}$ |
| Silver | $5{\cdot}93\times10^{-2}$ | $2{\cdot}51\times10^{-2}$ |
| Lead | $3{\cdot}2\times10^{-4}$ | $1{\cdot}3\times10^{-4}$ |
| Mercury | $5\times10^{-4}$ | $8\times10^{-4}$ |

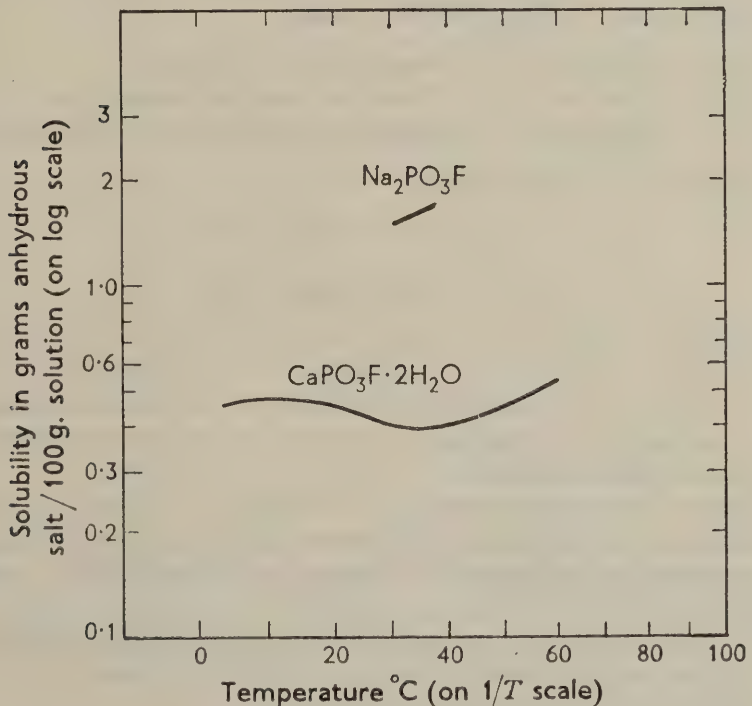

FIG. 2.—Solubilities of sodium and calcium monofluorophosphates

A subsequent determination of the solubility of barium monofluorophosphate gave a value of $7{\cdot}7\pm0{\cdot}6\times10^{-4}$ moles/l. The mean activity coefficient of barium monofluorophosphate as a function of ionic strength was found to approach the limiting Debye–Hückel slope for a 2:1 electrolyte.[138]

**Refs. p. 868**

*X*-Ray diffraction studies[42-3] provide further evidence of sulphate–monofluorophosphate isomorphism. The powder diagrams of $BaSO_4$ and $BaPO_3F$[42] are almost identical, as are those of $K_2SO_4$ and $K_2PO_3F$.[43] Barium monofluorophosphate usually crystallizes in the orthorhombic system, with unit cell dimensions *a* 8·68, *b* 5·63, *c* 7·28 A. and *V* 356 $A^3$., although the compound may assume a more stable monoclinic form. Lead fluorophosphate, $PbPO_3F$, also appears to have an orthorhombic lattice, with $a = 6{\cdot}951$, $b = 8{\cdot}521$, $c = 5{\cdot}470$ A., $d_{obs.} = 6{\cdot}15$, $d_{calc.} = 6{\cdot}24$ g./c.c. It is probably isostructural with lead sulphate and barium sulphate, *H*2 type.[139] Single crystal studies of the potassium salts indicate that both are orthorhombic (space group *Pnam* $D_{2h}^{16}$). Each ion is tetrahedral although the $PO_3F^{2-}$ ion is slightly distorted.

Bond distances (A.) are given below:

| | | | |
|---|---|---|---|
| $S{-}O_1$ | $1{\cdot}54 \pm 0{\cdot}06$ | $P{-}F_1$ | $1{\cdot}55 \pm 0{\cdot}08$ |
| $S{-}O_2$ | $1{\cdot}51 \pm 0{\cdot}16$ | $P{-}O_2$ | $1{\cdot}44 \pm 0{\cdot}16$ |
| $S{-}O_3$ | $1{\cdot}47 \pm 0{\cdot}12$ | $P{-}O_3$ | $1{\cdot}53 \pm 0{\cdot}10$ |
| Mean | $1{\cdot}52 \pm 0{\cdot}02$ | Mean | $1{\cdot}52 \pm 0{\cdot}04$ |

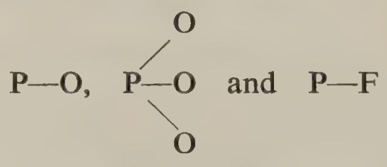
Bond angles (°) are as follow:

| | | | |
|---|---|---|---|
| $O_1{-}S{-}O_2$ | $112 \pm 8$ | $F_1{-}P{-}O_2$ | $115 \pm 8$ |
| $O_1{-}S{-}O_3$ | $107 \pm 4$ | $F_1{-}P{-}O_3$ | $96 \pm 5$ |
| $O_2{-}S{-}O_3$ | $110 \pm 8$ | $O_2{-}P{-}O_3$ | $119 \pm 8$ |
| $O_3{-}S{-}O_3$ | $111 \pm 5$ | $O_3{-}P{-}O_3$ | $109 \pm 7$ |
| Mean | $109 \pm 2$ | Mean | $106 \pm 9$ |

The infra-red spectra of a large number of monofluorophosphates have been examined[44-5, 97] including $(NH_4)_2PO_3F,H_2O$; $Li_2PO_3F,3H_2O$; $Na_2PO_3F$; $K_2PO_3F$; $CaPO_3F,xH_2O$; $SrPO_3F,xH_2O$; $BaPO_3F$; $PbPO_3F$; $Ag_2PO_3F$. The principal absorption regions occur in the following ranges:

| | |
|---|---|
| 1210 – 1120 cm.$^{-1}$ | Very strong broad peak |
| 1022 – 990 cm.$^{-1}$ | Strong or medium absorption |
| 832 – 721 cm.$^{-1}$ | Broad absorption often two peaks |

These regions probably correspond to



$$P{-}O,\quad P\!\begin{smallmatrix}\diagup O\\ {-}O\\ \diagdown O\end{smallmatrix}\quad \text{and}\quad P{-}F$$

groupings respectively. The position of the absorption bands associated with P–O stretching is anomalous. This anomaly is thought to be correlated with the electronegative character of the fluorine.

Nuclear magnetic resonance spectra of aqueous solutions of sodium monofluorophosphate have been obtained.[17] With an applied field of 6365 gauss a fluorine doublet was observed, of splitting 0·195 gauss, and chemical shift, with respect to trifluoracetic acid, $+2{\cdot}68 \times 10^{-5}$.

Conductivity measurements[46] indicate that the sodium salt behaves as a strong electrolyte with equivalent conductance $\Lambda_0 = 113{\cdot}5 \pm 0{\cdot}5$ ohm$^{-1}$ (at 25°C.). The ionic conductance of the $PO_3F^{2-}$ ion is 63·3 ohm$^{-1}$.

The density of aqueous solutions of sodium monofluorophosphate has been measured at 25°C. over the concentration range 0·4 to 2·0 M. The partial molal volume is a linear function of the square root of the molality.[140] The fluidity (reciprocal viscosity), $\phi$, of such solutions at the same temperature is given by:

$$\phi = 1 - 0{\cdot}01568c^{1/2} - 0{\cdot}4160c$$

over the concentration range 0·014 to 0·5 M.[141]

## Chemical Properties

Aqueous solutions of the monofluorophosphates of the alkali metals are alkaline to methyl orange and neutral to phenolphthalein. Provided that cations capable of forming less soluble phosphates or fluorides are absent, a neutral or weakly alkaline solution is exceedingly stable, even when boiled, whilst a 1% solution at 95°C. is hydrolyzed less than 1% per hour.[15] The hydrolysis reaction appears to be of first order[19,112] in monofluorophosphate concentration. The thermodynamic dissociation constant of $HPO_3F^-$ is $0{\cdot}76 \times 10^{-5}$ at 25°C.[113] The considerably greater acidity of $HPO_3F^-$ (compared with that of $H_2PO_4^-$) has been shown to be due mainly to the respective enthalpies of dissociation. The alkaline hydrolysis of monofluorophosphate, which has been studied in the temperature range 120°–140°C.,[114] appears to take place by two parallel processes, the velocities $v_1$ and $v_2$ being given by $v_1 = k_1[PO_3F^{--}]$, $v_2 = k_2[PO_3F^{--}][OH^-]$. However, in strongly alkaline or acidic conditions rapid hydrolysis takes place[4] as shown in Fig. 3.

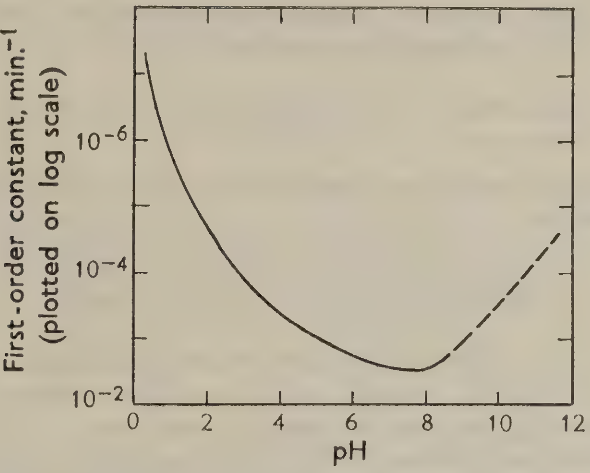


Fig. 3.—Hydrolysis of monofluorophosphate at 80°C

$$K_2PO_3F + H_2O \rightarrow KH_2PO_4 + KF$$

The activation energy for this hydrolysis is 8 kcal./mole.[19,111]

Hydrolysis of a saturated solution of the dihydrate of the calcium salt[115] results in the comparatively slow formation of calcium fluoride and monocalcium phosphate at room temperature:

$$2CaPO_3F{,}2H_2O \rightarrow CaF_2 + Ca(H_2PO_4)_2 + 2H_2O$$

At temperatures somewhat above 50°C. the decomposition is much more rapid and the two products of the reaction combine in the presence of water to give fluorapatite, whilst at still higher temperatures pyrophosphates are formed as discussed below.

Sodium, potassium and ammonium monofluorophosphates have been electrolyzed in aqueous solution[28,47] giving rise to mono-and di-peroxyfluorophosphoric acids which have not been isolated, although thay have been identified by studying the variation in alkalinity of the electrolyte. The potassium salt gives the greatest yields, which can be enhanced by the addition of fluorides. If the pH of the electrolyzed solutions is allowed to rise the peroxy-acids decompose, the first reverting to a monofluorophosphate and the other hydrolyzing to a peroxyphosphate.

The action of heat on monofluorophosphates in the solid state invariably brings about decomposition,[34] especially if moisture is present in the atmosphere, when hydrolysis occurs as discussed above. Thus thermogravimetric analysis of calcium monofluorophosphate dihydrate indicates that it eventually decomposes to calcium pyrophosphate, hydrogen fluoride and water[48]:

$$\mathrm{CaPO_3F,2H_2O} \xrightarrow{100°\mathrm{C}} \underset{\text{phase}}{\text{amorphous}} \xrightarrow{400°\mathrm{C}} \alpha\text{-}\mathrm{Ca_2P_2O_7} \xrightarrow{550°\mathrm{C}} \beta\text{-}\mathrm{Ca_2P_2O_7}$$

When the corresponding strontium compound is heated[116–7] it decomposes eventually forming strontium pyrophosphate, strontium fluorapatite, and phosphoryl trifluoride:

$$\mathrm{5SrPO_3F,H_2O} \xrightarrow{90\text{–}150°\mathrm{C}} \mathrm{5SrPO_3F} \xrightarrow{460°\mathrm{C}} \mathrm{2Sr_2P_2O_7 + SrF_2 + POF_3}$$

$$\mathrm{18Sr_2P_2O_7 + 14SrF_2} \xrightarrow{800°\mathrm{C}} \mathrm{5Sr_{10}(PO_4)_6F_2 + 6POF_3}$$

Any moisture present brings about the evolution of hydrogen fluoride:

$$\mathrm{2SrPO_3F + H_2O \rightarrow Sr_2P_2O_7 + 2HF}$$

Similar analyses of the potassium salt revealed transition points at 443°C. and 800°C.[49] The following sequence was suggested:

$$\underset{\text{orthorhombic}}{\beta\text{-}\mathrm{K_2PO_3F}} \xrightarrow{443°\mathrm{C}} \underset{\text{hexagonal}}{\mathrm{K_2PO_3F}} \xrightarrow{800°\mathrm{C}} \alpha\text{-}\mathrm{K_2PO_3F}$$

although a subsequent investigator[43] pointed out that the following reactions would explain the observations:

$$\mathrm{5K_2PO_3F \rightarrow 2K_4P_2O_7 + 2KF + POF_3}$$
$$\mathrm{2K_2PO_3F + H_2O \rightarrow K_4P_2O_7 + 2HF}$$

The view that phosphoryl trifluoride may be produced is supported by evidence from the reaction between calcium fluoride and phosphorus pentoxide,[50] where a slight trace was detected among the gaseous reaction products.

Sodium fluorophosphate melts at 625°C., and has been reported to decompose at higher temperatures in the presence of moisture yielding pyrophosphate and hydrogen fluoride.[34] Furthermore the molten salt is very reactive towards metal surfaces,[15] a property which renders it suitable as a flux. The main application of sodium monofluorophosphate is however in the prevention of dental caries, where it has been shown to act by diminishing the rate of solution of tooth enamel.[53, 142]

Ammonium monofluorophosphate monohydrate loses its water of crystallization at 105°C., and further heating causes the loss of one molecule of ammonia giving an acid salt, $\mathrm{NH_4HPO_3F}$, which melts at 225·5°C. without further decomposition. If the monohydrate is exposed to the atmosphere it tends to effloresce.

Mono-amidophosphates have been prepared[51] from alkali metal monofluorophosphates. Under alkaline conditions, at pressures between 5 and 20 atm. and at temperatures between 90° and 100°C., ammonia reacts with sodium monofluorophosphate to yield $\mathrm{NaHPO_3NH_2,\frac{1}{2}H_2O}$.

It has been suggested,[11] on the basis of data obtained from a study of the $\mathrm{(KPO_3)_n}$–KF system (Fig. 1), that a double salt between potassium monofluorophosphate and potassium fluoride is formed (see also Ref. 131 and page 848).

## DIFLUOROPHOSPHORIC ACID

Difluorophosphoric acid was first recognized in the dilute aqueous solution obtained by the action of dilute nitric acid on a cold saturated solution of the nitron salt,[5] but was not isolated because of hydrolysis. Although the acid appears in the general sequence of equilibria which relate to the fluorophosphoric acids:

$$\mathrm{H_3PO_4} \underset{\mathrm{H_2O}}{\overset{\mathrm{HF}}{\rightleftharpoons}} \mathrm{H_2PO_3F} \underset{\mathrm{H_2O}}{\overset{\mathrm{HF}}{\rightleftharpoons}} \mathrm{HPO_2F_2} \underset{\mathrm{2H_2O}}{\overset{\mathrm{4HF}}{\rightleftharpoons}} \mathrm{HPF_6}$$

these reactions do not afford a convenient basis of preparation. However, like monofluorophosphoric acid, difluorophosphoric acid can arise from the interaction of phosphorus pentoxide and hydrofluoric acid[12]:

$$P_2O_5+(2+x)HF+(1-x)H_2O \rightarrow xHPO_2F_2+(2-x)H_2PO_3F$$

Yields are greatest when $x$ is unity, i.e. when anhydrous hydrofluoric acid is used. The two acids can be separated by vacuum distillation. Fluorosulphonic acid has been used as a catalyst for the reaction.[143]

A novel method of preparation consists in causing monofluorophosphoric acid to react with phosphoryl trifluoride,[54] since no water or hydrogen fluoride is present to lead to the formation of other fluorophosphoric acids:

$$\underset{\text{anhydrous}}{H_2PO_3F}+\underset{\text{gaseous}}{POF_3} \rightarrow 2HPO_2F_2$$

Pure difluorophosphoric acid can be obtained in high yield by distilling the liquid product under reduced pressure. The anhydrous acid has also been obtained[50] from the reaction between calcium fluoride and phosphorus pentoxide. Here it probably arises by hydrolysis of phosphoryl trifluoride, the major product of the reaction, brought about by traces of water present in the reagents.

## Physical Properties

The anhydrous acid is a clear mobile liquid at ordinary temperatures. On exposure to a damp atmosphere dense irritant fumes form. Vapour pressure measurements in the temperature range 50°–90°C. have been published.[54] Below are experimental and calculated data (Table IV) obtained by substituting in the equation:

$$\log_{10}p\ (\text{mm.}) = -\frac{1732{\cdot}2}{T}+7{\cdot}333$$

*Table IV.—Vapour Pressure of Difluorophosphoric Acid*

| $T$ (°K.) | $p_{\text{mm.}}$(observed) | $p_{\text{mm.}}$(calculated) |
|---|---|---|
| 324·8 | 100·5 | 100·4 |
| 335·4 | 147·7 | 148·0 |
| 344·3 | 201·4 | 201·2 |
| 351·0 | 251·4 | 251·0 |
| 356·8 | 301·4 | 301·9 |
| 366·0 | 399·9 | 399·7 |

Other authors have given the vapour pressure equation:

$$\log_{10}p\ (\text{mm.}) = -\frac{421{\cdot}195}{T}-0{\cdot}478214\log T+0{\cdot}0137121T$$

covering the range −22° to 108°C.[143] Because the acid tends to decompose on distillation the boiling point at 760 mm. has been obtained by extrapolation and found to be 115·9°C. Other sources report 108°–111°C.,[50] 107·6°C.[143]

The density is given by the equation:

$$d_t = 1{\cdot}6397-2{\cdot}451\times10^{-3}t+1{\cdot}12\times10^{-6}t^2 \qquad (t = -40 \text{ to } 60°\text{C.})^{143}$$

a value of $d_4^{25}$ 1·583 has also been recorded.[54] The viscosity is given by:

$$\log\eta = -1{\cdot}27912+\frac{405{\cdot}35}{T}-0{\cdot}0045507T \qquad (-40 \text{ to } +45°\text{C.})^{143}$$

Other physical data include: m.p. −96·5 ± 1°C.,[54] −91·3°C.[143]; molar heat of evaporation 7925 g.-cal.,[54] 9125 g.-cal.[143]; Trouton constant 20·4,[54] 23·7–24·6.[143]

Qualitatively the anhydrous acid is similar to perchloric and fluorosulphonic acids.[4]

The infra-red spectra in the region 4000–400 cm.$^{-1}$ of liquid and of associated and monomeric gaseous difluorophosphoric acid have been reported and assigned. The free O–H stretching frequencies are at 3662/3679/3694 cm.$^{-1}$.[144]

In common with the other fluorophosphoric acids nuclear magnetic resonance spectra have been examined.[16–8, 98–9] Details are given in Table V.

*Table V.—Nuclear Magnetic Resonance Data for Difluorophosphoric Acid*

| Resonance | Line structure | Applied field (gauss) | Splitting (gauss) | Chemical shift* |
|---|---|---|---|---|
| Fluorine | (1–1) | 6365<br>4180 | 0·244<br>0·242 | $0{\cdot}90\times10^{-5}$ |
| Phosphorus | (1–2–1) | 6365 | 0·570 | $2{\cdot}1\times10^{-5}$<br>$(2{\cdot}01\times10^{-5})$ |

* Referred to trifluoracetic acid and phosphoric acid respectively.

The (1–2–1) structure suggests two fluorine atoms covalently bonded to one phosphorus atom. There seems to be no evidence of any interaction between the two fluorine atoms themselves, although at lower field strengths certain changes in the fluorine doublet take place.[17] At about 500 gauss the doublet is still present but in the vicinity of 237 gauss the two lines coalesce to a single broad line ($\Delta H$ approx. 0·250). However, when the applied field is reduced to as little as 37 gauss,[99] normal splitting is observed, i.e. 0·245 (±0·003). This anomaly at 237 gauss is not understood.

The difluorophosphate anion has $C_{2v}$ symmetry with P–O = 1·470, P–F = 1·575 Å., <F–P–F = 97·1°, <O–P–O = 122·4°, suggesting about 83% double bond character for the P–O bond.[145]

## Chemical Properties

An aqueous solution of difluorophosphoric acid hydrolyzes but when freshly made it behaves as a strong monobasic acid. When titrated with alkali the neutral point occurs at pH 7·3, but the salt produced in solution rapidly hydrolyzes to monofluorophosphate and fluoride.[15]

The nitron salt is precipitated by the acid from cold aqueous solutions of nitron acetate, a property which is useful analytically.[55]

As expected from the equilibria already discussed the mono- or hexa-fluorophosphoric acid can be obtained by the addition of water or hydrofluoric acid respectively. In general mixtures are obtained.[4]

The anhydrous acid attacks most common metals except aluminium, silver and platinum. However if the acid is diluted, aluminium soon dissolves. The corrosion of steel by aqueous solutions of the acid can be inhibited, even at 300°F., by various organic compounds.[106] In the absence of moisture borosilicate glass is resistant provided that the temperature does not exceed 50°C. Normal polymeric hydrocarbons and fluorocarbons, butyl rubber and wax are inert to the acid at ordinary temperatures.[15]

With alcohols the acid yields a *mono*fluorophosphate ester.[15]

Organic applications include the use of the acid as a catalyst for the polymerization of olefines,[21] in the non-oxidizing refinement of oils[12] and, in a boron trifluoride complex, $HPO_2F_2,0{\cdot}5BF_3$, as an alkylation catalyst.[94] Its use as an improver for asphaltic bitumens is claimed.[100] With other fluorophosphoric acids, difluorophosphoric acid has been used to remove the residual sand from metals cast in sand moulds,[23] and to improve the permeability of certain geological formations.[24,103] Several patents[101-2,104-5] have described its role in 'acidizing' oil wells.

## DIFLUOROPHOSPHATES

A difluorophosphate was first obtained in admixture with the monofluorophosphate as a result of fusing phosphorus pentoxide and ammonium fluoride. This is discussed under monofluorophosphates. More generally difluorophosphates may be prepared by neutralizing the acid,[11] provided that adequate precautions are taken to prevent hydrolysis. However they are best prepared by a double decomposition technique. Many organic bases give insoluble crystalline difluorophosphates when their acetates are mixed with dilute solutions of the ammonium salt.[5] Thus tetramethylammonium, strychnine, brucine, morphine, cocaine and nitron salts have been characterized:

$$\underset{\text{nitron acetate}}{C_{20}H_{16}N_4.OOC.CH_3} + NH_4PO_2F_2 \rightarrow$$
$$C_{20}H_{16}N_4.PO_2F_2\downarrow + NH_4OOC.CH_3$$

These salts are easily recrystallized from water, and are convenient starting points for the preparation of alkali metal difluorophosphates which are very soluble. Boiling solutions of nitron difluorophosphate are added to solutions containing the calculated quantities of the metallic nitrates. The resultant mixtures are cooled and kept at 0°C.; insoluble nitron nitrate is filtered off, the filtrate being evaporated to dryness under vacuum. Potassium and cæsium salts have been made in this way. Alkali metal difluorophosphates have also been made by reaction of metal chlorides with difluorophosphoric acid.[145]

A method, which has much in common with that of Hill and Audrieth for monofluorophosphates, has been devised.[56] Hexafluorophosphates are allowed to react with various oxides or metaphosphates at high temperatures in silver or platinum vessels:

$$NaPF_6 + 2NaPO_3 \rightarrow 3NaPO_2F_2$$
$$3KPF_6 + 2B_2O_3 \rightarrow 3KPO_2F_2 + 4BF_3$$

Almost quantitative yields are claimed.[146]

### Physical Properties

From the scanty information available, difluorophosphates have been claimed to resemble both perchlorates and fluorosulphonates in their solubility. Thus a particular metal having a perchlorate of limited solubility also has a difluorophosphate of limited solubility, though almost without exception difluorophosphates are much more soluble than the corresponding perchlorates.[4,93]

The resemblance between the two series of salts does not extend to their crystal habits.[5]

Potassium difluorophosphate is the best characterized salt. It is readily soluble in water, and crystallizes from methanol or aqueous *iso*propanol in colourless orthorhombic prisms. An *X*-ray determination showed that the space group was *Pnma* with $a = 8{\cdot}03_9$, $b = 6{\cdot}20_5$, $c = 7{\cdot}63_5$ A., $Z = 4$, the crystal structure resembling that of barium sulphate.[145] The density is 2·442 g./c.c., molar volume 57·4 c.c./mole, m.p. 255°C., and refractive indices $n\gamma = 1{\cdot}435$, $n\alpha = 1{\cdot}387$.[146] The symmetrical and asymmetrical infra-red absorption frequencies of the $PO_2$ group in sodium and potassium difluorophosphate have been reported, and compared with those in compounds of similar structure.[147]

The infra-red spectrum (Table VI) of ammonium difluorophosphate has been determined.[15,44] This salt forms colourless rhombic prisms, which melt without decomposition at 213°C.

*Table VI.—The Infra-red Absorption Spectrum of Ammonium Difluorophosphate*

| Position of absorption (cm.$^{-1}$) | Intensity |
|---|---|
| 2900–2550 | medium weak |
| $\left\{\begin{array}{l}1445\\1414\end{array}\right.$ | weak<br>strong |
| 1262 | strong |
| 1125 | strong |
| 1005 | very weak |
| $\left\{\begin{array}{l}870\\832\end{array}\right.$ | weak<br>strong |

Nitron difluorophosphate melts at 230·5–232·5°C. (uncorr.) and at 18°C. dissolves to the extent of 1 : 300 in water.[4]

### Chemical Properties

In general difluorophosphates are not very stable. They easily hydrolyze in water, particularly above room temperature or in the presence of ions which can precipitate insoluble compounds.[5] Initially the solutions are neutral but soon become acidic even when stored at low temperatures.

A study[118] of the hydrolysis of difluorophosphate in the temperature range 0°–25°C. has shown the reaction to be of second order. The activation energy and entropy of activation are 14·5 kcal. and $-17{\cdot}8$ e.u. respectively. At higher temperatures (110°–140°C.) the route of hydrolysis is more complex and the experimental results have been interpreted on the assumption that atoms of phosphorus and fluorine are simultaneously attacked by different molecules of water.[119]

Difluorophosphates are readily converted to the corresponding monofluorophosphates, this being a preparative technique for the latter.[6]

It has been claimed that the zinc, cobalt, lead, iron and cadmium salts function as catalysts in the preparation of $\beta$-lactones.[57]

## HEXAFLUOROPHOSPHORIC ACID

Hexafluorophosphoric acid occurs to the extent of about 0·4% in the products of the reaction between phosphorus pentoxide and 40% aqueous hydrofluoric acid, whence it was first isolated as its nitron salt.[58] It is also formed in small quantities by the action of hydrogen fluoride on phosphoryl trifluoride and phosphorus pentafluoride. The presence of some moisture seems to be necessary to promote the reaction with phosphorus pentafluoride[4]:

$$HF + PF_5 \rightarrow HPF_6$$

Products containing as much as 98% of hexafluorophosphoric acid can be prepared by carrying out the above reaction in liquid sulphur dioxide at temperatures in the range $-15°$ to $-30°$C.[63] This reaction can be extended to include other phosphorus halides which may be fluorinated *in situ*, in a diethyl ether medium, by adding excess of hydrofluoric acid. A suspension of red phosphorus has been fluorinated with chlorine trifluoride[120] to give hexafluorophosphoric acid. A liquid product, $HPF_6,2Et_2O$ results, which boils at 114°C. and melts at −35°C.[107]

The acid is more usually prepared[15] by causing anhydrous hydrofluoric acid to react with phosphorus pentoxide in silver or aluminium equipment:

$$P_2O_5 + 12HF \rightarrow 2HPF_6 + 5H_2O$$

operating in a closed system with cooling to prevent loss of volatile material.

By choosing suitable conditions based on the sequence of equilibria already discussed (p. 843) good yields are obtainable:

| Reactants | Mole ratio | Equilibrium concentration of $HPF_6$ |
|---|---|---|
| HF, $H_3PO_4$ | 6:1 | 52·6% |
| HF, $HPO_2F_2$ | 4:1 | 75·0% |

Provided that a fairly concentrated solution of the acid is available, it is possible to deposit hygroscopic crystals of hexafluorophosphoric acid hexahydrate by adjusting the water content of the system to the proper value and cooling the solution rapidly.[4]

As soon as the crystals melt the equilibria are re-established and other fluorophosphoric acids appear as impurities. A typical analysis of commercially available acid is shown in Table VII.

*Table VII.—Typical Composition of Hexafluorophosphoric Acid*[15]

| Component | Percentage |
|---|---|
| $HPF_6$ | 65 |
| HF | 6 |
| $HPO_2F_2$<br>$H_2PO_3F$<br>$H_3PO_4$ | 8 |
| $H_2O$ | 21 |

Hexafluorophosphoric acid has also been prepared by the action of hydrogen fluoride on uranyl phosphates[148] or diphenyl phosphoramidate[149]:

$$(PhO)_2PONH_2 + 7HF \rightarrow 2PhOH + H_2O + NH_4F + HPF_6$$

Aqueous solutions of the acid[121] may be prepared by passing solutions of the sodium salt over a cation exchange resin.

## Physical Properties

Typical samples of hexafluorophosphoric acid are colourless clear liquids which fume considerably. The fuming of a 65% $HPF_6$ solution is comparable with that of 50% HF solution. The hexahydrate melts at 31·5°C. and an octahydrate has been detected.[15]

Nuclear magnetic resonance spectra[16−8,98] suggest that the hexafluorophosphate ion contains six fluorine atoms covalently bonded to a single phosphorus atom. The multiplets, splittings and chemical shifts are listed in Table VIII.

*Table VIII.—Nuclear Magnetic Resonance Data for Hexafluorophosphoric Acid*

| Resonance | Line structure | Applied field (gauss) | Splitting (gauss) | Chemical shift* ($\times 10^{-5}$) |
|---|---|---|---|---|
| Fluorine | (1–1) | 6365 | 0·178 | −0·55 |
| | | 4180 | 0·179 | |
| | | 175 | 0·177<br>(±0·001) | |
| Phosphorus | (1–6–15–20–15–6–1) | 6365 | 0·41 | +14·8<br>(+11·8) |
| | | 275 | 0·406<br>(±0·010) | |

*Referred to trifluoroacetic and orthophosphoric acids respectively.

The nuclear magnetic resonance spectra in deuterium oxide are very similar (chemical shifts $\delta_{\mathrm{F}}=6{\cdot}9$, $\delta_{\mathrm{P}}=145{\cdot}4$ p.p.m., and fluorine coupling constant $J_{\mathrm{P-F}}=711$ c.p.s.).[149]

As anticipated, little change occurs in the splittings as the applied fields are varied over quite a wide range. However if the applied magnetic field is reduced to a very low value, the $^{19}$F doublet loses its symmetry,[92] owing to polarization and proton resonance effects.

The crystal structure of hexafluorophosphoric acid hexahydrate has been elucidated very fully (Fig. 4).[59] The compound crystallizes in a cage-type lattice which is rather different from the clathrate structures of the gas hydrates. The symmetry is cubic, of space group $O_h^9$ $Im3m$. The parameters are $a$, 7·678 A., $Z=2$. The P–F bond lengths are 1·73 A. (cf. 1·58 A. in $KPF_6$).[60] Each phosphorus atom may be considered as in the centre of an octahedron with fluorine atoms at the apices, the whole being enclosed in a cubo-octahedral cage of water molecules probably linked by hydrogen bonds.[11]

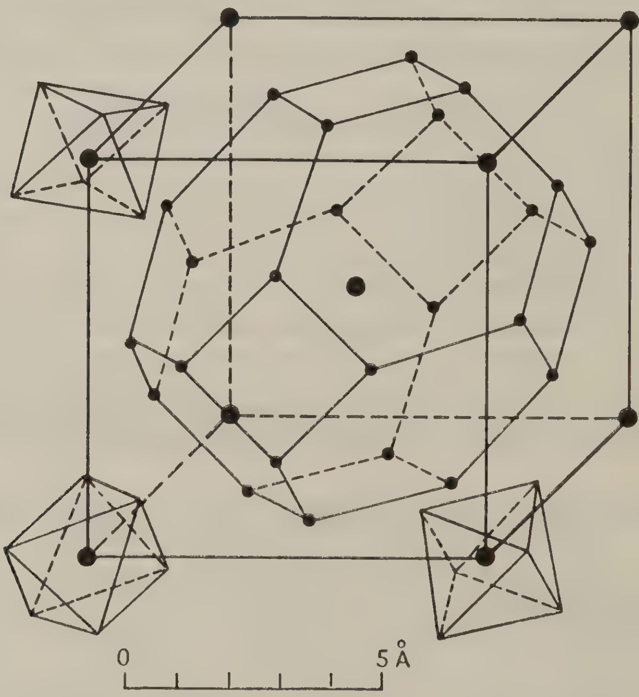

Fig. 4.—Structure of hexafluorophosphoric acid hexahydrate

## Chemical Properties

In the presence of moisture, hexafluorophosphoric acid soon decomposes into a mixture of acids, and the properties of the pure acid cannot therefore be readily investigated. However, it appears to behave as a strong monobasic acid.[15]

The typical mixture attacks nickel, copper and their alloys, lead and stainless steel, if left in contact with these metals. If the mixture is diluted, most metals except aluminium are inert. Silver, platinum, most polyhydrocarbons and polyfluorocarbons, butyl rubbers and wax coatings are not attacked. The anhydrous fluorophosphoric acid does not react with metallic calcium, magnesium, manganese, zinc, chromium or tin[120]; it does however attack silver. Silver fluoride dissolves in the acid to give a colourless solution which deposits silver hexafluorophosphate on evaporation.

Hexafluorophosphoric acid resembles perchloric acid in its behaviour toward sterols.[61] Both acids precipitate colourless crystalline salts from concentrated chloroform solutions of those sterols which contain the 3-$\beta$-hydroxy-$\Delta^5$-ene group.

Many organic bases, such as nitron, also form insoluble salts.[58] Solid adducts are formed between hexafluorophosphoric acid and organic divalent sulphur compounds. The resultant complexes have been applied in the petroleum industry to separate sulphur-bearing materials from hydrocarbons.[108-9]

Salts may be prepared from the acid by straightforward neutralization techniques, although many more efficient methods are available for the preparation of hexafluorophosphates.[15]

The acid can be used in the electrolytic polishing of stainless steels.[62] In common with other fluorophosphoric acids it has found application in the removal of residual sand from metals cast in sand,[23] in the improvement of permeability of certain geological formations,[24] in the 'acidizing' of oil wells,[101-2, 110] and as an improver for asphaltic bitumens.[100]

## HEXAFLUOROPHOSPHATES

Hexafluorophosphates were first obtained by double decomposition reactions in a similar manner to the mono- and di-fluorophosphates.[10, 58] The insoluble nitron hexafluorophosphate is easily precipitated from a solution of the acid and converted into metal hexafluorophosphates, e.g., potassium or barium salts, by treatment with the corresponding nitrates; or into ammonium hexafluorophosphate by the action of ammonia in chloroform. The ammonium salt is a very convenient starting point for many other hexafluorophosphates. Insoluble salts, e.g. those of organic bases, may be precipitated from their acetate solutions. Soluble salts are readily obtained by carefully evaporating to dryness a solution containing ammonium hexafluorophosphate and the appropriate metal hydroxide. Potassium, rubidium, cæsium, sodium and copper hexafluorophosphates have been obtained in this way[10];

$$NH_4PF_6 + NaOH \rightarrow NaPF_6 + H_2O + NH_3$$

If a metal salt is allowed to react with ammonium hexafluorophosphate in the presence of an amine, complex metal ammine hexafluorophosphates are produced, e.g. $Cu(PF_6)_2,5NH_3,H_2O$; $Co(PF_6)_2,6NH_3$; $Ni(PF_6)_2,6NH_3$. The preparation of hexafluorophosphates by this type of reaction is not restricted to the use of the ammonium salt as a starting point, any soluble salt being equally suitable. Thus aryldiazonium hexafluorophosphates have been prepared[15] by precipitation from the appropriate chloride and potassium hexafluorophosphate. Instances of double decomposition reactions in non-aqueous solvents have been recorded, e.g. the reaction of tetramethylammonium hexafluorophosphate with nitrosyl hexachloroantimonate in liquid sulphur dioxide to yield nitrosyl hexafluorophosphate[64]:

$$NOSbCl_6 + (CH_3)_4NPF_6 \rightarrow NOPF_6 + (CH_3)_4NSbCl_6$$

**Refs. p. 868**

On the industrial scale hexafluorophosphates have been prepared by the direct neutralization of the acid with an appropriate base, though the salts prepared in this way, being contaminated by hydrolysis products, must be fractionally crystallized to obtain them in the pure state.[15]

Most other preparative methods described in the literature depend on exhaustive fluorination of suitable phosphorus compounds, usually halides or phosphates. Many fluorinating agents including hydrofluoric acid, metallic fluorides and arsenic and bromine trifluorides, have been investigated. A method that is suitable only for laboratory use consists in heating phosphorus pentachloride with a metallic fluoride at a temperature of 80°–100°C.[65]:

$$PCl_5 + 6MF \rightarrow MPF_6 + 5MCl$$

The reaction product is extracted with water and the nitron salt precipitated. High yields were obtained when potassium fluoride was used. However, with other fluorides yields were lower since the phosphorus pentachloride tended to volatilize before fluorination occurred.

| Fluoride | % Yield |
|---|---|
| Potassium | 80 |
| Ammonium | 67 |
| Sodium | 6 |
| Divalent metals | very low |

It has been suggested that the mechanism of the reaction involves the production of the intermediate pentafluoride, which then combines with the metallic fluoride to give the hexafluorophosphate. Certainly if a metal fluoride is heated in an atmosphere of phosphorus pentafluoride, the following equilibrium is established[4]:

$$KF + PF_5 \rightleftharpoons KPF_6$$

This is also consistent with the recommended modification[66] in which the reaction is carried out in anhydrous hydrofluoric acid. As hydrofluoric acid is such a good fluorinating agent, the metallic chloride may be used and converted to the fluoride *in situ*:

$$MCl + HF \rightarrow MF + HCl$$
$$MF + PCl_5 + 5HF \rightarrow MPF_6 + 5HCl$$

The use of trichloride and liquid chlorine has also been suggested[107] as an alternative to phosphorus pentachloride. Excess hydrofluoric acid is used since this can be driven off subsequently by heating in a current of nitrogen, together with the hydrochloric acid formed as by-product. Substantially theoretical yields of sodium, potassium, ammonium, barium and nitrosyl hexafluorophosphates are claimed, with purities in excess of 95%

Virtually the same reactions occur if bromine trifluoride is substituted for hydrofluoric acid,[67,71] although if phosphorus pentachloride and a metallic chloride are used the hexafluorophosphate is contaminated by the metal bromofluoride. This contamination may be avoided by replacing the pentachloride by the pentabromide.

In non-aqueous solvents phosphorus pentachloride can behave as the salt $(PCl_4)^+(PCl_6)^-$. In these circumstances arsenic trifluoride is able to fluorinate the anion $(PCl_6)^-$.[68] Hence when arsenic trifluoride is added to a solution of phosphorus pentachloride in arsenic trichloride a white hygroscopic salt $(PCl_4)^+(PF_6)^-$ precipitates:

$$2AsF_3 + P_2Cl_{10} \rightarrow 2AsCl_3 + (PCl_4)^+(PF_6)^-$$

In like manner tetrabromophosphonium hexafluorophosphate is precipitated by arsenic trifluoride from a solution of phosphorus pentabromide in carbon disulphide or carbon tetrachloride[69]:

$$2AsF_3 + 2PBr_5 \rightarrow 2AsBr_3 + (PBr_4)^+(PF_6)^-$$

These reactions appear to have a great deal in common with that described above between a metallic fluoride and phosphorus pentachloride, and thus shed a little more light on its possible mechanism. It seems very likely that a similar mechanism also obtains in the reactions of nitrosyl fluoride or dinitrogen tetroxide, with phosphorus pentabromide in bromine trifluoride, which give rise to nitrosyl and nitronium hexafluorophosphates, $NOPF_6$ and $NO_2PF_6$, respectively.[70-1]

Phosphorus (red or white) or phosphorus trichloride reacts with nitrosyl fluoride hydrogen fluoride, $NOF(HF)_3$, to form nitrosyl hexafluorophosphate.[122-4] The same product may be obtained from the reaction of dinitrogen tetroxide, phosphorus pentachloride and hydrogen fluoride. Phosphorus or its pentafluoride reacts with nitryl fluoride to form nitronium hexafluorophosphate[107,125-6]

$$P + 5NO_2F \rightarrow PF_5 + 5NO_2$$
$$PF_5 + NO_2F \rightarrow NO_2PF_6$$

The reaction of chloryl fluoride with phosphorus pentafluoride to give the solid adduct $ClO_2F.PF_5$ (sublimes *in vacuo* at −35°C.) is presumably similar in character.[150] However, the reaction of dioxygen difluoride takes a somewhat different course:

$$O_2F_2 + PF_5 \rightarrow O_2PF_6 + \tfrac{1}{2}F_2$$

Dioxygen hexafluorophosphate, a white solid, is a powerful oxidizing agent. It decomposes rapidly at room temperature, and slowly even at −80°C., giving phosphorus pentafluoride, oxygen and fluorine, according to the equation[151]:

$$O_2PF_6 \rightarrow O_2 + \tfrac{1}{2}F_2 + PF_5$$

Phosphates are readily converted into the hexafluoro-derivatives by the action of bromine trifluoride. The metaphosphates yield reasonably pure metallic hexafluorophosphates, but these are contaminated by bromofluorides if orthophosphates are used.[67,71] The sodium, potassium, silver and barium salts have been prepared in this way. The silver salt has also been prepared from silver powder, phosphoric oxide and boron trifluoride.[152] It reacts with copper powder in boiling toluene, giving silver and a colourless solution of copper(I) hexafluorophosphate which can be kept unchanged, but decomposes on evaporation or treatment with water.[153]

Ammonium hexafluorophosphate has been obtained in a unique reaction between anhydrous hydrofluoric acid and trimeric phosphonitrilic chloride[60]:

$$(PNCl_2)_3 + 18HF \rightarrow 3NH_4PF_6 + 6HCl$$

## Physical Properties

Similarities to perchlorates and halides have been noted. Hexafluorophosphates resemble perchlorates with respect to their solubilities in water and their molecular volumes.[10] In general their solubilities are high except in the case of substituted ammonium salts.[15]

The solubilities of a selection of hexafluorophosphates and perchlorates are given in Table IX.

The ammonium and sodium salts are soluble in organic solvents, e.g., methyl and ethyl alcohol, acetone and methyl acetate.[66] The silver salt also strongly resembles silver perchlorate in being soluble in benzene, toluene, *m*-xylene and mesitylene.[152]

The solubility of potassium hexafluorophosphate in water (see Table X) has been investigated in the range 0–100°C. The equation

$$\log_{10}\frac{1}{N} = -14{\cdot}83906\,\frac{1831{\cdot}26}{T} - 4{\cdot}34237\log_{10}T$$

was found to fit the data very well.[91]

*Table IX.—Solubilities of Hexafluorophosphates and Perchlorates*[4]

| Cation | Hexafluorophosphate (moles/litre of water at room temperature) | Perchlorate |
|---|---|---|
| Potassium | 0·432 | 1·120 |
| Rubidium | 0·076 | 0·071 |
| Cæsium | 0·030 | 0·084 |
| Hexammino-nickel | 0·0018 | 0·0069 |
| Tetramethylammonium | 0·0077 | 0·0652 |
| Benzenediazonium | 0·036 | 0·070 |
| Pyridine | 0·180 | 0·530 |
| Strychnine | 0·0033 | 0·0040 |
| Brucine | 0·0034 | 0·0054 |
| Nitron | 0·0002 | 0·00005 |
| Tetraethylammonium | 0·0294 | 0·1056 |

Freezing-point depressions of hexafluorophosphates and perchlorates[72] indicate further similarities between the two ions.

The refractive indices of both perchlorates and hexafluorophosphates are of the same order. However, there are significant crystallographic differences between the two series of salts. The alkali perchlorates are normally rhombic, whilst the hexafluorophosphates tend to crystallize in the cubic system.[4] Various investigators[73–4] have pointed out the similarity to the alkali halides which also crystallize in a cubic face-centred lattice. Thus crystals of halides and hexafluorophosphates produced by evaporating solutions from freshly cleaved mica surfaces show an oriented growth (epitaxy) which often seems to occur in salts crystallizing with cubic face-centred structures.

*Table X.—Solubility of Potassium Hexafluorophosphate*

| Temperature °C. | % w/w (observed) | % w/w (calculated) |
|---|---|---|
| 0·0 | 3·560 | 3·551 |
| 4·5 | 4·242 | 4·223 |
| 10·5 | 5·270 | 5·255 |
| 16·2 | 6·400 | 6·389 |
| 20·2 | 7·300 | 7·28 |
| 25·0 | 8·35 | 8·45 |
| 30·0 | 9·69 | 9·80 |
| 35·0 | 11·15 | 11·27 |
| 40·0 | 12·85 | 12·87 |
| 45·0 | 14·82 | 14·58 |
| 50·0 | 16·48 | 16·42 |
| 55·0 | 18·22 | 18·35 |
| 60·0 | 20·29 | 20·38 |
| 65·0 | 22·49 | 22·49 |
| 70·0 | 24·61 | 24·69 |
| 75·0 | 27·29 | 26·94 |
| 80·0 | 29·38 | 29·23 |
| 85·0 | 31·96 | 31·57 |
| 90·0 | 34·03 | 33·91 |
| 95·0 | 35·88 | 36·27 |
| 100·0 | 38·30 | 38·62 |

The crystal structures of several hexafluorophosphates have been determined.[60, 75–7] The anhydrous salts of the alkali metals and thallium form primitive cubic unit cells containing four molecules. The metal and phosphorus atoms form a cubic lattice of the sodium chloride type with the fluorine atoms distributed octahedrally around each phosphorus. The unit cell dimensions are tabulated below:

| | A. |
|---|---|
| $NaPF_6$ | 7·61[75] |
| $KPF_6$ | 7·71[60] |
| $NH_4PF_6$ | 7·90[60] |
| $CsPF_6$ | 8·22[60] |
| $TlPF_6$ | 7·49[76] |

At −15·6°C. α-potassium hexafluorophosphate transforms into a rhombohedral β-form of the barium fluorosilicate type having *a* 4·85 A. and α 94°. The energy associated with this phase change is 1·4 g.-cal. per g.,[79] which is consistent with the transition of the $PF_6$ groups from oscillatory motion about the cell diagonal to a stationary state.

The monohydrate of the sodium salt is not cubic but orthorhombic. It crystallizes in colourless prisms of hexagonal habit which show parallel extinction and are optically biaxially negative. Very full structural data have been obtained.[77] There are 4 molecules per unit cell the dimensions of which are *a*, 7962; *b*, 10·594; *c*, 6·116 A. The space group is given as $D_{2h}^{28}$ *Imma* and the positions of the atoms are given in Table XI.

*Table XI.—Atomic Co-ordinates in Sodium Hexafluorophosphate Monohydrate*

| Atom | Number/cell | *x* | *y* | *z* |
|---|---|---|---|---|
| Phosphorus | 4 | 0 | 0 | 0 |
| Sodium | 4 | 0·25 | 0·25 | 0·75 |
| Oxygen | 8 | 0 | 0·25 | 0·52 |
| Hydrogen | 8 | 0 | 0·011 | 0·282 |
| Fluorine (apical) | 8 | 0 | 0·011 | 0·282 |
| Fluorine (planar) | 16 | 0·140 | 1·106 | 0·013 |

The $PF_6^-$ ion in the hydrate is not a regular octahedron as in the anhydrous salts. The P–F distances vary, the four equatorial P–F bond lengths being 1·58 A. while the remaining two at the apices are 1·73 A. It has been calculated[11] that a σ-bond distance corrected for ionic effects would be 1·63 ± 0·02 A., suggesting that the planar bonds have only a small amount of π-character and that the apical bonds are deficient in both σ and π character.

The other interatomic distances are as follow:

| | | | |
|---|---|---|---|
| Na–F (planar) | 2·29 A. | Na–O | 2·44 A. |
| O–F (apical) | 2·90 A. | | |

bond angles are given as:

| | | | |
|---|---|---|---|
| F–HOH–F | 121° | Na–O–Na | 109° |

*X*-Ray powder diagrams have indicated similarities in structure between hexafluorophosphates and hexafluoroarsenates.[68–9] Thus tetrabromophosphonium and tetrachlorophosphonium hexafluorophosphates resemble tetrachloroarsonium hexafluoroarsenate.

The infra-red spectra[78] of several hexafluorophosphates provide evidence of the covalent character of the P–F bonds, which is substantiated by nuclear magnetic resonance data.[11, 16–7]

However, the nuclear magnetic resonance spectra observed[17] for aqueous solutions of potassium hexafluorophosphate were too weak, with an applied field of 6365 gauss, for any conclusions to be drawn about the nature of the fluorine-phosphorus interaction. Nevertheless a fluorine doublet was observable, of splitting 0·176 gauss and chemical shift $-0{\cdot}77 \times 10^{-5}$ p.p.m. measured with respect to trifluoracetic acid.

All the above data are consistent with an octahedral configuration for the hexafluorophosphate ion based upon $sp^3d^2$ hybridization at the phosphorus atom. Analogous alkyl- and aryl-pentafluorophosphates containing ions such as $[CH_3{-}PF_5]^-$ are known,[154] as is the unstable cæsium tetrachlorodifluorophosphate prepared by the reaction[155]:

$$2PCl_2F_3 + 2CsF \rightarrow CsPF_6 + CsPCl_4F_2$$

The densities, viscosities and conductances[127] of aqueous solutions of potassium hexafluorophosphate have been measured at 25° and 40°C. Isopiestic vapour pressure measurements have been made at 25°C. and the osmotic and activity coefficients calculated. The equivalent conductances at infinite dilution are 132·83 and 203·25 cm.$^2$ int. ohm$^{-1}$ equiv.$^{-1}$ at 25° and 50°C., respectively, and the corresponding association constants are 2·42 and 1·43 litres mole$^{-1}$.

The electrical conductivity measurements that have been made[46] at 25°C. show that hexafluorophosphates are strong electrolytes. The equivalent conductance of the potassium salt is $130{\cdot}4 \pm 0{\cdot}5$ ohm$^{-1}$ and the ionic conductance of the $PF_6^-$ anion, 56·9 ohm$^{-1}$. The ionic nature of such compounds as the tetrachloro- and tetrabromo-phosphonium salts is confirmed by conductivity studies in various non-aqueous solvents.[68-9] The values for the equivalent conductances (in nitromethane) of nitrosyl hexafluorophosphate and the corresponding perchlorate lie very close to one another; they are respectively 74·0 and 61·2 ohm$^{-1}$.[64] The heat capacities of ammonium, rubidium and potassium hexafluorophosphate have been measured[128] over the temperature range 20–300°K.

Investigation of the sulphur tetrafluoride–phosphorus pentafluoride system[80] has revealed a certain degree of interaction. It has been suggested that sulphur tetrafluoride tends to form complexes with a higher degree of symmetry than either of the components. Thus a *cis*-cyclic or a *trans*-linear dimer is envisaged, the ligand achieving pseudo-octahedral symmetry by virtue of a lone pair orbital (see Fig. 5). Such a compound would be expected to behave as a salt, $(SF_3)^+(PF_6)^-$.

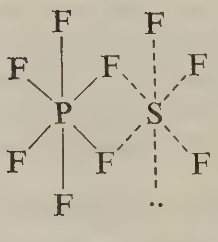

FIG. 5.—Proposed structure of $SF_4$–$PF_5$ complex

### Chemical Properties

Chemically the hexafluorophosphates are relatively inert. This is to a certain extent understandable when the $PF_6^-$ ion is considered in relation to the isoelectronic sulphur hexafluoride molecule which is noted for its inert character. Thus the salts do not decompose spontaneously when dried nor are they sensitive to shock.[10]

The alkali and alkaline earth metal salts dissolve in water to form stable neutral solutions, although if the solution of akaline earth hexafluorophosphate is evaporated, even at very low temperature, it begins to decompose as it approaches saturation.[11] The alkaline hydrolysis of $PF_6^-$[129] takes place at a rate convenient for measurement over the range 160°–190°C. The reaction is of first order with respect to $PF_6^-$ and of zero order with respect to $OH^-$. Its rate is decreased by high concentrations of potassium salts. The hydrolysis takes place by a solvolytic dissociation mechanism, water taking part in the formation of the transition state. The rate of alkaline hydrolysis is increased in the presence of alkali metal ions, their effect increasing in the order $K^+ < Na^+ \ll Li^+$. The temperature dependence of the rate constant is given by the equation:

$$\log 0{\cdot}4343K = 11{\cdot}095 - \frac{6147{\cdot}3}{T}$$

in the range $T = 160°$–191°C. and at an ionic strength of 0·12. The energy and entropy of activation of the process at 175°C. are 28·1 kcal. and −17·0 e.u. respectively. Acid catalysis of the hydrolysis at room temperature is slight. Salts of substituted phosphonium ions are decomposed by water, and must therefore be formed under anhydrous conditions. Tetrabromophosphonium hexafluorophosphate hydrolyzes to yellow-brown solutions with strong oxidizing properties which suggests the formation of bromine together with some lower phosphorus acids.[69] Nitrosyl hexafluorophosphate may be hydrolyzed to the acid and a mixture of nitric oxide and nitrogen dioxide[64]:

$$2NOPF_6 + H_2O \rightarrow 2HPF_6 + NO + NO_2$$

Hexafluorophosphates are easily decomposed by mineral acids, especially when heated,[10] but with alkalis the behaviour varies. In dilute alkaline solutions the salts of the common cations are very stable,[4] although those of somewhat more complex cations are rather less so. Thus the action of alkali on tetrachlorophosphonium hexafluorophosphate decomposes the cation leaving the $PF_6^-$ anion intact:

$$[PCl_4][PF_6] + 7KOH \rightarrow K_2HPO_4 + 5KCl + KPF_6 + 3H_2O \text{ }^{68}$$

However, in the case of tetrabromophosphonium hexafluorophosphate the hydrolysis proceeds further and all the fluorophosphates together with orthophosphate can be detected in the alkaline hydrolysate.[69]

Fusion with caustic alkalis does not normally bring about decomposition of the ion until exceedingly high temperatures are reached.[58]

The action of heat on the hexafluorophosphates usually causes dissociation into phosphorus pentafluoride and a simple fluoride:

$$KPF_6 \rightarrow KF + PF_5 \text{ }^{4}$$

this reaction being the reverse of one of the preparative procedures described above. Dry diazonium hexafluorophosphates decompose harmlessly in a similar manner although the reaction is not reversible[10]:

$$(ArN_2)(PF_6) \rightarrow ArF + PF_5 + N_2$$

As this decomposition takes place at relatively low temperatures, it affords a convenient method for the preparation of phosphorus pentafluoride. Other hexafluorophosphates have been reported to decompose in a somewhat similar manner:

$$\begin{aligned}(PCl_4)(PF_6) &\rightarrow PF_5 + PCl_4F \text{ }^{81}\\ (PBr_4)(PF_6) &\rightarrow PF_5 + PBr_4F \text{ }^{69}\\ NOPF_6 &\rightarrow PF_5 + NOF \text{ }^{64}\end{aligned}$$

The nature of the phosphorus tetrachlorofluoride produced by the thermal decomposition of tetrachlorophosphonium hexafluorophosphate seems to depend on the initial experimental conditions. If the reaction is carried out *in vacuo* the mixed halide is obtained as a homopolar liquid, but in a medium of arsenic trichloride phosphorus tetrachlorofluoride is precipitated as an ionic solid.

Various reactions of a less general nature have been reported. The ammonium salt crystallizes in the presence of ammonium fluoride to yield a double salt, $NH_4PF_6,NH_4F$, which does not melt but sublimes at 140°C.[4] The system, ammonium hexafluorophosphate–ammonia, has been studied tensiometrically in the temperature range $-10°$ to $-70°$C.[20, 111] By varying the composition, pressure and temperature, the following complexes were established:

| *Complex* | *Temperature range* (°C.) |
|---|---|
| $NH_4PF_6,NH_3$ | (−70)–(+28) |
| $NH_4PF_6,2NH_3$ | (−70)–(−15) |
| $NH_4PF_6,4NH_3$ | (−70)–(−33) |

They are stable over the temperature ranges indicated.

Halogen exchange can take place in the cations of the halogen-substituted phosphonium salts:

$$3(PCl_4)(PF_6) + 4AsF_3 \rightarrow 6PF_5 + 4AsCl_3$$ [68]

$$3(PBr_4)(PF_6) + 4AsCl_3 \rightarrow 3(PCl_4)(PF_6) + 4AsBr_3$$ [69]

$$3(PBr_4)(PF_6) + 4PCl_3 \rightarrow 3(PCl_4)(PF_6) + 4PBr_3$$ [69]

In the first case substitution of fluorine for chlorine gives rise to the entity $(PF_4)^+ (PF_6)^-$ which is the ionic form of phosphorus pentafluoride.

The chemistry of nitrosyl hexafluorophosphate has been investigated fairly thoroughly[64, 156] and several reactions have been described:

$$NOPF_6 + C_2H_5OH \rightarrow C_2H_5O.NO + HPF_6$$

$$NOPF_6 + (Me_4N)N_3 \rightarrow N_2O + N_2 + Me_4N.PF_6$$

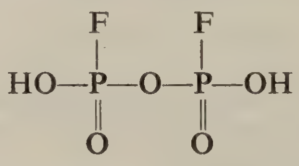
$$NOPF_6 + (Me_4N).SNC \rightarrow NO.SCN + Me_4N.PF_6$$

$$NOPF_6 + BF_3 \rightarrow NOBF_4 + PF_5$$

$$NOPF_6 + ArH + RNH_2 \rightarrow ArR + N_2 + H_2O + HPF_6$$

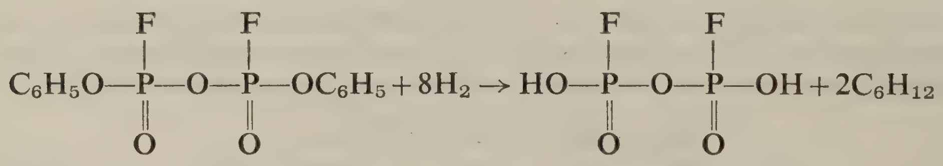
## FLUOROPOLYPHOSPHORIC ACIDS

Although the existence of monofluoropyrophosphoric acid (fluorodiphosphoric acid) has not been established, symmetrical difluorodiphosphoric acid (formulated below) and its salts have been described by several authors.



$$HO-\underset{\underset{O}{\|}}{\overset{\overset{F}{|}}{P}}-O-\underset{\underset{O}{\|}}{\overset{\overset{F}{|}}{P}}-OH$$

The acid is obtained by the hydrogenation of *sym.* difluorodiphenyldiphosphate[157] in ether:

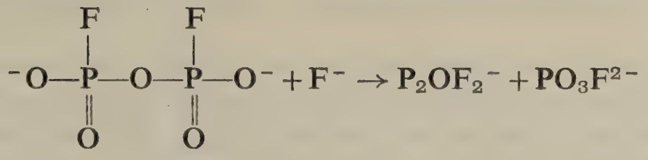


$$C_6H_5O-\underset{\underset{O}{\|}}{\overset{\overset{F}{|}}{P}}-O-\underset{\underset{O}{\|}}{\overset{\overset{F}{|}}{P}}-OC_6H_5 + 8H_2 \rightarrow HO-\underset{\underset{O}{\|}}{\overset{\overset{F}{|}}{P}}-O-\underset{\underset{O}{\|}}{\overset{\overset{F}{|}}{P}}-OH + 2C_6H_{12}$$

It is a viscous, nearly colourless hygroscopic liquid. An attempt[158] to prepare the free acid by the reaction of *sym.* difluorodiphenyldiphosphate with halogen acid was only partially successful, difluorodiphosphoric acid being only one of a number of products.

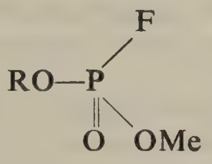
The dilithium salt of the acid has been prepared by reaction of *sym.* difluorodiphenyldiphosphate with lithium chloride in acetone.[158] Alternative methods of preparing the di-alkali metal salts are by the reaction of the metal alkoxide with the acid,[157] the diphenyl ester or the pyridinium salt, $(C_5H_5NH)_2P_2O_5F_2$.[158] The alkali metal salts form colourless crystals.

The ethyl esters of the diphosphoric acids are strong alkylating agents towards alkali and hydrogen halides. The $P_2O_5F_2^{2-}$ ion is comparatively stable in neutral aqueous solution but the P–O–P bridge is split by potassium fluoride[159]:



$$^{-}O-\overset{\overset{\displaystyle F}{|}}{\underset{\underset{\displaystyle O}{\|}}{P}}-O-\overset{\overset{\displaystyle F}{|}}{\underset{\underset{\displaystyle O}{\|}}{P}}-O^{-}+F^{-}\rightarrow P_2OF_2^{-}+PO_3F^{2-}$$

The organic esters are much less stable than the diphosphate ion and react instantaneously with water; they also react with potassium fluoride or silver nitrate to give compounds of the type:



Me = (K or Ag)

The infra-red spectra of disodium and dipotassium difluorodiphosphate have been reported.[147,160] The asymmetrical P–O–P vibrations lie at higher frequencies than in the corresponding pyrophosphates.

Fluoride ions react with trimetaphosphate ions in aqueous solution to yield monofluorotriphosphate:

$$F^{-}+[P_3O_9]^{3-} \rightleftharpoons [P_3O_9F]^{4-}$$

The reaction is reversible, recyclization being more facile in alkaline than in acid solution. At high fluoride concentrations $[P_3O_9F]^{4-}$ is further degraded to $[P_2O_7]^{4-}$ and $[PO_2F_2]^{-}$. Fluorotriphosphoric acid has been isolated in the form of crystalline salts: $(NH_4)_4[P_3O_9F],H_2O$ (plates); $Ag_4[P_3O_9F],H_2O$ (needles); $(Ag, Na)_4[P_3O_9F]$ (Ag/Na = 10·2 : 1 or 8·4 : 1); $(Ag_3K)[P_3O_9F]$ (needles); $Ag_{3\cdot5}(NH_4)_{0\cdot5}[P_3O_9F],H_2O$; $Ba_2[P_3O_9F]$ (long spangles).

Tetrametaphosphate undergoes a similar reaction, especially in concentrated solutions of the ammonium salt:

$$F^{-}+[P_4O_{12}]^{4-} \rightleftharpoons [P_4O_{12}F]^{5-}$$

Like fluorotriphosphate, the fluorotetraphosphate will either recyclize or degrade further to $[P_3O_{10}]^{5-}$ and $[PO_2F_2]^{-}$, according to conditions. Triphosphate also reacts with fluoride ion, but no monofluorodiphosphate has been detected[161]:

$$[HP_3O_{10}]^{4-}+F^{-}\rightarrow [PO_3F]^{2-}+[P_2O_7]^{4-}+H^{+}$$

## ANALYTICAL CHEMISTRY OF THE FLUOROPHOSPHATES

Several physical techniques have been developed for the separation and identification of the fluorophosphates. Paper chromatography has been used[69] with slight modifications[83–4] to the Ebel system normally used to separate condensed phosphates. Electrophoresis using a neutral buffer has also found application.[82] To avoid coincidence of certain spots uranyl and lead salts were added to inhibit the movement of phosphate and monofluorophosphate ions.

It is possible to identify various organic fluorophosphates by microscopical examination,[85] and it is claimed[88] that Raman and infra-red spectroscopy may be used analytically. On the basis of the information[16] obtained from nuclear magnetic resonance spectra, it seems possible that this technique may prove a useful analytical tool in this field. Structural entities in the $HF–P_2O_5–H_2O$ system are recognizable, including a unit hitherto unknown and containing one fluorine atom per phosphorus atom.

**Refs. p. 868**

When mixtures of fluorophosphates are encountered[82] they may be hydrolyzed to orthophosphates and fluorides by digestion with nitric acid. The orthophosphate is separable by ion exchange and the fluoride may be estimated by some standard procedure.

Classical methods for the determination of fluorine such as the precipitation of lead chlorofluoride have been used.[86] Many methods depend on a Willard–Winter distillation followed by a titration or colorimetric finish. Several reagents are bleached by fluoride or fluorosilicate ion, e.g. titanium complexes,[87] or iron salicylate.[89] Free fluoride ion which frequently occurs in samples of fluorophosphates is estimated in this way after removing other salts by precipitation with silver nitrate. A novel method of releasing the fluorine from fluorophosphates, particularly of organic origin, consists of treating the compound with sodium ethoxide at room temperature to liberate sodium fluoride which can be titrated against thorium nitrate using alizarin sulphonate as indicator.[90]

Various gravimetric procedures have been devised[15,86] which rely on the precipitation of very insoluble fluorophosphates themselves. Thus the monofluorophosphate can be precipitated from 80% ethanol solutions by the addition of a suitable silver salt. Nitron acetate precipitates quantitatively both the di-[55] and the hexafluorophosphates. Tetraphenylarsonium chloride has also been used to precipitate the hexafluorophosphate, and to determine it amperometrically.[162]

### SECTION XXXII

# CHLORINE-SUBSTITUTED OXYACIDS OF PHOSPHORUS

### BY D. A. PALGRAVE

## THE CHLORO-PHOSPHOROUS AND -PHOSPHORIC ACIDS

THE ions corresponding to these acids may be regarded as being derived from phosphite or phosphate by successive replacement of oxygen by chlorine:

| | | | | |
|---|---|---|---|---|
| | $HPO_3^{--}$<br>phosphite | $HPO_2Cl^-$<br>monochlorophosphite | $HPOCl_2$<br>'dichlorophosphine' oxide | |
| $PO_4^{---}$<br>phosphate | $PO_3Cl^{--}$<br>monochloro-phosphate | $PO_2Cl_2^-$<br>dichloro-phosphate | $POCl_3$<br>phosphoryl trichloride | $PCl_6^-$<br>hexachloro-phosphate |

Their existence is not well established, probably because of their relative instability. Dichlorophosphoric acid, as the only member of the series to be isolated, has received the most attention from investigators.

## MONOCHLOROPHOSPHOROUS ACID (Phosphorochloridous Acid)

Investigations[1-2] of the hydrolysis of phosphorus trichloride revealed a previously unknown compound, which was produced in yields up to 75%. Its acidic nature and powerful reducing properties suggested that this entity might be monochlorophosphorous acid, $H_2PO_2Cl$. By carrying out the hydrolysis in ethereal solution, and examining the heat evolved as water was added, the curve shown in Fig. 1 was obtained.[3] The four linear portions on the curves make three intersections which correspond to 1, 2 and 3 moles of water per mole of phosphorus trichloride.

It was claimed on the basis of this work that the hydrolysis of phosphorus trichloride to phosphorous acid involves the production of two intermediates:

$$PCl_3 \xrightarrow{H_2O} P(OH)Cl_2 \xrightarrow{H_2O} P(OH)_2Cl \xrightarrow{H_2O} P(OH)_3$$

Attempts[4] to isolate these bodies by hydrolysis in various solvents at temperatures between $-70°$ and $-20°$C. have so far proved unsuccessful.

## MONOCHLOROPHOSPHORIC ACID (Phosphorochloridic Acid)

Although monochlorophosphoric acid has never been obtained in a pure condition, its existence has been established using nuclear magnetic resonance techniques.[5] By examining the products of the reaction, in a sealed tube at 25°C. and at 100°C., between orthophosphoric acid and phosphoryl trichloride, several species were identified by their chemical shifts measured with respect to 85% orthophosphoric acid in a field of 9395 gauss. The peak at $-18{\cdot}2$ p.p.m. was assigned to monochlorophosphoric acid and that at $-13{\cdot}0$ p.p.m. to a monochlorophosphate end group, $HO(Cl)P(O)O_{1/2}^-$. Monochlorophosphoric acid occurs only when the reagents are present in equimolar proportions. It has been claimed[6] as a hydrolysis product of dichlorophosphoric acid, though no trace of it could be found in the products of hydrolysis of phosphoryl trichloride by varying proportions of sodium hydroxide.[35]

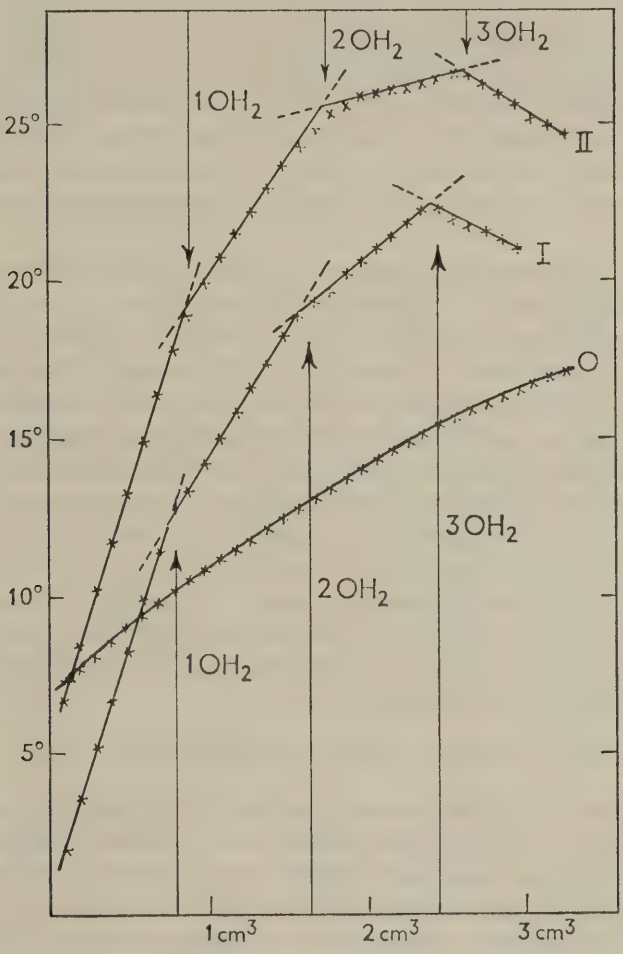
## DICHLOROPHOSPHORIC ACID (Phosphorodichloridic Acid)

### Preparation

Dichlorophosphoric acid was first obtained[7] by hydrolyzing phosphoryl trichloride in an ethereal medium:

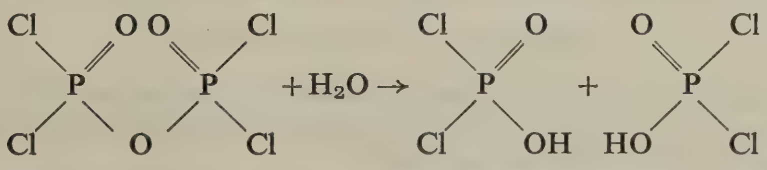
$$POCl_3 + H_2O \rightarrow HPO_2Cl_2 + HCl$$

Later investigators[4] dispensed with the use of ether by working at temperatures between −20° and −10°C. Equimolar quantities of the starting materials resulted in the production of anhydrous dichlorophosphoric acid. If the water content was doubled and the temperature allowed to rise, the monohydrate, $HPO_2Cl_2,H_2O$, was formed. The anhydrous acid has subsequently been prepared[8−10] by the hydrolysis either by water or by alcohols[12−4,24] of pyrophosphoryl chloride at temperatures below −30°C.:



Curves I and II: variations of temperature of ethereal solution of $PCl_3$ as a function of the volume of water added. The arrows indicate the stoicheiometric quantities of water corresponding to the three stages of the hydrolytic reaction.

FIG. 1.—Hydrolysis of phosphorus trichloride



The use of an alcohol yields the corresponding ester as a co-product.

Dichlorophosphoric acid is the main product formed when phosphoryl trichloride is heated with phosphoric acid in a sealed tube between 25° and 110°C., provided that the proportion of the chloride is greater than 50 mole-%.[5] However, free hydrochloric acid and various species including dichlorophosphate end groups, $Cl_2P(O)O_{1/2}^-$, tend to predominate if the concentration of phosphoryl trichloride does not exceed 60 mole-%. At higher temperatures[25] the equilibrium:

$$2POCl_3 + H_3PO_4 \rightleftharpoons 3HPO_2Cl_2$$

is reached quickly, and from stoicheiometric proportions a yield of 93% of the dichlorophosphoric acid is obtained. The reactions:

$$P_4O_{10} + 6H_2O + 8POCl_3 \rightarrow 12HPO_2Cl_2$$

and

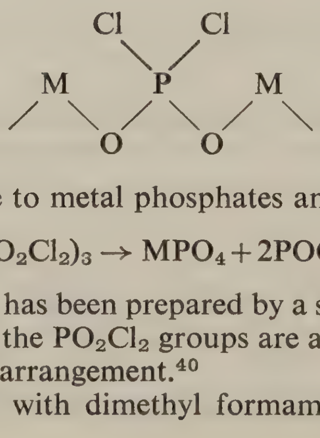
$$P_4O_{10} + 6PCl_5 + 5H_3PO_4 \rightarrow 15HPO_2Cl_2$$

were brought about by heating the reactants at 230°C. in a sealed tube for 72 hr.[5] About 93% of the total phosphorus in the reaction products was present as dichlorophosphoric acid, as estimated by N.M.R. determinations. However, using a different analytical technique,[26] i.e. precipitating the nitron salt of the dichlorophosphoric acid or causing the latter to react with phosphorus pentachloride, it was estimated that not more than 60% of the dichlorophosphoric acid was present in these mixtures.

Salts of common inorganic cations have not been isolated from aqueous solution, although good evidence for the existence of a barium salt in solution[7] was afforded by the data obtained when phosphoryl trichloride or phosphorus pentachloride was titrated with barium hydroxide solution, using thymolphthalein as indicator. When the quantity of base equivalent to barium dichlorophosphate had been added, no precipitation occurred, but at the point corresponding to complete hydrolysis of the starting materials barium phosphate was precipitated. Similarly only mono- and polyphosphates and trimetaphosphates were detected chromatographically among the products of hydrolysis of phosphoryl trichloride by sodium hydroxide solution in molar proportions varying from $POCl_3 : NaOH = 1$ to $100:1$.[36] It should, however, be noted that such condensed phosphates may be artefacts, formed under the conditions of paper chromatography.[37] However in phosphoryl chloride the solvated chlorides $BeCl_2$ and $MCl_3$ ($M = Al, Ga, In, Fe$) react with dichlorine oxide to form the corresponding dichlorophosphates,[39] e.g.,

$$MCl_3 + 3POCl_3 + 3Cl_2O \rightarrow M(PO_2Cl_2)_3 + 6Cl_2$$

These are very hygroscopic compounds, insoluble in non-polar solvents, soluble in dimethyl sulphoxide or dimethyl formamide and violently decomposed by water. All are colourless with the exception of the lemon yellow ferric salt. The dichlorophosphates of gallium, indium and iron are isotypic. The infra-red spectra show that only the beryllium compound is composed of discrete ions, $Be^{2+}$ and $PO_2Cl_2^-$. The trivalent elements, on the other hand, form polymeric structures with oxygen bridges:



When heated they decompose to metal phosphates and phosphoryl chloride:

$$M(PO_2Cl_2)_3 \rightarrow MPO_4 + 2POCl_3$$ [39]

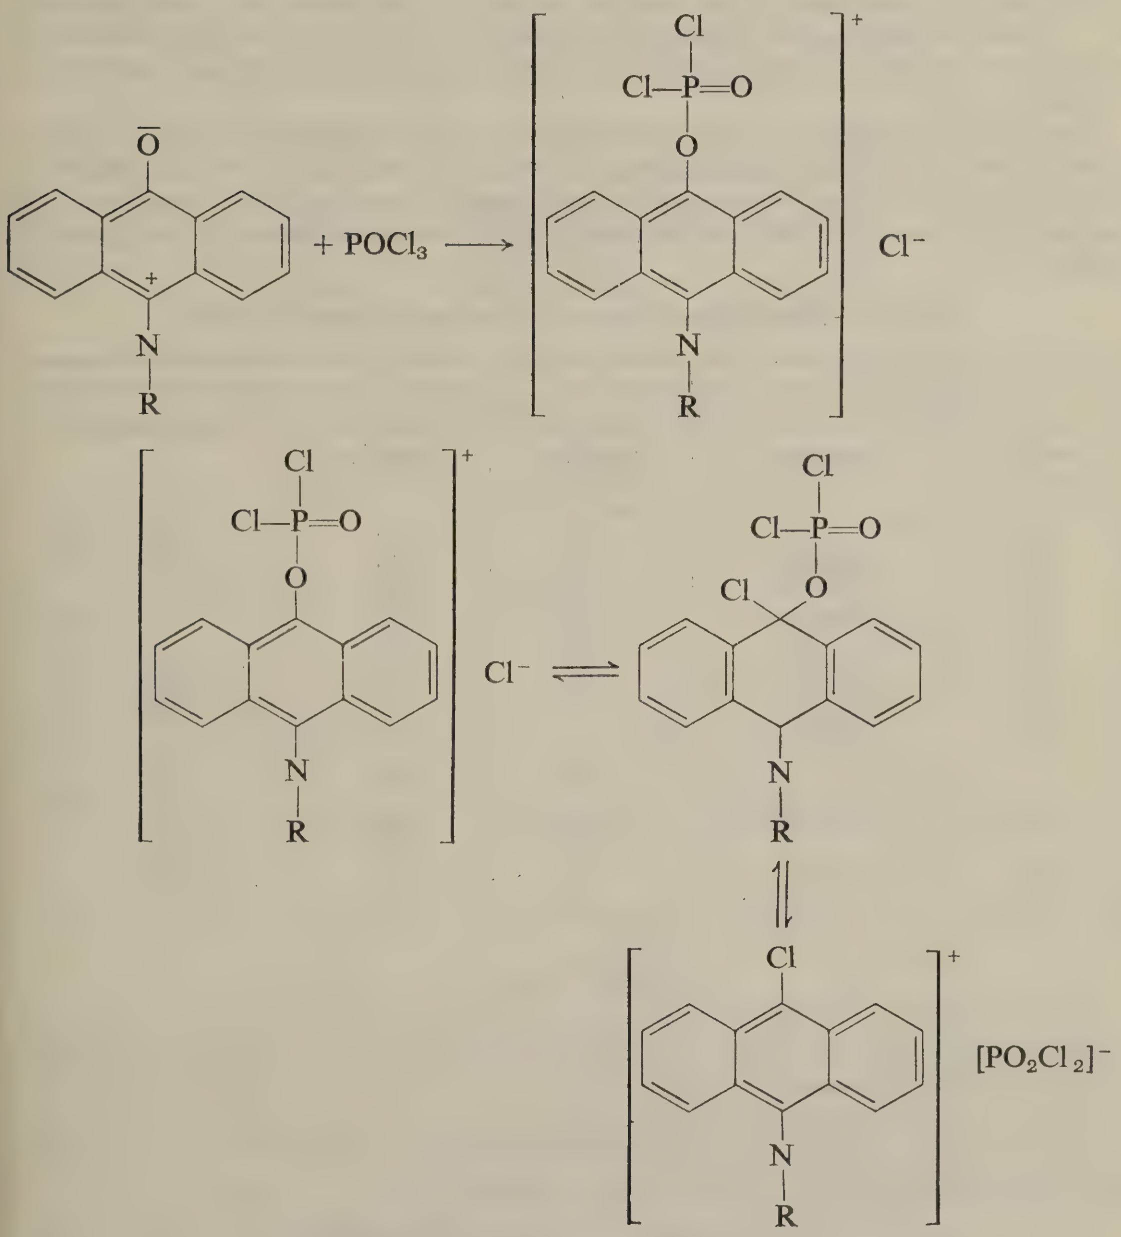
The thallium salt (m.p. 83°) has been prepared by a similar method. This again has a different structure, in which the $PO_2Cl_2$ groups are attached to the central Tl atom in an octahedral chelate-type arrangement.[40]

Phosphoryl chloride reacts with dimethyl formamide in anhydrous acetonitrile giving the crystalline compound $ClCH{=}NMe_2.OPOCl_2$. If treated with sodium perchlorate this yields sodium dichlorophosphate. The tetrachlorostibonium salt, $SbCl_4PO_2Cl_2$ (m.p. 136–8°), can be similarly isolated from the reaction products of $ClCH{=}NMe_2.OPOCl_2$ and antimony(V) chloride in chloroform.[41]

Nitron and brucine salts have been precipitated from solutions of the acid at temperatures in the region of $-15°C$.[4,15] In addition, strychnine and copper ethylenediamine, $[Cu(en)_2]^{++}$, salts have been obtained,[15] although these compounds decomposed on recrystallization.

It has been known for some time[27–8] that certain metal oxides (e.g. those of divalent manganese, zinc, magnesium and calcium) react with phosphoryl trichloride alone, or in solvents such as ethyl acetate, to give complexes containing a metal, phosphorus, oxygen and chlorine. A recent repetition[29] of this work has confirmed the results, the products being crystalline hygroscopic compounds of the formula $MO.P_2O_3Cl_4,(CH_3COOC_2H_5)_2$. *X*-Ray structural determinations on the manganese compound have shown it to be a dichlorophosphate $Mn(PO_2Cl_2)_2,(CH_3COOC_2H_5)$.

An interesting molecular rearrangement results when N-alkylacridones react with phosphoryl trichloride[16]:



The salt-like complexes formed are 9-chloroacridinium dichlorophosphates, and the dichlorophosphate ion is stable enough to survive reaction with other compounds containing active hydrogen atoms to produce well defined 9-substituted acridinium dichlorophosphates,[17] suitable for the characterization of the acridone concerned.

### Physical Properties

Anhydrous dichlorophosphoric acid forms colourless crystalline needles which melt at $-28$°C.[6,8] to a clear mobile liquid having an odour similar to that of phosphoryl trichloride.[5] At 25°C.[5] the density of 93% dichlorophosphoric acid is 1·77 g./c.c., but a more accurate determination using the anhydrous acid yielded the result $d_{25} = 1{\cdot}6878$.[8] The vapour pressure of the 93% material at 25°C. was found to be 17 mm.

Dichlorophosphoric acid is soluble in water and in organic solvents, the solutions in toluene, carbon disulphide, acetone and ligroin being noticeably reddish in colour.[6] It seems probable that reaction occurs on solution in alcohol, with the formation of the dialkyl ester of orthophosphoric acid.[5]

Nuclear magnetic resonance spectra have been examined in a field of 9395 gauss.[5] The position of the chemical shift seems to depend to a certain extent on the ratio of chlorine to phosphorus in the reaction mixture. Thus peaks have been observed at $-9{\cdot}5$ p.p.m. and $-10{\cdot}5$ p.p.m. with respect to 85% orthophosphoric acid. A further peak at $+8{\cdot}3$ p.p.m. has been assigned to the dichlorophosphate end group, $Cl_2P(O)_{1/2}^-$.

The Raman spectra[18] provide evidence of strong hydrogen bonding, with a pronounced effect on the apparent bond orders of the phosphorus–oxygen bonds in the molecule. The effect is weaker if the hydrogen is replaced by deuterium. The spectra of the normal and the deuterated dichlorophosphoric acid are given in Table I.

*Table I.—The Raman Spectra of Dichlorophosphoric Acids*

| $HPO_2Cl_2$ | | $DPO_2Cl_2$ | | Assignment |
|---|---|---|---|---|
| position (cm.$^{-1}$) | intensity | position (cm.$^{-1}$) | intensity | |
| 200 | (8) | 197 | (8) | δ $PCl_2$ ($A_1$) |

### Chemical Properties

Dichlorophosphoric acid is a fairly strong monobasic acid; indeed, it has been claimed that the hydrogen ion is more strongly dissociated than any of the hydrogen ions of orthophosphoric acid.[5] It hydrolyzes in water to give hydrochloric and orthophosphoric acids. The rate of the hydrolysis is similar in acidic and basic solutions, and this, together with the effect of pyridine on the kinetics, suggests that the hydrolysis goes through some such bimolecular mechanism as:

$$HOPOCl_2 \rightleftharpoons H^+ + Cl_2PO_2^- \xrightarrow{H_2O} HCl + HOPClOO^- \quad \text{etc.}^{38}$$

Monochlorophosphoric acid may be formed as an intermediate in the hydrolysis.[6] The acid is quite stable in the absence of air,[8] but decomposes if distilled even *in vacuo*, the main product at 300°C. being pyrophosphoryl chloride with traces of phosphoryl trichloride.[6,9,31] The same result can be achieved by distillation in a stream of hydrogen chloride at 180°C.

Variations in the composition of the products occur if the acid is distilled at ordinary pressures. In general, hydrogen chloride is lost and a condensed phosphoryl chloride produced.[8] The extent of dehydrochlorination depends on the temperature and duration of distillation.[5] At 100°C. a mixture of pyro- and trimeta-phosphoryl chlorides is produced,[6,8] although it has been reported[4] that under these conditions and also at higher temperatures two layers are obtained, the upper consisting of phosphoryl trichloride and the lower of a substance which on further heating yields pyrophosphoryl chloride. In general the residues from these distillations seem to consist of condensed chlorophosphoric acids.

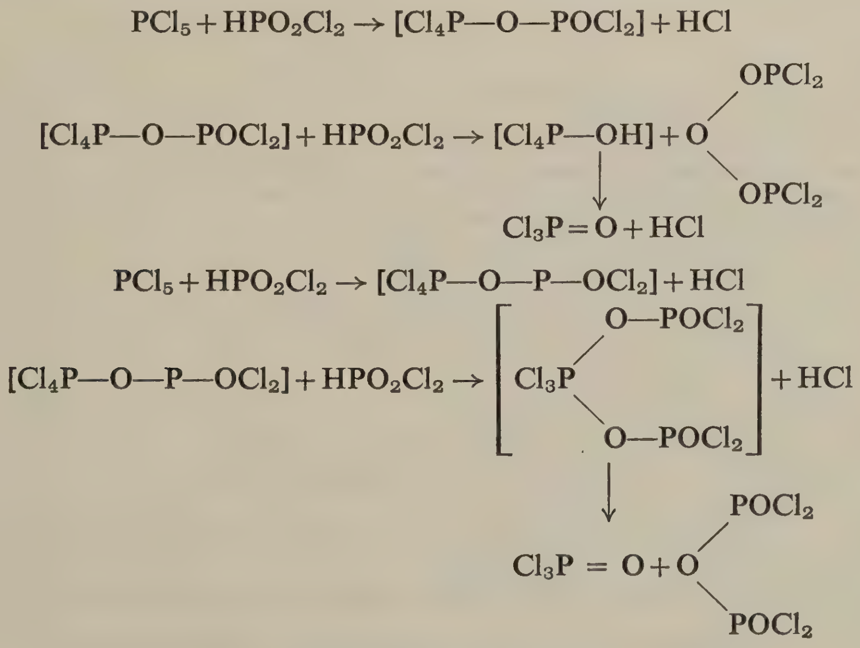
The monohydrate, when kept for about four weeks *in vacuo*, deposits fine crystals of indeterminate composition.[4]

Addition of acid chlorides to dichlorophosphoric acid[25] gives the corresponding anhydrides in the yields listed in Table II.

*Table II.—Reaction of Acid Chlorides with Dichlorophosphoric Acid*

| Acid chloride | Product | Yield % w/w. |
|---|---|---|
| $POCl_3$ | $Cl_2P(O)OP(O)Cl_2$ | 34 |
| $SOCl_2$ | $Cl_2P(O)OSOCl$ | 15 |
| $SO_2Cl_2$ | $Cl_2P(O)OSO_2Cl$ | 19 |
| $Me_3SiCl$ | $Cl_2P(O)OSiMe_3$ | 90 |

Phosphorus pentachloride reacts[30,32] with dichlorophosphoric acid to give pyrophosphoryl chloride possibly by one of the following routes:



$$PCl_5 + HPO_2Cl_2 \rightarrow [Cl_4P\text{—}O\text{—}POCl_2] + HCl$$

$$[Cl_4P\text{—}O\text{—}POCl_2] + HPO_2Cl_2 \rightarrow [Cl_4P\text{—}OH] + O\begin{matrix} \diagup OPCl_2 \\ \diagdown OPCl_2 \end{matrix}$$

$$[Cl_4P\text{—}OH] \downarrow Cl_3P{=}O + HCl$$

or

$$PCl_5 + HPO_2Cl_2 \rightarrow [Cl_4P\text{—}O\text{—}P\text{—}OCl_2] + HCl$$

$$[Cl_4P\text{—}O\text{—}P\text{—}OCl_2] + HPO_2Cl_2 \rightarrow \left[ Cl_3P\begin{matrix} \diagup O\text{—}POCl_2 \\ \diagdown O\text{—}POCl_2 \end{matrix} \right] + HCl$$

$$\downarrow$$

$$Cl_3P = O + O\begin{matrix} \diagup POCl_2 \\ \diagdown POCl_2 \end{matrix}$$

## Dibromophosphoric Acid

Dibromophosphoric acid[33-4] is formed by the controlled hydrolysis of phosphorus oxybromide. The sparingly soluble nitron salt has been prepared by precipitation from a mixture of phosphoryl bromide, acetone and water.

## HEXACHLOROPHOSPHORIC ACID

This acid is known only by virtue of the hexachlorophosphate ion $[PCl_6]^-$. In the phosphorus pentachloride lattice, discrete $[PCl_4]^+$ and $[PCl_6]^-$ ions are postulated (see page 477), and there is abundant evidence of the $[PCl_6]^-$ ion in various non-aqueous solvent systems.[22]

The existence of potassium, cæsium and tetramethylammonium salts with a monovalent cation has been demonstrated by means of conductimetric titrations[19] in iodine monochloride. Similarly, studies of the systems tetramethylammonium chloride–methyl cyanide–phosphorus pentachloride[20] and methyl cyanide–hydrochloric acid–phosphorus pentachloride[21] have established the salts $[Me_4N]^+[PCl_6]^-$ and $[(CH_3CN)_nH]^+[PCl_6]^-$. If phosphorus dichlorotrifluoride is heated for 8 hr. in boiling carbon tetrachloride, a compound is obtained[23] which ionizes in methyl cyanide. Transport measurements indicate an ionic composition of $[PCl_4]^+[PCl_5F]^-$, i.e. tetrachlorophosphonium pentachlorofluorophosphate.

Unstable cæsium tetrachlorodifluorophosphate is formed by the interaction of cæsium fluoride and phosphorus dichloride trifluoride:

$$2PCl_2F_3 + 2CsF \rightarrow Cs^+[PF_6]^- + Cs^+[PCl_4F_2]^-$$

The sparingly soluble cæsium hexafluorophosphate is filtered off, but the filtrate slowly decomposes, yielding more $[PF_6]^-$. Cæsium tetrachlorodifluorophosphate is also very sensitive to moisture.[42]

It seems very likely that the hexachloro- and hexafluoro-phosphate ions are structurally very similar, both being associated with $d^2sp^3$ hybridization at the phosphorus atom. As the sizes of the halide atoms increase, the stability of this type of ion appears to decrease. No hexaiodophosphate is known and the hexabromophosphate ion has only been detected in a solution of phosphorus pentabromide in methyl cyanide[11] (see page 523). The tetrachlorodicyanophosphate ion has been isolated as the tetrapropylammonium and tetrabutylammonium salts (m.p. 157° and 142°C. respectively) from the products of reacting phosphorus pentachloride and potassium cyanide in acetonitrile at 40°–50°C. They are white solids, which slowly evolve hydrogen cyanide when moist.[42]

## SECTION XXXIII

# THE ORGANIC DERIVATIVES OF PHOSPHORUS

## BY P. A. T. HOYE

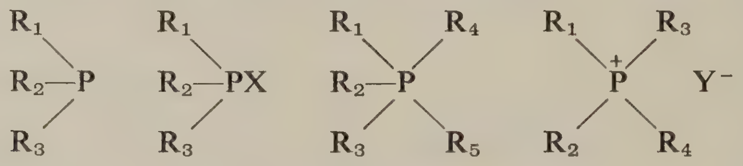
Wöhler in 1828 founded the science of synthetic organic chemistry by his synthesis of urea from ammonium cyanate. Eight years earlier than this Lassaigne[1122] had prepared the first recorded synthetic organophosphorus compounds, crude mixtures of alkyl phosphates, which were made by heating alcohols with syrupy phosphoric acid. Some 20 years later phosphine derivatives were studied by Thénard (cf. ref. 1) and others and since that time the chemistry of organophosphorus compounds has developed at a rapid and accelerating pace.

Although many early workers contributed to the growth of organophosphorus chemistry, it is to the German chemist Michaelis and co-workers that we owe most of the development during the latter half of the nineteenth century. They synthesized vast numbers of organophosphorus compounds, particularly those with carbon–phosphorus bonds, and developed many of the methods of preparation which are in use today. This work was continued and extended by Arbuzov in Russia, particularly in the field of phosphorous acid tri-esters.

During the late 1930's and early 1940's research work in Germany and Great Britain showed that certain organophosphorus compounds are highly toxic and could be used as war gases. This work led, after the 1939–45 war, to the development of a considerable number of compounds of commercial and industrial significance which may be used as insecticides.[1247]

Over the last 10–15 years a number of factors have contributed to the growth of organophosphorus chemistry. Amongst these can be mentioned: (i) the discovery by Wittig that alkylidene phosphoranes react with carbonyl compounds to form olefins, (ii) the realization by physical-organic chemists that organophosphorus chemistry offers a fruitful field for theoretical study and investigation of reaction mechanisms, (iii) the enormous industrial and commercial developments of organophosphorus compounds, (iv) recent advances in physical techniques such as nuclear magnetic resonance, which have provided tools for the investigation of organophosphorus structures,[581] and (v) rapid developments in the biological and biochemical aspects of phosphates in life processes.

Organophosphorus compounds can be represented by the general formulae:



where $R_1$, $R_2$, etc., represent combinations of organic substituents, mercapto, amino, etc., X is O, S, $=NR$, $=CR_2$ and Y an acid radical. The problem of naming the many possible variations is difficult and several nomenclative systems have been used. A system of nomenclature has been agreed between the Chemical Society of Great Britain and the American Chemical Society for compounds which contain one phosphorus atom.[1969] This system is somewhat cumbersome in use and is not entirely free from ambiguities and has been strongly criticized.[2163] Nevertheless it is in general usage in British and American literature and has been adopted in this review. Numerous examples are given in the text.

In view of the long history of organophosphorus compounds it is surprising that many of the standard textbooks of organic chemistry make little or no reference to the subject. The first book entirely devoted to organophosphorus chemistry was published in 1938 by Plets,[2132] and the first such book written in English, *Organophosphorus Compounds*,[1] was published only in 1950. Three further books have been published; these are *Organophosphorus Monomers and Polymers*,[2139] *Methoden der Organischen Chemie*[2] and *Structure and Mechanism in Organo-Phosphorus Chemistry*.[2433] In addition to these a considerable number of book reviews, review articles and essays which are generally devoted to one aspect or class of organophosphorus compounds, have been published. These are referred to in the appropriate sections of the text.

## PHOSPHINES

Phosphines are derivatives of phosphorus hydrides, known and hypothetical, in which one or more of the P–H bonds are replaced by a phosphorus–carbon linkage. Such compounds form an extensive series of highly reactive organophosphorus compounds, which together with their many derivatives embody a considerable proportion of organophosphorus chemistry.

| Known or hypothetical phosphine | Type of known derivatives | | |
|---|---|---|---|
| $PH_5$ | $R_5P$<br>phosphorane | | |
| $PH_3$ | $RPH_2$<br>primary, | $R_2PH$<br>secondary, | $R_3P$<br>tertiary phosphine |
| $P_2H_4$ | $R_2P—PR_2$ | $RHP—PHR$ | |
| $P_nH_{(2n+1)}$ | $P_nR_{(2n+1)}$ | | |
| $(PH)_n$ | $R_4P_4$ | $R_5P_5$ | |

### Phosphoranes

Few compounds having phosphorus bonded to five carbon atoms are reported; all are penta-aryl compounds. Pentaphenylphosphorane was first obtained by Wittig and Rieber[4] by the reaction of tetraphenylphosphonium iodide with phenyl lithium:

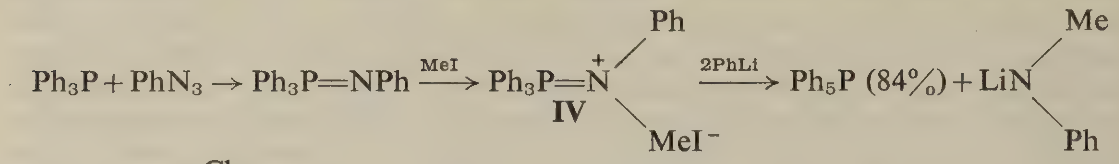
$$Ph_4PI + PhLi \rightarrow Ph_5P + LiI$$

The phosphoranes $(C_6H_5)_4PC(C_6H_5)_3$ and $p$-$CH_3.C_6H_4P(C_6H_5)_4$[6] are prepared similarly.

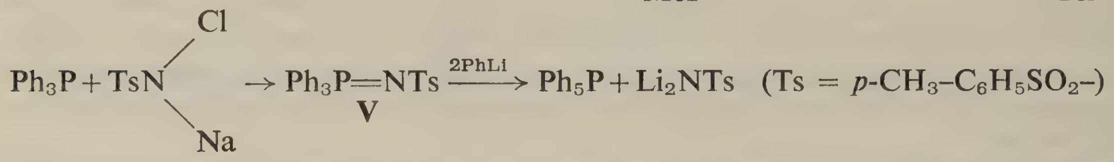
Pentaphenylphosphorane has a measurable dipole moment; *X*-ray analysis shows it to have a trigonal bipyramidal configuration, but the molecule possesses no symmetry owing to asymmetric orientation of the benzene rings[7]; the two P–C axial and three P–C equatorial bond lengths are 1·987 and 1·850 A., respectively.[7]

$Ph_5P$ reacts with hydrogen halides giving tetraphenylphosphonium salts, $Ph_4PX$,[5] and is decomposed thermally giving a mixture of benzene, diphenyl, triphenylphosphine, and a small amount of *P*-phenyl-*o*-diphenylenephosphine (I).[5,8] Initial dissociation to $Ph_4P$– and Ph– radicals has been suggested to account for the variety of products formed when $Ph_5P$ decomposes either by itself or when dissolved in organic solvents such as chloroform, carbon tetrachloride, benzene or pyridine.[8,10] In pyridine, at room temperature, $Ph_5P$ gives a 60% yield of **I** and a trace of 4-phenylpyridine.[8] Equivalence of the five phenyl groups in $C_6D_5(C_6H_5)_4P$ has been demonstrated by reaction with hydrogen bromide.[6,8,9]

Two relatively recent reactions provide a route to a number of novel phenyl *spiro*phosphoranes (II). These are the reactions of an aryl lithium compound with the immonium iodide **IV**, formed by adding methyl iodide to *N*-phenyliminotriphenylphosphorane,[11] or with *N*-(*p*-toluenesulphonyl)iminotriphenylphosphorane **V**[12-3]

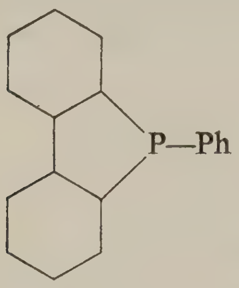


$$Ph_3P + PhN_3 \rightarrow Ph_3P{=}NPh \xrightarrow{MeI} \underset{\mathbf{IV}}{Ph_3P{=}\overset{+}{N}}\begin{smallmatrix}Ph\\ MeI^-\end{smallmatrix} \xrightarrow{2PhLi} Ph_5P\ (84\%) + LiN\begin{smallmatrix}Me\\ Ph\end{smallmatrix}$$

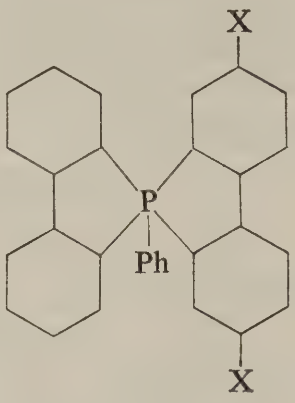


$$Ph_3P + TsN\begin{smallmatrix}Cl\\ Na\end{smallmatrix} \rightarrow \underset{\mathbf{V}}{Ph_3P{=}NTs} \xrightarrow{2PhLi} Ph_5P + Li_2NTs \quad (Ts = p\text{-}CH_3\text{–}C_6H_5SO_2\text{–})$$

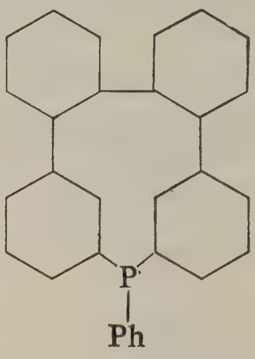
Compounds such as phenyl bis-*o*-phenylenephosphorane, **II**, ($X = H$) are obtained starting from **I** and 2:2′-dilithium diphenyl. At the melting point, compound **II** ($R = H$) decomposes to form phenyl(*o*-tetraphenyl 2′,2′,2′)phosphine, **III**, as the main product.



**I**

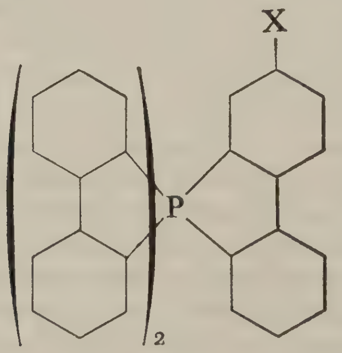


**II** ($X = Me_2N$)



**III**

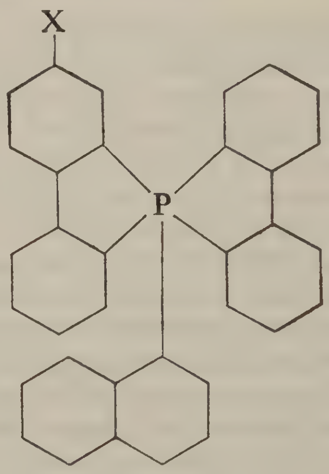
Reaction of phosphorus pentachloride with 2,2′-dilithium diphenyl affords the alkali metal salt of tris(biphenylene)phosphate, **VI** ($X = H$). The octahedral structure of the phosphate anion has been demonstrated by its resolution with brucine methiodide into *d*- and *l*-forms which show extraordinarily high specific rotations. The partially stereospecific acid cleavage of the optically active ate-complexes *d*- and *l*-potassium bis(biphenylene)-4-methylbiphenylene phosphate **VI** ($X = CH_3$) with hydrochloric acid in methanol/acetone led to the first optically active penta-aryl phosphoranes, *d*- and *l*-biphenylene(4-methylbiphenylene)-biphenyl-2-yl phosphorane **VII** ($X = CH_3$). In contrast, acidic cleavage of optically active compound **VI** ($X = H$) affords an optically inactive phosphorane **VII** ($X = H$).[2174-6]
The chemistry of phosphoranes to 1966 is reviewed by Wittig.[2429]



**VI**

$X = H$, $[\alpha]_{578}^{24} = \pm 1930 \pm 30°$

$X = CH_3$, $[\alpha]_{578}^{24} = \pm 1870 \pm 30°$



**VII**

$X = CH_3$, $[\alpha]_{578}^{24} = \pm 94 \pm 1°$

## Derivatives of Phosphine

Simple physical properties of many phosphines are recorded by Kosolapoff[1] and by Houben-Weyl.[2] Vapour pressure data on relatively few phosphines have been determined[39, 210, 242–3, 252] (Table I). Boiling points and heats of evaporation, determined from vapour pressure data, and densities of a large number of phosphines and phosphonous dichlorides are recorded and the boiling points correlated using the quantity $M\rho^2$.[2244]

Electron diffraction study of trimethylphosphine shows the molecule to be pyramidal with a C–P–C bond angle of $100 \pm 4°$ and a P–C bond length of $1{\cdot}87 \pm 0{\cdot}02$ Å.[241, 251]; the molecular weight in the vapour phase indicates a monomeric structure. The heat of formation and the mean dissociation energy of the P–C bonds derived from heat of combustion data are $-30{\cdot}1$ kcal.mole$^{-1}$ and 65·3 kcal. respectively.[253] The crystal structure of triphenylphosphine similarly shows a pyramidal configuration about phosphorus, but owing to unequal rotation of the benzene rings about the P–C bonds the molecule has no symmetry; the P–C bond length is 1·828 Å.[254] The heat of formation, phenyl–phosphorus bond energy, and heat of sublimation of $Ph_3P$ are given as $(Ph_3P, g) = 72{\cdot}4 \pm 2{\cdot}3$ kcal.mole$^{-1}$, $D(P\text{–}Ph) = 70{\cdot}6 \pm 4$ kcal. and $\Delta H_{sub.} = 18{\cdot}1$ kcal.mole$^{-1}$ respectively.[1855]

Many optically active tertiary phosphines have been obtained by Horner and co-workers[33, 41–6] by cathodic reduction of optically active quaternary phosphonium salts at a mercury cathode. Such compounds are optically stable at room temperature and can be distilled under vacuum without noticeable racemization,[45] but racemization occurs if they are heated in solvents. In hydrocarbon solvents the racemization of (+) methyl *n*-propylphenylphosphine follows a first order rate law; the activation energy is 29–31 kcal.mole$^{-1}$.[33, 45] The preparation and reactions of optically active phosphines are reviewed by Horner,[33] who has recently reported the determination of the absolute configuration of ethylmethylphenylphosphine by asymmetric synthesis,[2316] and by Kamai and Usacheva.[2422]

Dipole moments of a number of primary, secondary and tertiary phosphines,[256] and dipole moments and spectroscopic data for a number of arylphosphines and their corresponding oxides and sulphides are recorded.[255, 1705]

Phosphines are basic compounds, forming salts with acids which are structurally analogous to ammonium compounds:

$$R_3P + H^+ \rightleftharpoons R_3PH^+$$

Successive replacement of the hydrogen atoms in phosphine with organic substituents results in a stepwise increase in basicity, the degree of which is determined by the nature of the substituent.[251] Until recently the basicity of relatively few phosphines had been measured and few attempts made to correlate basicity values with structure.[246–7] Streuli[244] measured the basicity of a number of phosphines by potentiometric titration in nitromethane solution (see Table II) and with Henderson[245] demonstrated a correlation of the data with the Taft $\sigma$ values of the substituent groups in the form, $pK_a = A + B\Sigma\sigma$. The results show that the basicity is determined largely by the inductive effects of the substituents. Other factors do operate but are of sufficiently minor importance to enable the $pK_a$ of a phosphine to be predicted to within 1 unit provided the $\Sigma\sigma$ values of the substituents are known. The values of $A$ and $B$ for primary, secondary, and tertiary phosphines are: 2·46, $-2{\cdot}64$; 5·13, $-2{\cdot}61$; 7·85, $-2{\cdot}67$ respectively. Refinements to this method are suggested by Kabachnik and Balueva.[257] Base strengths of a number of phosphines, diphosphines, and aminophosphines, determined by potentiometric titration in aqueous ethanolic solution, are given by Issleib and Bruchlos.[290] $K_b$ values for some hydroxymethyl substituted phosphines are given by Grinshtein *et al.*[2318]

Acid dissociation constants of several primary and secondary phosphines,

$$>P\text{–}H \rightleftharpoons\ >P^- + H^+$$

## Preparation of Phosphines

### FROM ELEMENTAL PHOSPHORUS

Although considerable progress has been made in the synthesis of organophosphorus compounds from elemental phosphorus, the yields which can be obtained are generally poor and, except for a few specific compounds which are otherwise difficult to obtain, synthesis by conventional routes is more satisfactory. The subject has been reviewed by Grayson[20] and by Rauhut.[21]

Hofmann in 1861 obtained $Et_3P$ in low yield by alkylation of white phosphorus with ethyl iodide in the presence of zinc.[14] Complex mixtures of organophosphorus compounds are formed by the action of alkyl iodides on a mixture of white phosphorus and sodium hydroxide solution.[15] Mixtures of tertiary phosphines and phosphonium compounds are formed by heating white phosphorus, olefin, alkyl halide, and hydrogen at high temperatures and pressures.[153] In such reactions, low yields are due to alkylation and halogenation of the intermediate phosphines giving quaternary phosphonium salts and trialkyl dihalophosphoranes respectively; indeed, moderately good yields of tertiary phosphine oxides result from the reaction of phosphorus with alkyl halides either alone[22] or in the presence of iodine or the iodide $P_2I_4$[23, 238] followed by hydrolysis:

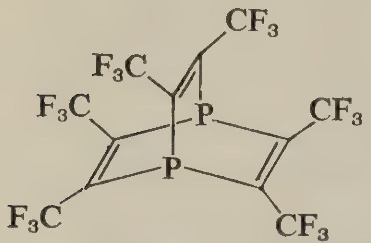
$$RI_{(\text{excess})} + P_2I_4 \rightarrow R_3PI_2 \xrightarrow{H_2O} R_3PO$$

Perfluoroalkyl iodides and white phosphorus form mixtures of the phosphonous di-iodide, phosphinous iodide, and trisperfluoroalkylphosphine, the ratios of which depend on reaction temperatures and time.[154, 240]

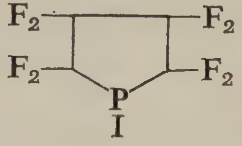
$$CF_3I + P \rightarrow CF_3PI_2 + (CF_3)_2PI + (CF_3)_3P$$

The chemistry of perfluoroalkyl derivatives of phosphorus is reviewed by Banks and Haszeldine.[1313]

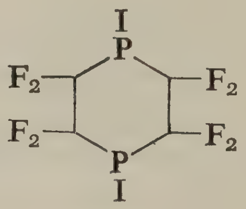
Krespan and co-workers have shown that red phosphorus and bistrifluoromethylacetylene react in the presence of iodine giving the substituted diphosphabi*cyclo*-octatriene, **VIII**,.[152, 264] Tetrafluoroethylene, phosphorus and iodine react to form the cyclic phosphinous iodides **IX** and **X**.[239]



**VIII**



**IX**



**X**

Treatment of white phosphorus with organolithium compounds or Grignard reagents followed by hydrolysis gives small yields of monoalkyl or arylphosphines[18-9]; much of the phosphorus is converted to insoluble substances believed to be organic polyphosphines: phenyl sodium or butyl aluminium gives organopolyphosphines exclusive of monomeric phosphines.[18] Addition of an alkyl bromide to the reaction mixture formed from an aryl lithium or aryl sodium compound and white phosphorus gives isolable products which consist largely of tertiary phosphines, for example:

$$m\text{-}CF_3.C_6H_4Li + P + BuBr \xrightarrow[(2)\,H_2O]{(1)\,Et_2O} m\text{-}CF_3.C_6H_4PBu_2\ (36\%) + (m\text{-}CF_3.C_6H_4)_2PBu\ (37\%)$$

In contrast, the Grignard reagent butyl magnesium bromide, white phosphorus, and butyl bromide react to form tetrabutyl*cyclo*tetraphosphine as the sole major product in up to 42% yield.[18]

Triphenylarsine and phosphorus are reported to undergo exchange at 300° giving $Ph_3P$ and elemental arsenic[16]; tetraphenyl tin reacts with phosphorus at 250° giving a product diphenyltin triphenylphosphine which on oxidation forms diphenyltin oxide and $Ph_3PO$.[17] Small amounts of $PhPH_2$ and $Ph_2PH$ are among the products formed by heating red phosphorus with phenol and water at 250°.[1457]

### FROM METAL PHOSPHIDES

Although the first synthetic phosphines were obtained by passing methyl chloride over heated calcium phosphide,[1] the preparation of phosphines from phosphides has been slow to develop. Inorganic phosphides, such as $Na_3P$ and $Mg_3P_2$, react poorly with alkyl halides owing to their low solubility in organic media. Not until the past few years, with better understanding of the preparation and handling of the alkali metal salts of phosphine and substituted phosphines and their reactions, often in situ in ether solvents, have phosphides emerged as major starting materials for organic phosphines. The preparation, properties and reactions of phosphides and P-substituted phosphides are reviewed by Issleib.[81]

### *Preparation of Phosphides*

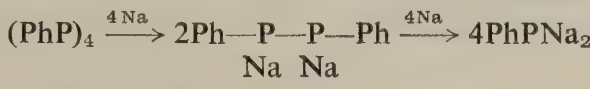
(*a*) Metalation. Alkali metal salts of phosphine are obtained by interaction of phosphine with alkali metals in hydrocarbon solvents,[56] or with sodium emulsion in hydrocarbon–polyglycolether solvent[287] or sodium in liquid ammonia,[52, 64] and by transmetallation with organometallic compounds such as butyl lithium,[57] phenyl lithium[24, 53] or sodium triphenylmethyl.[67] Sodium salts of primary and secondary phosphines are conveniently prepared by using sodium emulsions in hydrocarbon media[51,55] which react with $RPH_2$ at temperatures below 80° and above 95° to give the mono- and the disodium salts respectively,[51] or by using sodamide[56] or sodium in liquid ammonia.[55] Lithium salts are generally obtained by transmetalation reactions with compounds such as phenyl,[24,66,73-4] butyl[62] or methyl lithium[85]:

$$PH_3 \xrightarrow{\text{Na dispersio}} NaPH_2$$

$$RPH_2 \xrightarrow{\text{Na}} RPHNa \xrightarrow{\text{Na}} RPNa_2$$

$$RPH_2 \xrightarrow{\text{2PhLi}} RPLi_2 + 2C_6H_6$$

(*b*) Reduction. Compounds having a P–P or P–Halogen bond are readily cleaved by alkali metals in organic solvents such as dioxan, giving the corresponding phosphides. Examples are the reduction of phosphobenzene, phosphinous halides, and tetra-alkyldiphosphine disulphides:



$$(PhP)_4 \xrightarrow{4\,\text{Na}} 2\,Ph\text{—}\underset{Na}{P}\text{—}\underset{Na}{P}\text{—}Ph \xrightarrow{4\text{Na}} 4PhPNa_2\ ^{38}$$

$$R_2PCl \xrightarrow{2\text{Na}} R_2P\text{—}PR_2 \xrightarrow{2\text{Na}} 2R_2PNa\ ^{25,31,68}$$

$$Et_2PCl \xrightarrow[\text{THF}]{\text{Li}} Et_2PLi\ ^{65}$$

$$R_2PS.PSR_2 \xrightarrow{4\text{Na}} R_2P\text{—}PR_2 + 2Na_2S \xrightarrow{2\text{Na}} 2R_2PNa\ ^{25}$$

(*c*) Cleavage. Tertiary phosphines having at least one aryl substituent are cleaved by metals with loss of the aryl group.[48] Triphenylphosphine can be converted to salts of diphenylphosphine, $Ph_2PM$, by use of lithium in tetrahydrofuran,[26,32,60] sodium or potassium in hot dioxan[70] or by sodium in liquid ammonia[65]:

$$Ph_3P + 2M \rightarrow Ph_2PM + MPh$$

Metal phosphides are readily oxidized by air[55] and react with carbon dioxide[26,77]; they form complexes with dioxan containing 0·2 → 3 moles of dioxan. A number of these complexes, e.g., $(R_2PNa)_2.C_5H_{10}O$, $Ph_2PM.C_5H_{10}O$ ($M = Li$, Na), and $Ph_2PK.(C_5H_{10}O)_2$, have been isolated and characterized by Issleib.[24-5,87] Halogeno–magnesium salts of phosphine and P-substituted phosphines are readily obtained by the action of phosphines on Grignard reagents[54,67,84]:

$$R_nPH_{3-n} + (3\text{–}n)RMgX \rightarrow R_nP(MgX)_{3-n} + (3\text{–}n)RH \qquad (n = 0, 1, 2).$$

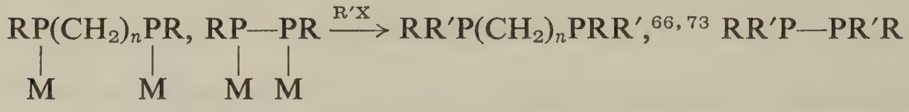
P,P-disubstituted phosphides of magnesium, zinc and a number of heavy metals, $(R_2P)_nM$ ($M = Co$, Ni, Ti(II), V(III), Cr(III)) and mixed metal phosphides $(R_2P)_{n+1}MM'$ ($M = Li$, K; $M' = Mn$, Ni, Cu), have been described.[82,91-3] Their preparation is indicated in the equations below:

$$2R_2PH + MEt_2 \rightarrow (R_2P)_2M + 2C_2H_6 \qquad (M = Mg,^{91}\ Zn^{82})$$
$$nR_2PM + MX_n \rightarrow (R_2P)_nM \qquad (M = Mg, Zn, Co, Ni, V, Cr)$$
$$3LiPR_2 + TiCl_3.3THF \rightarrow Ti(PR_2)_2 + 0{\cdot}5(R_2P)_2\ (R = C_6H_{11})^{92}$$

Phosphides react readily with compounds having a Z-halogen bond (Z = C, Si, Sn, P) with elimination of metal halide and formation of a P–Z bond; they add to carbonyl compounds, olefins, isocyanates, isothiocyanates, and olefin oxides, to form products having a new P–C bond. Solvent and reaction conditions can sometimes markedly affect the nature of the products, e.g., tetraethylethylene-1 : 2-diphosphine is obtained in 94% yield by reaction of $Et_2PLi$ with 1 : 2-dichloroethane in tetrahydrofuran (THF), whereas if the reaction is conducted in ether only ethylene and tetraethyldiphosphine result.[65] The reactions of various phosphides (M = metal) with simple mono- and difunctional alkyl halides (X = halogen) are indicated below. Reactions of monometallic salts of $PH_3$, $RPH_2$, and $R_2PH$, with a number of compounds are indicated in Charts I and II.

$$\mathrm{CaPH} \xrightarrow{R'X} R'_2PH \quad [52]$$

$$PH_2M,\ RPHM,\ RPM_2 \xrightarrow{R'X} R'PH_2,\ [56,67]\ \ RR'PH,\ [51,55-6]\ \ R'_2RP\ [51,55]$$



$$\underset{\substack{| \\ M}}{R}P(CH_2)_n\underset{\substack{| \\ M}}{P}R,\ R\underset{\substack{| \\ M}}{P}—\underset{\substack{| \\ M}}{P}R \xrightarrow{R'X} RR'P(CH_2)_nPRR',\ [66,73]\ \ RR'P—PR'R$$

With polymethylene terminal dihalides, $X(CH_2)_nX$,

FROM ORGANOMETALLIC COMPOUNDS

Tertiary phosphines have been prepared by interaction of phosphorus halides and tertiary phosphites with organometallic compounds of the alkali metals, magnesium, zinc, aluminium, tin and lead.[1,2] By the use of Grignard reagents numerous symmetrical tertiary phosphines, e.g., trialkyl-,[206-7] triaryl-, trisindolyl-,[211] and tris-(trimethylsilyl)methyl-[215] phosphines, have been obtained from phosphorus trichloride; similarly mixed trialkyl, dialkylaryl,[208,216] aryldialkyl, and mixed triarylphosphines may be obtained from phosphonous dihalides or phosphinous halides:

$$PX_3 + 3RMgX \rightarrow R_3P + 3MgX_2$$
$$R'PX_2 + 2RMgX \rightarrow R'R_2P + 2MgX_2$$
$$R'_2PX + RMgX \rightarrow R'_2RP + MgX_2$$

Yields of trialkylphosphines from the Grignard reaction are frequently poor (40–50% for $Bu_3P$) owing to by-product formation of phosphonium salts and amorphous phosphorus. Reactions of the type:[213]

$$Bu_3P + PCl_3 \rightarrow Bu_3PCl_2 + P$$

followed by:

$$Bu_3PCl_2 + RMgX \rightarrow Bu_4PCl + MgCl_2$$

may account for the low yield.

Aliphatic 1,4- and 1,5- diGrignard reagents react with phenylphosphonous

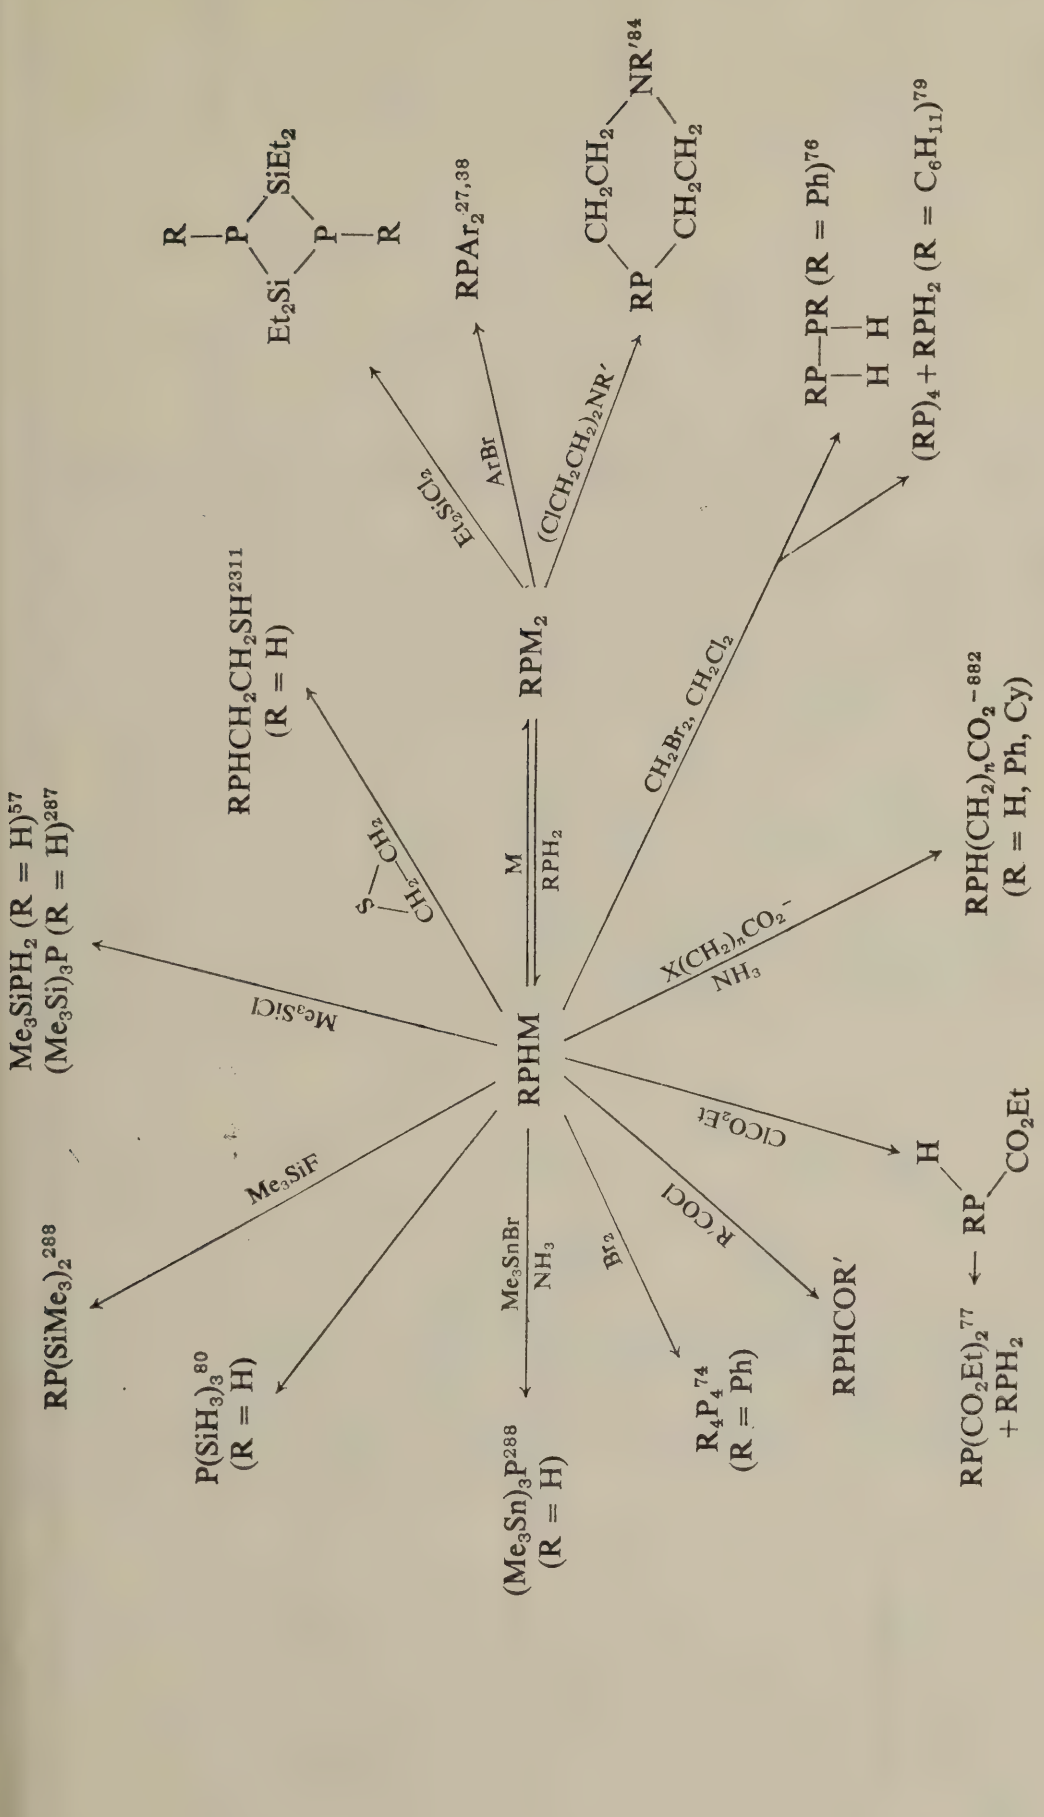

CHART I.—Some reactions of metallic salts of phosphine and monosubstituted phosphines.

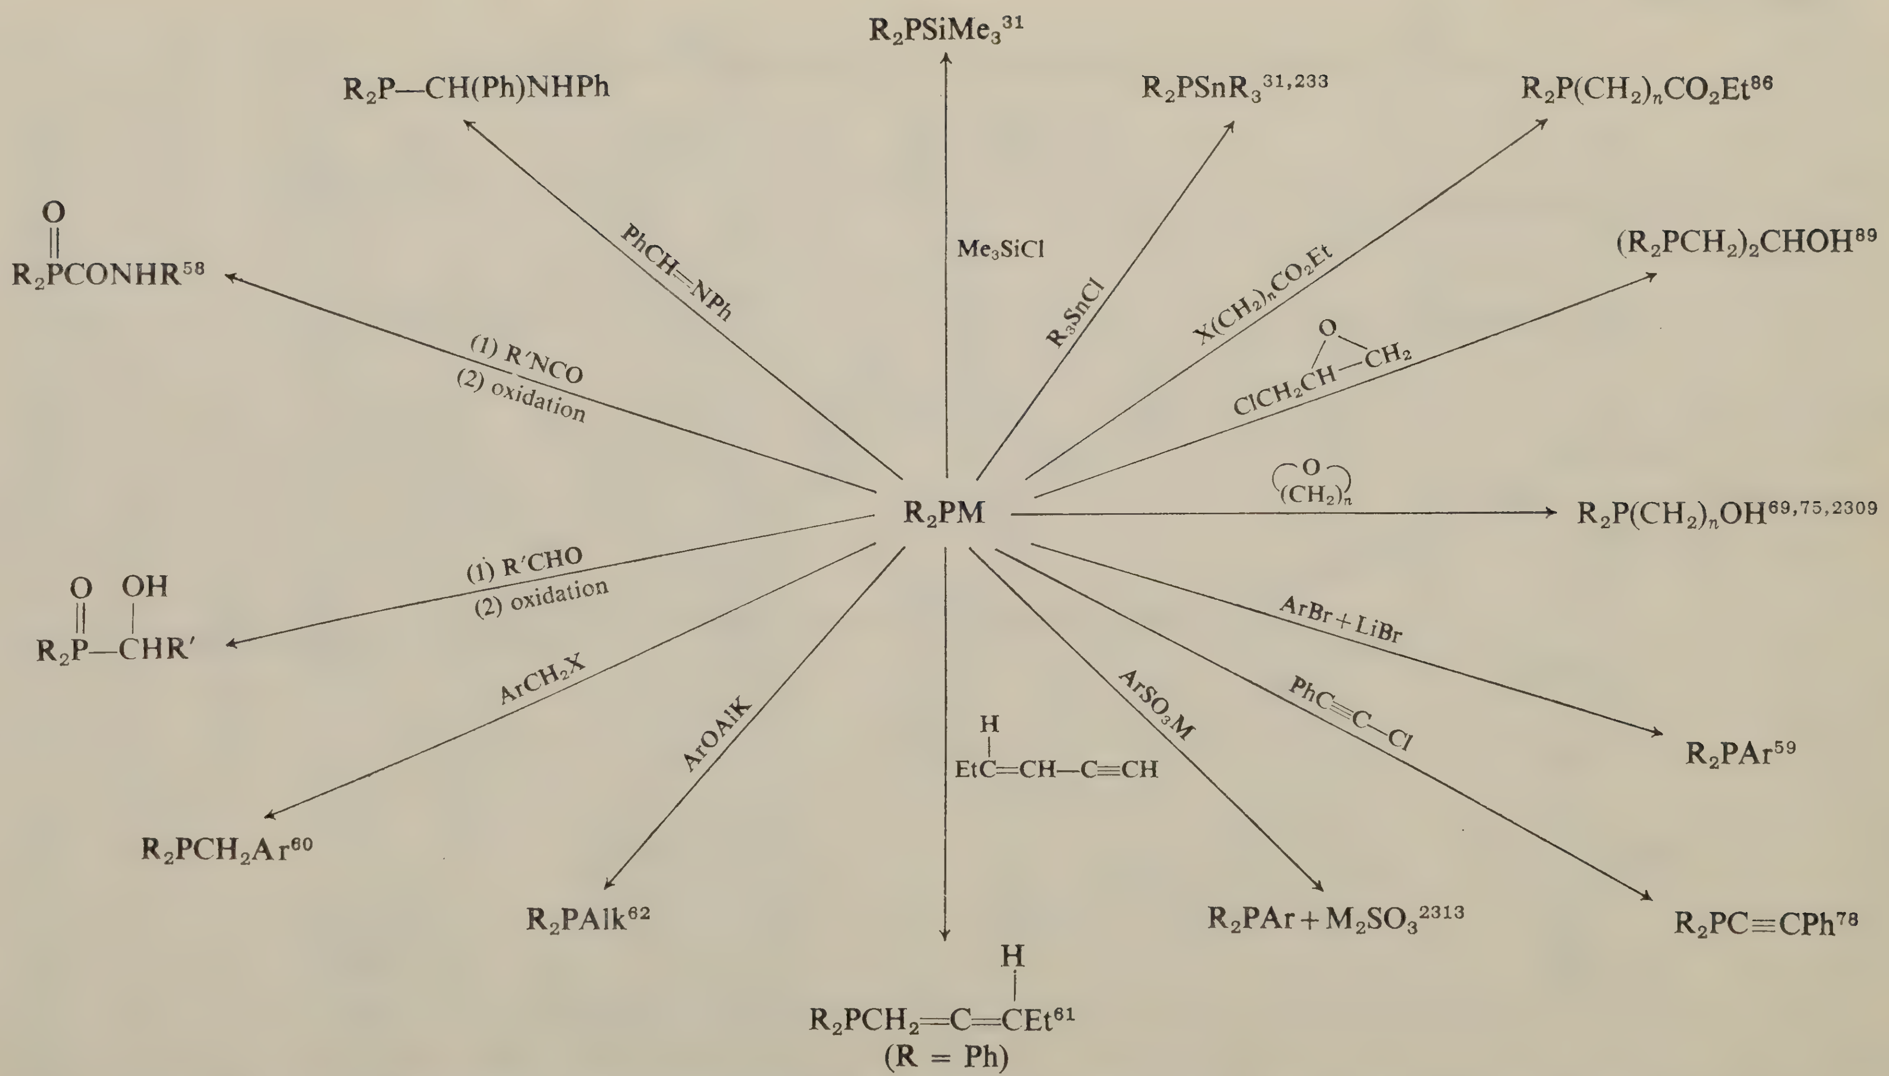

CHART II.—Some reactions of salts of diphenylphosphine (R = monovalent organic group; Ar = aryl group; Alk = alkyl group; M = metal) dichloride to form *P*-phenyl cyclic polymethylenephosphines **XI**.[217] Toluene 3,4-dimagnesium iodide and diethylphosphinous chloride form the diphosphine **XII**.[218]

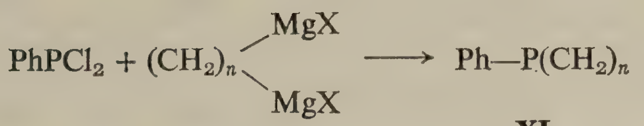
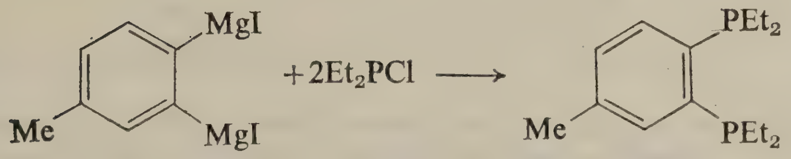


$$PhPCl_2 + (CH_2)_n\begin{matrix}MgX\\MgX\end{matrix} \longrightarrow Ph—P(CH_2)_n$$

**XI**



**XII**

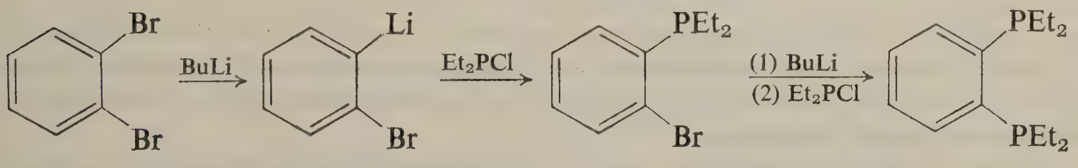
Phosphorus pentachloride and phenylmagnesium bromide form a mixture of diphenyl, triphenylphosphine, triphenyldichlorophosphorane and tetraphenylphosphonium chloride.[231]

Vinyl substituted phosphines, trivinylphosphine,[210,214] vinylalkylphosphines[210] and vinylarylphosphines[98] are obtained using vinylmagnesium chloride. Acetylenic phosphines, $R_2P–C\equiv CPR_2$,[94] $R_nP(C\equiv CR')_{3-n}$ $(n=0, 1, 2)$,[95,6] $R_2P–C\equiv CH$[97] and $Ph_2P(C\equiv C)_nCH_3$ $(n=1, 2, 3)$[2310] are obtained from acetylenic Grignard reagents and the appropriate phosphorus halides. Dialkylethynyl phosphines may be obtained by the reaction of sodium or lithium acetylide with *O*- or *S*-ethyl esters of phosphinous acids in liquid ammonia,[97]

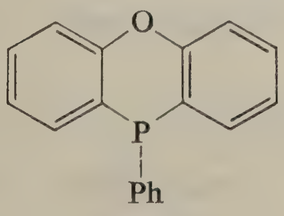
$$EtAPR_2 + R'—C\equiv C^- \rightarrow R'C\equiv CPR_2 + AEt^- \qquad (A=O, S)$$

Mercury phenylacetylide and $PBr_3$ react to form tris(phenylethynyl)phosphine; $PCl_3$ is reported to be unreactive.[95]

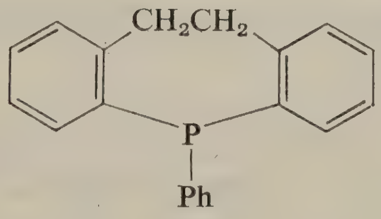
Alkyl[200] or aryl[219-22] lithium compounds react like Grignard reagents with phosphorus halides to replace all the available P–X bonds by P–C bonds. *p*-Dilithiumbenzene and diphenylphosphinous chloride form *p*-bis(diphenylphosphinyl)-benzene.[221] *o*-Phenylenebisdiethylphosphine has been prepared from $Et_2PCl$ and *o*-dibromobenzene[1877]:



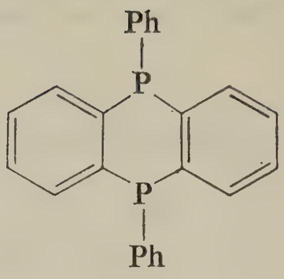
By the use of organolithium compounds a number of novel cyclic phosphines have been obtained; thus phenylphosphonous dichloride reacts with *o,o*-dilithiumdiphenyl ether,[223] *o,o*-dilithium-1,2-diphenylethane,[224] bis(*o*-lithiumphenyl)phenylphosphine,[29] and 1,4-dilithium-1,2,3,4-tetraphenyl butadiene[225-6] giving **XIII, XIV, XV,** and pentaphenyl phosphole **XVI** respectively. The heat of combustion of **XVI** is reported by Bedford and co-workers.[234]



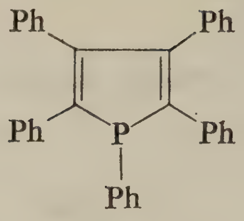
**XIII**



**XIV**

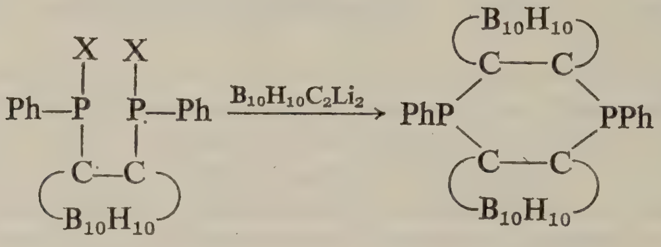


**XV**



**XVI**

Dilithiumcarborane and diphenylphosphinous chloride yield the phosphocarborane (**XVII**, X = Ph), phenylphosphonous dichloride gives the carboranephosphonous chloride (**XV**, X = Cl) which can be converted to the cyclic compound **XVIII**; $PCl_3$ gives a polymeric substance.[227]



**XVII** **XVIII**

One of the earliest methods used to prepare triarylphosphines was the Wurtz reaction[14, 228]:

$$PX_3 + 3ArX + 6Na \rightarrow PAr_3 + 6NaX$$

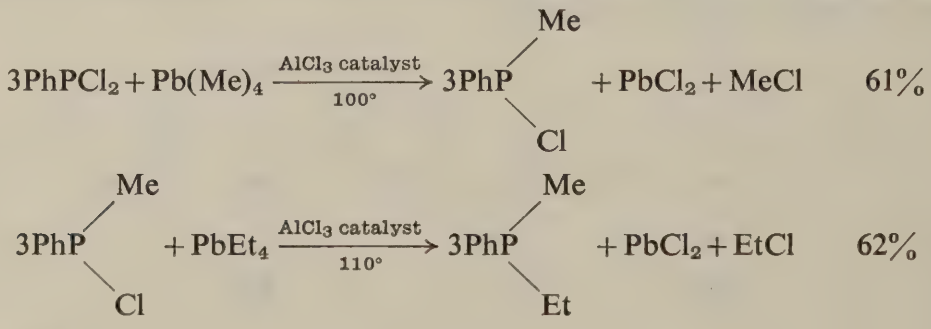
Catalytic amounts of $SbCl_3$ are effective in reactions of halides of low reactivity such as *o*-chlorodiphenyl.[229] Triphenylphosphine is best prepared by the addition of $PCl_3$ to a slight excess of preformed phenyl sodium in a suitable solvent:

$$3PhCl + 6Na \rightarrow 3PhNa + 3NaCl$$
$$3PhNa + PCl_3 \rightarrow PPh_3 + 3NaCl$$

Good yields of trialkylphosphines are reported to result from the reaction of triphenyl phosphite with alkyl halides and sodium in naphtha.[2312] Diphenylphosphinochloridite and sodium or potassium diethyl malonate react to form diphenyl biscarbethoxymethylphosphine.[1565]

Organoaluminium compounds react with phosphorus trichloride giving tertiary phosphines as end products; the yield of $R_3P$ is stated not to exceed about 30% even when an excess of trialkyl aluminium is used.[314]

Organolead compounds react with phosphorous chlorides or bromides to replace one halogen atom by an organic residue. Tertiary phosphines having three different substituents may thus be obtained by successive reactions starting from $PCl_3$[232] or a phosphonous dihalide:

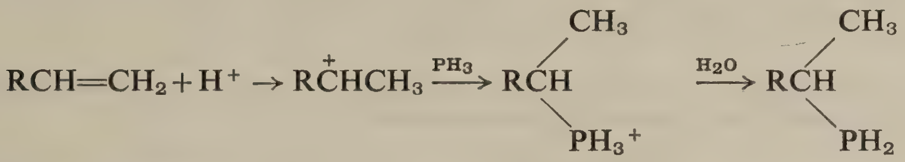


$$3PhPCl_2 + Pb(Me)_4 \xrightarrow[100°]{AlCl_3\ \text{catalyst}} 3PhP\begin{matrix}Me\\Cl\end{matrix} + PbCl_2 + MeCl \quad 61\%$$

$$3PhP\begin{matrix}Me\\Cl\end{matrix} + PbEt_4 \xrightarrow[110°]{AlCl_3\ \text{catalyst}} 3PhP\begin{matrix}Me\\Et\end{matrix} + PbCl_2 + EtCl \quad 62\%$$

### ADDITION REACTIONS

Phosphine adds to olefinic double bonds under a variety of conditions. Olefins, particularly tertiary olefins, react with phosphine under pressure in the presence of nearly stoichiometric amounts of strong non-oxidizing catalysts such as orthophosphoric acid, sulphonic acids or Lewis acids such as $BF_3$-etherate, to form primary phosphine and small amounts of secondary phosphine salts from which the phosphines can be liberated by treatment with water[100-1,145]:



$$RCH{=}CH_2 + H^+ \rightarrow R\overset{+}{C}HCH_3 \xrightarrow{PH_3} R\overset{\displaystyle CH_3}{\underset{\displaystyle PH_3^+}{CH}} \xrightarrow{H_2O} R\overset{\displaystyle CH_3}{\underset{\displaystyle PH_2}{CH}}$$

With free radical catalysts[146-7] or under the influence of ultra-violet light[147-8] the P–H bonds in $PH_3$ react with the double bonds in olefins to give successively the primary, secondary, and tertiary phosphine. By using an excess of either $PH_3$ or olefin the primary or tertiary phosphine can be made to predominate. Radical reactions of organophosphorus compounds are reviewed by Walling and Pearson.[2314]

$$RCH{=}CH_2 + PH_3 \xrightarrow{\text{radical catalyst}} RCH_2CH_2PH_2 \rightarrow (RCH_2CH_2)_2PH \rightarrow (RCH_2CH_2)_3P$$

$$EtCH{=}CH_2 + PH_3 \xrightarrow[\text{16 hours/122C°.}]{\textit{tert}\text{-Butyl peroxide}} Bu_3P$$ [146]

This method, which is probably the most promising general method of combining $PH_3$, $RPH_2$, and $R_2PH$ with olefins has been applied to ethylene, primary, secondary, and tertiary olefins,[147-8,160,164,166,2178] substituted olefins ($CH_2{=}CH{-}CH_2X$, $X = Cl$, OAc, $CO_2R$,[165] OH,[147] $NH_2$[147,165,2308]), fluoro-olefins,[163,167] trimethylallylsilane,[164] vinyltrichlorosilane and methylvinyldichlorosilane.[2306] In the addition of $PH_3$ to fluoro-olefins under the influence of ultra-violet light, addition of the $PH_2$ radical is exclusively to the $CF_2$ group of $CF_2{=}CFCl$ and the $CH_2$ group of $CH_2{=}CF_2$.[163] Tetrafluoroethylene, chlorotrifluoroethylene and 1,1-dichloro-2,2-difluoroethylene react with $PH_3$ to give some 1,2-ethylenediphosphine ($H_2PCX_2CF_2PH_2$, $X = Cl$, F) in addition to the expected products such as $CHF_2CF_2PH_2$ and $(CHF_2CF_2)_2PH$.[163,167] The photochemical reaction of phosphine with trifluoroethylene gives an 85 : 15 mixture of 1,2,2- and 1,1,2-trifluoroethylphosphine.[2307]

The addition of $PH_3$, phenylphosphine, dibutylphosphine, and 2-cyanoethylphosphine, to *cis*-butene-2 is reported to be reversible.[166]

The radical catalyzed addition of phosphines to acetylenic compounds has been briefly examined[160]; bis(2-cyanoethyl)phosphine and octyne-1 give a rather poor yield of bis(2-cyanoethyl)1-octenylphosphine[160]:

$$(CNCH_2CH_2)_2PH + C_6H_{13}C{\equiv}CH \rightarrow (CNCH_2CH_2)_2PCH{=}CHC_6H_{13}$$

Negatively substituted olefins react with phosphine in the presence of strongly basic catalysts giving by successive addition mono-, di-, and tri-$\beta$-substituted phosphines[149,150]:

$$PH_3 + CH_2{=}CHX \rightarrow H_2PCH_2CH_2X \rightarrow HP(CH_2CH_2X)_2 \rightarrow P(CH_2CH_2X)_3 \quad (X = CN,\ NO_2,\ CO_2R,\ CONH_2)$$

Phenylphosphine and diphenylphosphine undergo this reaction at elevated temperatures in the absence of added catalyst[151,161]; phosphine itself and fluoro-olefins react similarly[167]:

$$PhPH_2 + CH_2{=}CHX \xrightarrow{\Delta} PhP(CH_2CH_2X)_2 \qquad (X = CN,\ CO_2Me)$$

Phosphines add to aryl *iso*cyanates in the presence of basic catalysts giving *N*-arylcarbamoylphosphines,[156–7,168,200–1] and benzylideneaniline.[162] Phenyl *iso*thiocyanate is reported to react with primary and secondary phosphines giving *N*-phenylthiocarbamoyl substituted tertiary phosphines, but not with phosphine itself[203]:

$$R_nPH_{(3-n)}+(3\text{–}n)ArNCO \xrightarrow{\text{base}} R_nP(CONHAr)_{(3-n)} \qquad (n = 0, 1, 2)$$

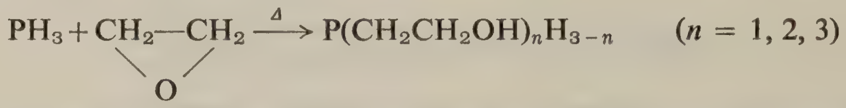
$$R_nPH_{(3-n)}+(3\text{–}n)PhNCS \xrightarrow{\Delta} R_nP(CSNHPh)_{(3-n)} \qquad (n = 1 \text{ or } 2)$$

$$PhPH_2+PhCH\!:\!NPh \rightarrow C_{38}H_{29}N_2P$$

Primary and secondary phosphines, but not phosphine itself, react with cyanic acid, generated *in situ* to form carbamoyl phosphines[2317]:

$$R_nP(CONH_2)_{3-n} \qquad (n = 1, 2)$$

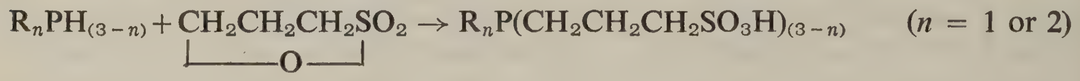
Epoxy-alkanes and phosphine undergo condensation at elevated pressure and temperature without catalyst to form a mixture of mono-, bis- and tris-β-hydroxyethylphosphines,[159] and with catalysts such as $BF_3$-complexes to form tertiary phosphine derivatives of hydroxypolyethers.[158] Dialkylaminoethylphosphines are readily prepared by the Mannich reaction of phosphines with formaldehyde and a secondary amine or with a tetra-alkylmethylenediamine[281,2178]:



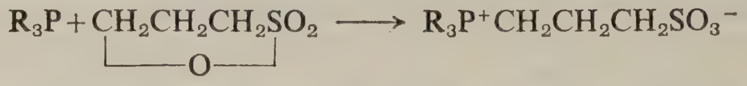
$$PH_3+\underset{\diagdown\;O\;\diagup}{CH_2\text{—}CH_2} \xrightarrow{\Delta} P(CH_2CH_2OH)_nH_{3-n} \qquad (n = 1, 2, 3)$$

$$R_nPH_{(3-n)}+(3\text{–}n)(R_2'NH+CH_2O) \rightarrow R_nP(CH_2NR_2')_{3-n} \qquad \begin{matrix}(R = \text{alkyl, aryl})\\(n = 0, 1, 2)\end{matrix}$$

Sultones react with primary and secondary phosphines giving phosphinosulphonic acids, while tertiary phosphines form quaternary phosphonium betaines[292]:



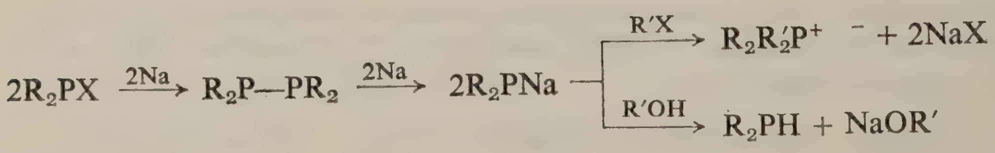
$$R_nPH_{(3-n)}+\underbrace{CH_2CH_2CH_2SO_2}_{O} \rightarrow R_nP(CH_2CH_2CH_2SO_3H)_{(3-n)} \qquad (n = 1 \text{ or } 2)$$



$$R_3P+\underbrace{CH_2CH_2CH_2SO_2}_{O} \longrightarrow R_3P^+CH_2CH_2CH_2SO_3{}^-$$

REDUCTION OF ORGANOPHOSPHORUS COMPOUNDS

The preparation of phosphines by the reduction of compounds having at least one carbon–phosphorus bond has achieved importance only during recent years. The classical methods of reduction used in organic chemistry have proved of little value for reducing pentavalent phosphorus compounds to trivalent ones or for reducing the trivalent ones to phosphines. Reduction of oxides, sulphides, acids, esters, and halides of organophosphorus compounds to phosphine has been accomplished in good yield by use of the more electropositive metals and metal hydrides, particularly lithium aluminium hydride.[28–9,50,71] Metal reductions give the metal salt of the phosphine which may be isolated,[25] reacted *in situ*,[26–7,31,36] or treated with an aqueous reagent to yield the phosphine:



$$2R_2PX \xrightarrow{2Na} R_2P\text{—}PR_2 \xrightarrow{2Na} 2R_2PNa \begin{cases} \xrightarrow{R'X} R_2R_2'P^+ \;\; {}^- + 2NaX \\ \xrightarrow{R'OH} R_2PH + NaOR' \end{cases}$$

Compounds containing oxygen are less readily reduced by metals than the chlorides[36] and have frequently been converted to chlorides or sulphides before reduction:

$$R_3PO \xrightarrow{P_2S_5} R_3PS \xrightarrow{\text{metal}} R_3P$$

$$R_2PO_2H \xrightarrow{PCl_5} R_2PCl_3 \xrightarrow{\text{metal}} R_2PH$$

Optically-active tertiary phosphines are obtained by cathodic reduction of optically-active quaternary phosphonium salts.[41-6]

By reducing phenylphosphonous dichloride with one molar equivalent of $LiBH_4$ the intermediate phenyl chlorophosphine was obtained as an unstable adduct, $PhPHClBH_3$.[72]

Table IV shows the various types of organophosphorus compounds used to prepare primary, secondary and tertiary phosphines, together with the reducing agent employed.

*Table IV.—Preparation of Phosphines by Reduction*

| Product | Source of organophosphorus compound |
|---|---|
| $PH_3$ | $PCl_3$ (Na[36]), $PCl_5$ ($LiBH_4$, $LiAlH_4$[37]) |
| $RPH_2$ | $RPCl_2$ (Li,[27] Na,[36,50] $LiAlH_4$,[28-9,50] $LiBH_4$[72]) |
| | $RPOCl_2$, $RPO(OR')_2$, $RPO_2H_2$ ($LiAlH_4$,[50,2187] LiH,[71] Na,[28] silanes[1610]) |
| | $(PhP)_4$ ($LiAlH_4$,[50] Na[38]) |
| $H_2P(CH_2)_nPH_2$ | $(CH_2)_n[PO(OR)_2]_2$ ($LiAlH_4$[2178]) |
| $R_2PH$ | $R_2PCl_3$, $R_2POCl$, $R_2P(O)OR$, $R_2POH$, $R_2PO_2H$ ($LiAlH_4$[28,90]) |
| | $R_2PCl$ (Na,[36] $LiAlH_4$,[28] Li[65]) |
| | $R_2P(S)P(S)R_2$ (Cu or Raney $Cu/H_2$,[30] Na,[25] $LiAlH_4$[34,39]) |
| | $R_2P{-}PR_2$ (Na[25,31]) |
| | $R_2P(O)OR$, $R_2POCl$ (silanes and $Cl_3SiH$[1610]) |
| | $R_2P{-}Ar$ (Li, Na, K, $Na/NH_3$ removes Ar-group[26,32,60,48]) |
| $R_3P$ | $R_4P^+X^-$ (cathodic reduction at Hg cathode[41-7,117]) |
| | $R_3P^+CH_2PhX^-$ ($LiAlH_4$ removes $PhCH_2$-group selectively[35,2001]) |
| | $R_3PO$ ($CaH_2$,[40] $SiHCl_3$,[1982] polymethyl siloxane,[40] $LiAlH_4$,[28] Na,[28] $Ca(AlH_4)_2$,[49] boranes and trialkylamine boranes) |
| | $R_3PX_2$ ($LiAlH_4$, Na[28]) |
| | $R_3PS$ (Raney Ni, Na, NaH,[28] Fe,[82] $LiAlH_4$, $Ca(AlH_4)_2$[49]) |

### DECOMPOSITION REACTIONS

Quaternary phosphonium halides decompose, usually at temperatures above 200°, giving tertiary phosphines[266-8,271,285]:

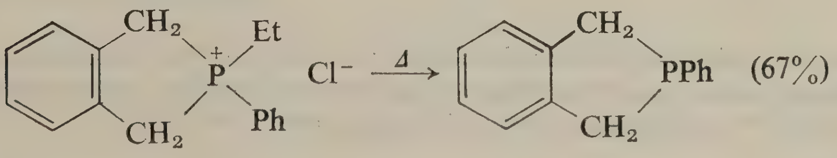
$$R_1R_2R_3R_4P^+X^- \rightarrow R_1R_2R_3P + R_4X$$

The ease of radical cleavage increases in the series:

phenyl < *iso*amyl < propyl < methyl < benzyl < ethyl[267]

However, radical cleavage from an unsymmetrical phosphonium salt is generally insufficiently specific to prevent the formation of a mixture of phosphines, and successful synthetic applications have been made only by eliminations from compounds containing groups such as phenyl and ethyl at the opposite ends of the cleavage order. Examples are the preparation of ethylbenzylphenylphosphine[271] and 2-phenyl*iso*phosphindole[272]:

$$Et_2\overset{+}{P}PhBz\overset{-}{Cl} \xrightarrow{\Delta} EtBzPhP + Et_2PPh$$

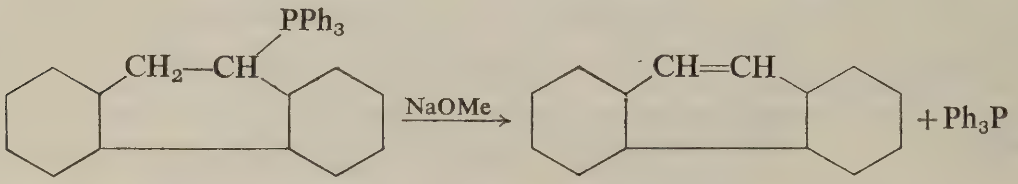


The majority of phosphonium compounds are decomposed by bases to form a tertiary phosphine oxide and a hydrocarbon (paraffinic degradation).[267] A few classes of compounds, notably those containing a 2-cyanoethyl substituent,[270] a hydroxymethylsubstituent,[273, 275–7, 279] a $\beta,\beta$-diphenylethyl substituent,[269] compounds having three or four chloromethyl substituents[274, 276] attached to phosphorus and 9:10-dihydrophenanthrene-10-triphenylphosphonium bromide[278] are readily cleaved by bases to form tertiary phosphine:

$$RP(CH_2CH_2CN)_3X \xrightarrow{NaOMe} RP(CH_2CH_2CN)_2 + MeOCH_2CH_2CN \qquad (R = \text{alkyl or aryl})$$

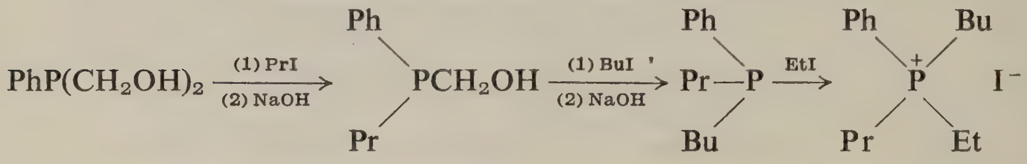
$$RP(CH_2Cl)_3Cl \xrightarrow{NaOH} RP(CH_2Cl)_2 + CH_2O \qquad (R = CH_2Cl, Ph, Et)$$

$$R_nP(CH_2OH)_{4-n}Cl \xrightarrow{base} R_nP(CH_2OH)_{3-n} + CH_2O \qquad (n = 0, 1, 2, 3)$$



Unsymmetrical tertiary phosphines and phosphonium salts have been prepared by successive quaternization and base decomposition of hydroxymethylphosphines[276]:

$$PhPH_2 \xrightarrow[CH_2O]{H^+} PhP(CH_2OH)_3Cl \xrightarrow{NaOH} PhP(CH_2OH)_2$$



$$PhP(CH_2OH)_2 \xrightarrow[(2)\ NaOH]{(1)\ PrI} \overset{Ph}{\underset{Pr}{PCH_2OH}} \xrightarrow[(2)\ NaOH]{(1)\ BuI} Pr{-}\overset{Ph}{\underset{Bu}{P}} \xrightarrow{EtI} \overset{Ph\quad Bu}{\underset{Pr\quad Et}{\overset{+}{P}}} \quad I^-$$

Similar reactions starting from tris(2-cyanoethyl)phosphine afford alkylbis(2-cyanoethyl)phosphine, dialkyl-2-cyanoethylphosphine and tetrakis(2-cyanoethyl)-ethylenediphosphine[270]:

$$2P(CH_2CH_2CN)_3 + XCH_2CH_2X \rightarrow [(CNCH_2CH_2)_3\overset{+}{P}CH_2]_2X^- \xrightarrow{NaOMe} [(CNCH_2CH_2)_2PCH_2]_2$$

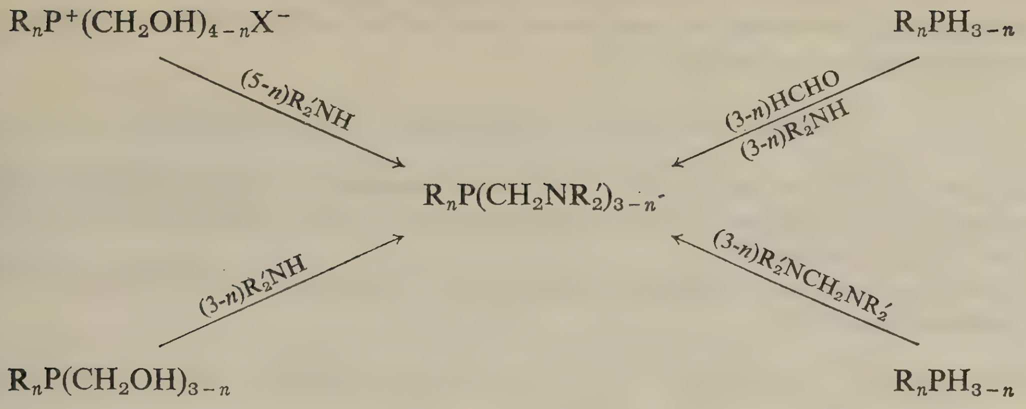
A novel quaternization-decomposition reaction is that of trishydroxymethylphosphine with unsaturated nitriles such as acrylonitrile to form, e.g., tris(2-cyanoethyl)-phosphine[286]:

$$P(CH_2OH)_3 + CH_2{=}CHCN + H_2O \rightarrow (CH_2OH)_3\overset{+}{P}CH_2CH_2CNOH^- \rightarrow (CH_2OH)_2PCH_2CH_2CN + HCHO$$

$$\Big\downarrow \text{2 steps}$$

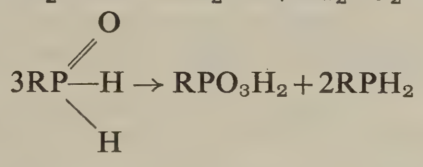
$$P(CH_2CH_2CN)_3 + 2CH_2O$$

Phosphorus analogues of Mannich bases are obtained by the action of primary and secondary amines on phosphonium salts which contain at least two hydroxymethyl groups,[280] and by other routes indicated below[280–2, 2178]:



Phosphonous acids and their salts undergo an oxidation–reduction reaction at temperatures in the range 100°–250° giving primary phosphine and phosphonic acid[83, 283]; secondary phosphine oxides (phosphinous acids) behave similarly when heated alone above 200°[282] or in the presence of sodium hydroxide[284]; primary phosphine oxides generally undergo oxidation–reduction in the pure state at or just above room temperature[1909]:

$$3PhPO_2H_2 \rightarrow PhPH_2 + 2PhPO_3H_2$$
$$2Bu_2POH \rightarrow Bu_2PH + Bu_2PO_2H$$



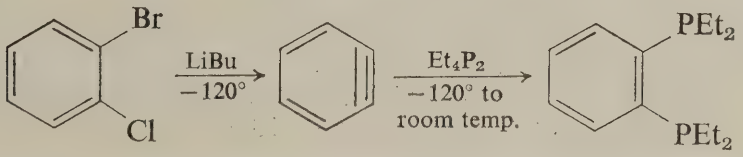
$$3RP(=O)(H)\text{—}H \rightarrow RPO_3H_2 + 2RPH_2$$

MISCELLANEOUS ROUTES TO PHOSPHINES

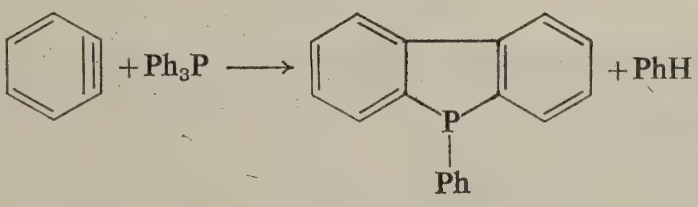
Mixtures of primary, secondary, and tertiary phosphines, and phosphonium salts, are obtained by heating phosphonium iodide with alkyl halides and zinc or zinc oxide.[240, 17, 38, 134, 250, 1740] Addition of water to the reaction mixture liberates any unreacted phosphine and primary alkylphosphine from their salts; the secondary[242] and tertiary phosphines are liberated by adding alkali or ammonia. Small amounts of tertiary phosphines are formed by heating the $PH_4I$ with alcohols.[1746] For reactions of carbonyl compounds which yield phosphines, see p. 929.

Tetra-alkyldiphosphines add across the carbon–carbon bond in unsaturated compounds such as ethylene and benzyne. The preparation of tetramethylethylenediphosphine[296] and *o*-phenylene-bis(diethylphosphine)[155] is indicated below:

$$Me_2P\text{—}PMe_2 + C_2H_4 \xrightarrow{\Delta} Me_2PCH_2CH_2PMe_2$$



Benzyne reacts with triphenylphosphine giving up to a 40% yield of 9-phenyl-9-phosphafluorene[298–9]:



Activated aromatic compounds such as *N,N*-dialkylanilines react with $PCl_3$ in the presence of bases such as pyridine and under reflux to form tertiary dialkylaminoarylphosphines as end products[230]:

$$3PhNR_2 + PCl_3 \longrightarrow (R_2NC_6H_4)_3P \qquad (R = Me, Et)$$

With zinc chloride as catalyst 1,3,5-trimethoxybenzene and phosphorus trichloride form tris(2,4,6-trimethoxyphenyl)phosphine in about 80% yield even when a large excess of $PCl_3$ is used.[99]

Phosphine and aroyl chlorides condense in the presence of pyridine giving trisaroylphosphines[300, 839]:

$$PH_3 + 3ArCOCl \rightarrow (ArCO)_3P \qquad (Ar = C_6H_5,\ p\text{-}CH_3.C_6H_4,\ \alpha\text{- and }\beta\text{-naphthyl}).$$

Condensation of phosphines with organometallic halides of lead[1741] or tin[1737] in the presence of a tertiary amine or the use of a metal phosphide in liquid ammonia[233] gives tertiary phosphine compounds having a phosphorus–metal bond:

$$Ph_3PbCl + Ph_2PH \xrightarrow{R_3N} Ph_3Pb{-}PPh_2$$
$$R_nSnX_{(4-n)} + (4{-}n)Ph_2PH \xrightarrow{R_3N} R_nSn(PPh_2)_{4-n} \qquad (n = 1, 2, 3)$$
$$Ph_2PNa + R_3SnX \xrightarrow{NH_3\,(1)} Ph_2P{-}SnR_3$$

Primary phosphines can be prepared by treating the $PH_3,AlCl_3$ complex with alkyl chlorides or bromides followed by hydrolysis with cold water[293-4]:

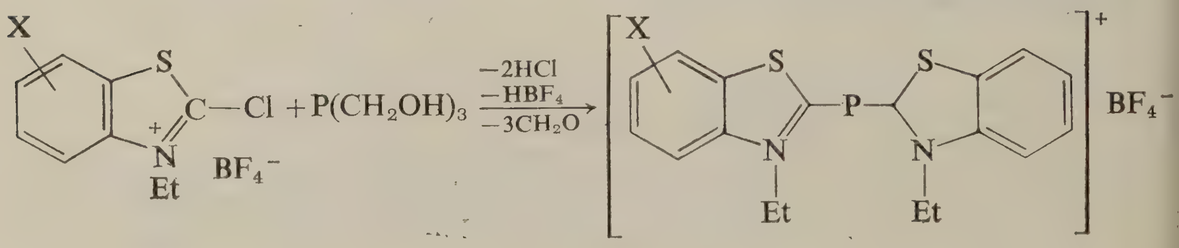
$$AlCl_3 + PH_3 \rightarrow PH_3,AlCl_3 \xrightarrow{RCl} RPH_3.AlCl_4 \xrightarrow{H_2O} RPH_2 + HAlCl_4 \text{ hydrate}$$

The phosphorus analogue of hydrocyanic acid, HCP, can be obtained as a very reactive colourless gas by passing phosphine through a low intensity rotating arc struck between graphite electrodes in a water-cooled copper reactor.[301] It is stable to storage in the pure state only at temperatures below its triple point, −124·2°C.; reaction with hydrogen chloride at −110°C. gives methylphosphonous dichloride.

Phosphines having the structure $>PCH_2X$ (where $X = PPh_2$, SR, OAr) may be obtained by condensation of dialkylaminomethylphosphines with compounds containing an active hydrogen atom such as mercaptans, phenols, ethylacetoacetate and diphenylphosphine:

$$P(CH_2NEt_2)_3 + 3RSH \xrightarrow{\Delta} P(CH_2SR)_3 + 3Et_2NH \,^{282}$$
$$R_2PCH_2NEt_2 + Ph_2PH \xrightarrow{\Delta} R_2PCH_2PPh_2 \,^{2319-20}$$

A new class of highly coloured phosphorus compounds termed 'phosphamethine cyanines', containing a tervalent phosphorus atom having a co-ordination number of 2, are formed by condensation of trishydroxymethylphosphine with 2-chloro-*N*-ethyl benzthiazolium fluoroborate in dimethyl formamide solution with a base.[2321] The crystal structure of bis[*N*-ethyl-benzthiazole-(2)] phosphamethine-cyanine perchlorate[2322] shows a C–P–C bond angle of 104·6° and both P–C bond lengths 1·76 Å.

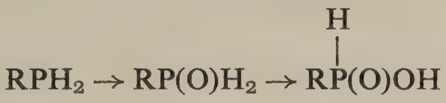


## Reactions of Phosphines

### OXIDATION

All phosphines are readily subject to oxidation. Primary, secondary and tertiary alkylphosphines are generally oxidized by atmospheric oxygen; tertiary arylphosphines are, in general, more stable to atmospheric oxygen but undergo oxidation at elevated temperatures with a wide variety of oxidizing agents.

Oxidation of monoalkylphosphines by air or oxygen is said to yield the corresponding phosphonic acid, phosphonous acid and orthophosphoric acid in a ratio of 3 : 6 : 1 which is independent of the temperature or oxygen concentration.[101] Under controlled conditions primary phosphines are oxidized by hydrogen peroxide, *tert*-butyl peroxide or nitrogen dioxide to monoalkylphosphine oxides[102–3]; more vigorous oxidation by the first reagent gives largely the phosphonous acid[145]:



$$RPH_2 \rightarrow RP(O)H_2 \rightarrow R\overset{H}{P}(O)OH$$

Secondary phosphines are oxidized by air[104–5] or oxygen[106] under controlled conditions to secondary phosphine oxides; more vigorous oxidation with air[170] or nitric acid[147,169] gives phosphinic acids:

$$R_2PH \rightarrow R_2P(O)H \rightarrow R_2PO_2H$$

The reactivity of tertiary phosphines, $R_3P$, towards oxygen decreases as

$$R = \text{benzyl} > \text{alkyl} > \text{aryl}^{107}.$$

Oxidation of trialkylphosphines is a relatively long chain free-radical process,[108] the major products being trialkylphosphine oxide, alkyldialkyl phosphinate, dialkylalkyl phosphonate and trialkyl phosphate[107]; oxidation of tributylphosphine in hexane solution by oxygen gives $R_3PO$, $R_2PO.OR$, $RPO.(OR)_2$, and $(RO)_3PO$ in the molar ratios 42 : 49 : 6 : 3 respectively. Triphenylphosphine is not oxidized by air in benzene solution at 80° but undergoes ready oxidation under these conditions in the presence of a free-radical initiator.[107]

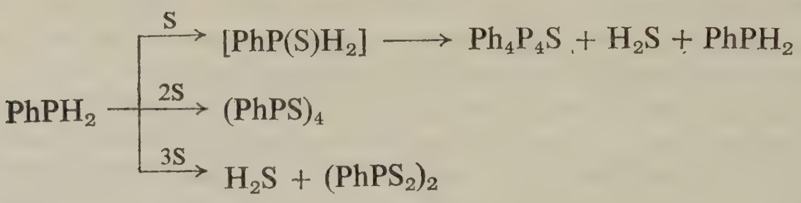
Tertiary alkyl/arylphosphines are readily oxidized by several reagents: aqueous $H_2O_2$[31,88,104,318]; ozone[130]; oxides of nitrogen such as $N_2O$,[110] NO[111–2] and $N_2O_4$[113,118]; other inorganic oxidizing agents such as $Na_2O_2$,[87] $CrO_3$,[1921] $KClO_3$,[228] HgO,[283] $FeCl_3$,[1742] $HNO_3$,[273–4,1939] $SO_2$ with $PBr_3$ or $POBr_3$ catalyst,[1681], $SeO_2$,[1854] $MnO_2$[1994]; a wide variety of organic oxidizing agents such as alkylhydroperoxides, peracids, alkylhydrochlorites or peresters[114–29]:

$$R_3P \xrightarrow{[0]} R_3PO$$

The stereochemistry of the oxidation of optically active phenylmethylpropylphosphine by percompounds such as $Me_3COOH$, $Me_3COCl$, and $Me_3CCO_3Me$, has been reported.[114] Sulphur trioxide forms in Freon solution at −78° 1 : 1 adducts with $PhPH_2$, $Ph_2PH$, $Ph_3P$, $Ph_2PCl$ and $PhPCl_2$; oxidation occurs at room temperature. The adduct $Ph_2PH,SO_3$ undergoes rearrangement in polar solvents giving $Ph_2P–SO_3H$, obtained also from $Ph_2PH$ and $ClSO_3H$.[109]

### REACTIONS WITH SULPHUR, SELENIUM AND TELLURIUM

Sulphur reacts with primary phosphines giving ill-defined products.[1] The nature of the products obtained from phenylphosphine and sulphur, reported to be $PhPH_2S$ and $Ph_3P_3S_2$,[1] has been clarified by Maier.[133] With a 1 : 1 molar ratio of $PhPH_2 : S$ the product is phenylphosphine sulphide, $PhP(S)H_2$, which is unstable and decomposes to a mixture of tetraphenyl*cyclo*tetraphosphine monosulphide, hydrogen sulphide and monophenylphosphine; a 1 : 2 ratio gives tetraphenyl*cyclo*tetraphosphine tetrasulphide $(PhPS)_4$; a 1 : 3 ratio gives an almost quantitative yield of *trans* dimeric phenylthionophosphine sulphide $(PhPS_2)_2$:



$$\begin{aligned} PhPH_2 &\xrightarrow{S} [PhP(S)H_2] \longrightarrow Ph_4P_4S + H_2S + PhPH_2 \\ PhPH_2 &\xrightarrow{2S} (PhPS)_4 \\ PhPH_2 &\xrightarrow{3S} H_2S + (PhPS_2)_2 \end{aligned}$$

In contrast with phenylphosphine, alkylphosphines yield only one product, tetraalkyl *cyclo*tetraphosphine tetrasulphide, on reaction with sulphur[2187]:

$$RPH_2 + S \rightarrow (RPS)_4 \sim 80\% \qquad (R = n\text{-butyl}, n\text{-octyl})$$

Reaction of phenylphosphine with selenium in benzene solution under reflux afforded tetraphenyl *cyclo*tetraphosphine tetraselenide in 80% yield.[2187] Secondary phosphines are oxidized by sulphur under controlled conditions giving successively secondary phosphine sulphides, $R_2P(S)H$,[66, 131, 1747] and phosphinodithioic acids, $R_2PS_2H$.[66] With an excess of sulphur, phosphinic acid derivatives, $[R_2PS]_2S_3$ and $[R_2PS]_2S$, are formed[134]; these, on treatment with basic aqueous reagents, give salts of phosphinodithioic acids[1, 134, 141] which are also formed by the action of sulphur and aqueous ammonia[585]:

$$R_2PH + 2S + NH_4OH \rightarrow R_2PS_2^- NH_4^+$$

Several secondary phosphines have been shown to react with selenium in benzene solution to form the secondary phosphine selenide $R_2P(Se)H$.[2177] Tertiary phosphines readily add sulphur giving the corresponding tertiary phosphine sulphides.[1, 200] Kinetics of the reaction of triarylphosphines with sulphur have been studied[132, 135-7] and the results to 1961 reviewed by Cadogan.[355] Selenium[1, 138, 141, 200] and tellurium[140, 2349] add to $R_3P$ less readily than does sulphur to form the corresponding selenide, $R_3PSe$, and telluride, $R_3PTe$, respectively.

### HALOGENATION

Primary and secondary phosphines react vigorously with halogens. Unless special precautions are taken the compounds are decomposed. Under controlled conditions halogenation yields halogenophosphines[142, 163] ($RPX_2$, phosphonous dihalide; $R_2PX$, phosphinous halide) which on further halogenation yield halogenophosphoranes[163]:

$$\begin{aligned} RPH_2 + 2X_2 &\rightarrow RPX_2 + 2HX \\ RPX_2 + X_2 &\rightarrow RPX_4 \qquad (X = Cl, Br, I) \end{aligned}$$

Chlorophosphines are best prepared from phosphines by halogenation using phosgene[143, 333, 534]:

$$R_nPH_{(3-n)} \xrightarrow{COCl_2} R_nPCl_{(3-n)} \qquad (n = 1 \text{ or } 2)$$

Tertiary phosphines readily add halogens forming dihalogenophosphoranes, $R_3PX_2$ ($X = Cl, Br, I$). Phenylphosphine and thionyl chloride react to give 20–30% $(PhPSO)_3$ and higher polymers.[171] Diphenylphosphine is readily converted to diphenylbromophosphine using *N*-bromosuccinimide.[289]

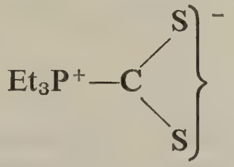
COMPLEXES WITH ORGANIC COMPOUNDS

Tertiary phosphines form adducts with many unsaturated compounds, particularly those having cumulative unsaturation. The adducts are generally solids and are frequently highly coloured. The structure of such adducts has been the subject of much hypothesis and discussion in the literature (cf. ref. 117); recent work has done much to clarify the situation.[173, 182–3, 192–3] Many of the adducts have the character of phosphonium zwitter-ions and react with alkyl halides or inorganic acids to form normal phosphonium salts[14, 180, 182–3, 190]:

$$R_3P + X{=}Y \rightarrow R_3\overset{+}{P}{-}X{-}Y^- \xrightarrow{MeI} R_3\overset{+}{P}{-}X{-}Y{-}MeI^-$$

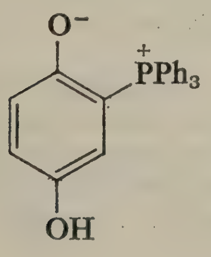
Tertiary phosphine adducts are reported with carbon disulphide,[139, 172–5, 190] carbon diselenide,[191] aryl isothiocyanates,[139, 176, 202] alkyl and aryl azides,[110] aliphatic diazo compounds,[110, 179, 180] diphenyl ketene,[177] ethylene-1 : 2-dicarbonyl compounds such as maleic anhydride,[181, 192, 195] and dibenzoylethylene, acetylene-1,2-dicarbonyl compounds such as dibenzoyldiacetylene and esters of acetylenedicarboxylic acid,[183, 193] highly polarized olefins, e.g., benzalmalonic esters and substituted benzalmalononitrile and vinylidene dicyanide[180] and 2-benzal-1,3-diketohydrindene,[180] aromatic compounds such as quinones,[139, 180–3, 186, 188] azlactones,[117, 180] triphenylmethane dyestuffs[187] and *o*-dinitrobenzene.[180]

The red, crystalline adduct of triethylphosphine with carbon disulphide, $Et_3P,CS_2$, was reported by Hoffmann in 1861[14]; many trialkylphosphines form similar red complexes but triphenylphosphine and trivinylphosphine give no colour with carbon disulphide.[210] *X*-Ray diffraction of the $Et_3P,CS_2$ complex has established the presence of a bond between the phosphorus atom and the carbon atom of the $CS_2$[173]; the shape of the molecule corresponds to that of a zwitter-ion of a quaternary phosphonium derivative of a dithioformate, i.e.,

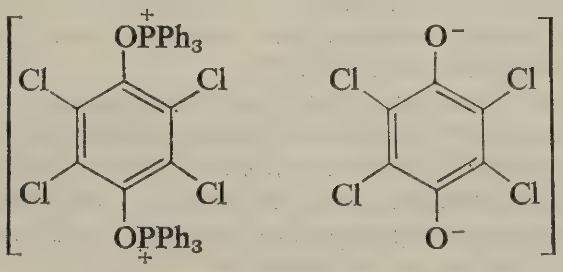


as proposed by Jensen.[172] The infra-red spectra and dipole moments of a number of tertiary phosphine–$CS_2$ adducts support a similar structure.[190, 2315] Carbon diselenide adducts of $Me_3P$ and $Et_3P$ are green; their infra-red spectra support the structure $R_3P^+{-}CSe_2^-$.[191]

*p*-Benzoquinone and triphenylphosphine form a 1 : 1 adduct in which phosphorus is attached to a carbon atom of the benzene ring **XIX**; chloranil gives an adduct with a 1 : 1 molar ratio but having a P–O–C bond (XX).[182–3, 186] The difference has been attributed to the resistance of chloranil to nuclear substitution and to its higher oxidation–reduction potential.[182]

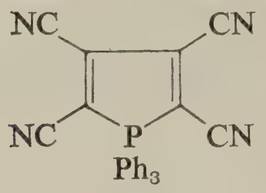


**XIX**

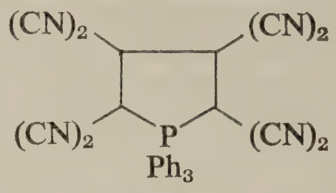


**XX**

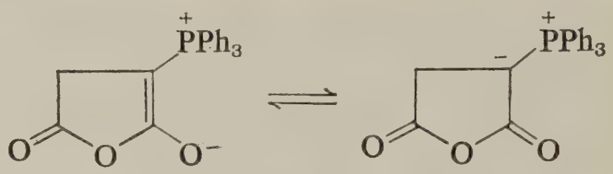
Triphenylphosphine combines with dicyanoacetylene and tetracyanoethylene to give tetracyano-*P*,*P*,*P*-triphenylphosphole (**XXI**) and octacyano-*P*,*P*,*P*-triphenylphospholidine (**XXII**) respectively.[184] With maleic anhydride the adduct has been shown by nuclear magnetic resonance and infra-red spectroscopy and by direct synthesis from chlorosuccinic anhydride to be anhydrosuccinylidine triphenyl phosphorane **XXIII**.[192]



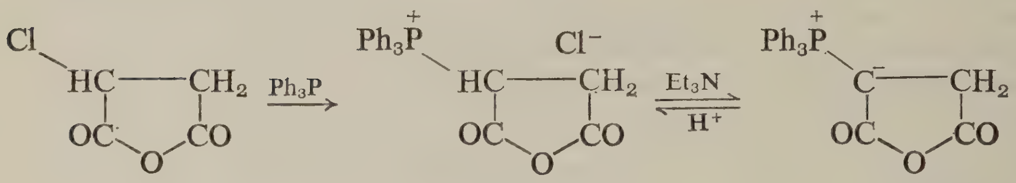
**XXI**



**XXII**

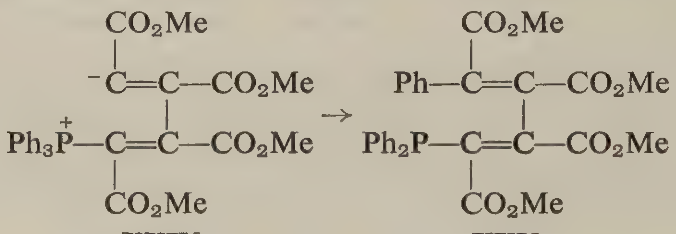


**XXIII**



i.e. **XXIII**

Triphenylphosphine forms a number of adducts with dimethyl acetylenedicarboxylate; at −50°C. an adduct formulated **XXIV** is formed, which rearranges at room temperature to **XXV**. This is the product obtained when the reaction is conducted in boiling ether[193]:



$$Ph_3\overset{+}{P}-C(CO_2Me)=C(CO_2Me)-C(CO_2Me)=\overset{-}{C}(CO_2Me) \rightarrow Ph_2P-C(CO_2Me)=C(CO_2Me)-C(CO_2Me)=C(CO_2Me)-Ph$$

**XXIV** **XXV**

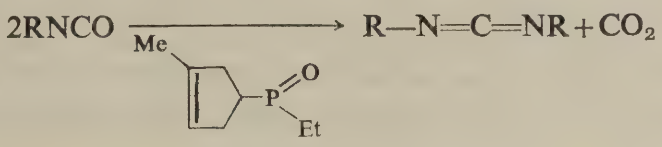
Thermodynamic parameters for the formation of adducts ArCH($\overset{+}{P}Bu_3$)–$\overset{-}{C}(CN)_2$ from tri-*n*-butylphosphine and seven arylmethylenemalononitriles in methanol solution have been evaluated.[582]

Adducts of tertiary phosphines with aliphatic diazo compounds (except with 9-diazofluorene[189]) and azides, phosphazines ($R_3P{=}N{-}N{=}CR_2$) and phosphazides ($R_3P{=}N{-}N{=}NR$) respectively, decompose on heating. The former give methylenephosphorane derivatives and the latter iminophosphoranes.[110,177,179,189,198]

The reaction of triphenylphosphine with aryldiazonium salts in aqueous solution proceeds according to the equation[1995-6]:

$$Ph_3P + ArN_2^+X^- \rightarrow [Ph_3\overset{+}{P}{-}N{=}NArX^-] \xrightarrow{Ph_3P} Ph_3\overset{+}{P}NHNHArX^- + Ph_3PO$$

Olefins of the type $CH_2{=}CHX$, where X is powerful electron acceptor ($CO_2R$, CHO, OAc, $NO_2$) are polymerized by tertiary phosphines to compounds of the type $R_3\overset{+}{P}CH_2(CHX\text{–}CH_2)_nCH^-X$[199]; the tertiary alkylphosphine catalysis of the polymerization of acrylonitrile is reported.[204, 209, 235] Isocyanates such as PhNCO can be polymerized to trimers by the addition of small amounts of tertiary phosphines.[180] A more important reaction is the formation of carbodi-imides by heating isocyanates with catalytic amounts of phosphines, particularly phosphorus-substituted phospholines or phosphorus-substituted phospholidines[236] or their corresponding oxides[237] (see phosphine oxides), e.g.,



$$2RNCO \longrightarrow R\text{—}N{=}C{=}NR+CO_2$$

PHOSPHINE COMPLEXES WITH INORGANIC COMPOUNDS

The ability of phosphines to form co-ordination compounds with metal salts has been known for over a century. Cahours and Hofmann in 1857 recorded the formation of a red complex salt of $Et_3P$ and $PtCl_4$[141] and later obtained similar complexes with $EtPH_2$[169] and $Et_2PH$.[1738] The formation of a zinc iodide complex of $Et_3P$ was noted by Cahours in 1862.[138] Co-ordination compounds are formed with many metal salts; these generally have characteristic melting points and may be used to characterize individual phosphines; many of the complexes, particularly those with the transition metals, are highly coloured.

More recently the ability of trivalent phosphorus compounds to form strong $p\pi\text{–}d\pi$ bonds to metals[1804, 1861] together with increased interest in the chemistry of co-ordination compounds in connection with problems in inorganic stereochemistry, the nature of the co-ordinate bond, the stabilization of valency states, and particularly the development of certain of the compounds as catalysts, has resulted in a rapid development of the use of tertiary phosphine ligands. The need for suitable phosphine ligands, particularly di- and polydentate ligands, has contributed in no small way to the development of synthetic methods for ditertiary phosphines such as **XXVI**, **XXVII** and **XXVIII**, tritertiary phosphines **XXIX** and **XXX** and tetratertiary phosphines **XXXI** and **XXXII**.

$CH_2(PR_2)_2$[1816]

Co-ordination compounds containing polydentate phosphorus ligands are reviewed by Venanzi.[1833]

### TERTIARY PHOSPHINE–METAL SALT COMPLEXES

With simple tertiary phosphines univalent copper[1750, 1754, 1758] and silver[1751, 1754] form fourfold macromolecular 1 : 1 co-ordination compounds such as $(R_3P,MI)_4$ ($M = Cu^+, Ag^+$), 2 : 1 adducts such as $[(PhPMe_2)_2,MI]$,[1754] 3 : 1 complexes $(R_3P)_3MX$ ($R_3P$ = 2-phenyl*iso*phosphindoline)[1758] and 4 : 1 adducts $[(R_3P)_4,MClO_4]$.[1756, 1758] The most frequently prepared gold(I) complexes are linear 1 : 1 complexes $[R_3P,AuX]$ ($X = Cl, Br, I$)[1751, 1852]; 2 : 1 and 3 : 1 complexes are formed with 2-phenyl*iso*phosphindoline.[1758] The 1 : 1 complexes react with halogens giving auric complexes, $R_3P,AuCl_3$.[1752] The *X*-ray crystal analysis of $Et_3P,AuBr_3$ shows a planar 4-co-ordinate gold(III) atom.[1761] The reaction of $Ph_3P,AuCl$ with sodium salts of metal carbonyls of iron, cobalt or manganese gives triphenylphosphine–gold metal carbonyls, e.g.,

$$Ph_3P,AuCl + NaMn(CO)_5 \rightarrow Ph_3PAu{-}Mn(CO)_5\ ^{1757}$$

Complexes of Cu(I) and Ag(I) with chelating ditertiary phosphines such as *P,P,P′,P′*,-tetraethylethylene-1,2-diphosphine contain a 4-co-ordinate chelated metal cation $[CuL_2]^+[CuLX_2]^-$, $[AgL_2][AgI_2]$ ($L = Et_2PCH_2CH_2PEt_2$; X = halogen). AuI forms the diphosphine-bridged complex $IAu,P(Et_2)CH_2CH_2P(Et_2),AuI$ which reacts with iodine to form the Au(III) bridged complex $I_3Au,Et_2PCH_2CH_2PEt_2,AuI$.[56] Compounds such as 4-methyltetraethyl-*o*-phenylenediphosphine form 4-co-ordinate Au(I) complex salts such as $[AuL_2]I$, and Au(III) complexes such as $[LAuI]X_2$ ($X = I, ClO_4$).[1762]

Zinc,[1754, 1784] cadmium[1754, 1763] and mercuric[1752, 1754] halides form 2 : 1 addition compounds $(R_3P)_2,MX_2$ with tertiary phosphines. Compounds which have a halogen-bridged structure having a higher ratio of metal halide to tertiary phosphine are formed from Cd(II) and Hg(II) halides, e.g., $[(R_3P,MX_2)_2]$, $[(R_3P)_3,(MX_2)_2]$ (M = Cd or Hg); and $[(R_3P)_2(HgX_2)_3]$, $[(R_3P)_2(HgX_2)_4]$. Tetraethylethylenediphosphine forms complexes of the type $ML_2X_2$ (M = Zn, Cd, Hg).[56]

Addition compounds of tertiary phosphines with halides and organometallic derivatives of the Group III metals are reviewed by Stone.[1776–7]

Silicon halides form tertiary phosphine complexes $[SiX_4,(PR_3)_2]$ (X = F, Cl, Br) which are non-electrolytes, and which dissociate to their constituents on being heated.[1782] Tertiary phosphine complexes of germanium iodide, $R_3P,GeI_2$,[1783] stannic halides, $(R_3P)_2,SnX_4$ (X = Cl, Br)[1784–5] and Pb(II) bromide, $PbL_2Br_2$ ($L = Et_2PCH_2CH_2PEt_2$),[56] are reported. Titanium(III) and titanium(IV) complexes $TiCl_3,(R_3P)_2$ and $TiCl_4,R_3P$ (R = Et, Ph) have been isolated.[1853]

Phosphine complex salts analogous to Reinecke salts, $Et_3\overset{+}{P}HCr(SCN)_4(R_3P)_2^-$, are obtained by treating *iso*-propanol solutions of $K_3Cr(SCN)_6$ with trialkylphosphine and then hydrochloric acid.[1841] Analogous compounds are formed with tetraethyl- or tetra*cyclo*hexyl-ethylenediphosphine:

$$[R_2\overset{+}{P}H{-}CH_2CH_2\overset{+}{P}HR_2][Cr(SCN)_4R_2P{-}CH_2CH_2PR_2]_2^{-\ 1787};$$

$Ph_3P$, $Ph_2PCH_2CH_2PPh_2$ and $(Ph_2P)_2CH_2$ do not react.

Vanadium trichloride and tertiary alkylphosphines react to give complexes such as $VCl_3,(PR_3)_2$, but triphenylphosphine and tri(*cyclo*hexyl)phosphine form complexes of variable composition.[1837]

Although uranium(IV) halide complexes $(R_3P)_2,UX_4$ (X = Cl, Br) have been reported by Allison and Mann,[1785] in a recent investigation Gans and Smith[1786] found no evidence for such compounds. They show that in ethanol, tetrahydrofuran or acetonitrile solutions the compounds formed are diphosphonium tetrahalogenodioxouranates $(R_3\overset{+}{P}H)_2(UO_2Cl_4)^{2-}$.

Purple red[1792] and yellow[1791] triphenylphosphine rhenium chloride complexes formulated as $ReCl_3,(Ph_3P)_2$ have recently been shown to be $ReOCl_3,(Ph_3P)_2$ and $ReCl_3,(Ph_3PO)_2$ respectively.[1760] Rhenium(II), rhenium(III), rhenium(IV) and rhenium(V)–tertiary phosphine complexes, $ReX_2(PPh_3)_2$ ($X = Cl$, I), $(ReCl_3,Ph_3P)_n$, $ReX_4,(PR_3)_2$ ($X = Cl$, Br, I), and $ReOX_3,(R_3P)_2$ respectively, are reported.[1788–90, 1880] The crystal structure of $(ReCl_3,PhPEt_2)_n$ shows it to be a trimer, i.e. tris(diethylphenylphosphine)nonachlorotrirhenium.[1851]

Numerous tertiary phosphine transition metal salt complexes have been prepared, particularly from nickel, cobalt, platinum and palladium salts. The most frequently reported cobalt and nickel complexes are Ni(II)[88, 1765, 1767, 1769, 1770, 1772–3, 1793, 1857] and Co(II)[88, 172, 1767, 1856] compounds of the type $(R_3P)_2MX_2$ ($M = Co$, Ni; $X = Cl$, Br, I, CN, CNS, $NO_2$, $NO_3$, CNO) which are generally prepared by the direct reactions:

$$MX_2 + 2R_3P \rightarrow (R_3P)_2MX_2 \quad \text{or} \quad (R_3P)_2MX_2 + 2X'^- \rightarrow (R_3P)_2MX'_2 + 2X^-$$

The cyanate complexes are prepared by the reaction:

$$M(CNO)_4^{2-} + 2R_3P \rightarrow (R_3P)_2M(NCO)_2 + 2NCO^- \qquad (M = Ni(II),\ Pd(II),\ Pt(II))$$

An *X*-ray study of the Ni(II) complexes shows a pseudo-tetrahedral structure about the Ni atom.[1773]

Pyramidal derivatives of nickel(III) and cobalt(III), $(R_3P)_2MX_3$ ($X = Cl$, Br), have been obtained by treating the appropriate Ni(II) or Co(II) halide complex with bromine or a nitrosyl halide.[1766–8] Salts of triphenylphosphine-coordinated Ni(II) anions such as $M^+[Ph_3P.NiX]$ ($M = Et_4N^+$, $Ph_4P^+$; $X = Br$, I) are recorded.[1777]

Platinous and palladous halides form planar 2:1, $(R_3P)_2,MX_2$, and dimeric halogen bridged 1:1, $[R_3PM(X)X_2M(X)PR_3]$, complexes with tertiary phosphines.[172, 1753, 1763, 1765, 1774–5, 1856] The platinum compounds can be isolated as *cis* and *trans* isomeric forms. Tertiary phosphines having a pent-4-enyl substituent form platinum(II) complexes of the type $R_3P,PtX_2$ ($X = Cl$, Br, I) in which a C═C bond and the phosphorus atom are co-ordinated to the platinum; the analogous palladium(II) complexes are dimeric and the C═C bond is not co-ordinated to the Pd atom.[1858]

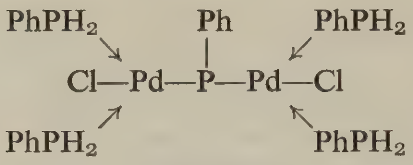
Ruthenium(II) and osmium(II)–tertiary phosphine complexes of the type $M_2Cl_3(PR_3)_6Cl$ ($M = Ru$, Os; $R_3P = PhPEt_2$, $PhPMe_2$) and *cis-trans* octahedral ditertiary phosphine complexes $[MX_2(\text{chelate})_2]$ ($M = Ru$, Os; X = halogen, SCN; chelate $= C_2H_4(PR_2)_2$, $CH_2(PPh_2)_2$, *o*-$C_6H_4(PEt_2)_2$) are reported.[1836] Ruthenium(III) forms monomeric complexes, e.g., $RhX_3,(PR_3)_3$ ($X = Cl$, Br) and two types of binuclear halogen-bridged complexes.[1835]

2-Phenyl*iso*phosphindole complexes with Ni(II), Pt(II) and Pd(II)[1760] and Co(II)[1759] halides to give unusual 5-coordinated compounds, $(R_3P)_3,MX_2$, in addition to the normal complexes $(R_3P)_2,MX_2$. Rh(III) halides give normal 6-coordinated Rh(III) complexes $(R_3P)_3RhX_3$, Ir(III) halides form complexes of the type $(R_3P)_3IrHX_2$ and $(R_3P)_3IrX_3$.[1759] Tetraethylethylenediphosphine forms the following nickel(II), nickel(III), and cobalt(II) complexes: $NiBr_2,L$, $NiBr_3,L$, $NiX_2,L_2$ ($X = ClO_4$, Br), $CoX_2,L$ ($X = Br$, I), $CoX_2,L_2$ ($X = Cl$, Br, I). Tris-(*o*-diphenylphosphinophenyl)phosphine (QP) complexes of the types $[MX(QP)]^+X^-$ ($M = Fe(II)$, Co(II), Ni(II), Pt(II); $X = ClO_4$, $Ph_4B$), and [Co(I)X(QP)] are described by Venanzi and co-workers.[1883–4]

### PRIMARY AND SECONDARY PHOSPHINE–METAL HALIDE COMPLEXES

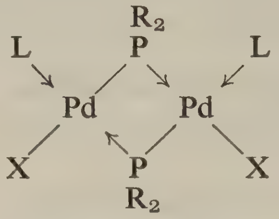
Complexes of primary and secondary phosphines with metal salts have been less extensively studied than those of tertiary phosphines. Complexes of phenylphosphine,[1839] diphenylphosphine,[1842] *cyclo*hexylphosphine[1840] di*cyclo*hexylphosphine[1838] and diethylphosphine[1838] with Cu(I), Cr(III), Fe, Co, Ni and Pd halides, are described by Issleib and co-workers; examples are, $(PhPH_2,CuCl)_4$, $(RPH_2)_2,MX_2$ (R = *cyclo*hexyl; $M = Co$, Ni, Fe); $(R_2PH)_2,MX_2$ ($R = Et$, Cy; $M = Co$, Fe);

$(R_2PH)_4,MX_2$ (M = Co, Ni; R = Et, Cy); $[PdCl(PPh_2),Ph_2PH]$; $CrCl_3L_3$ (L = $PhPH_2$, $Et_2PH$); and the phosphorus-bridged palladium compound **XXXIII**:



**XXXIII**

Novel phosphorus-bridged palladium compounds, **XXXIV**,



**XXXIV**

have been obtained by Hayter by treating complexes of the type $PdX_2,LL'$ (X = halogen, L = $R_2PH$, L′ = $R_2PH$ or $R_3P$) with an amine base,[1843–5,1849] e.g.

$$2PdCl_2(Et_2PH)_2 \xrightarrow[-B,HCl]{B} [PdClR_2P.R_2PH]_2 \qquad (R = Et, Ph)$$

The ruthenium complex $RhCl_3,(Me_2PH)_3$ does not form a bridged complex on treatment with a base.[1849] The chemistry of phosphorus-bridged complexes of transition metals has been reviewed.[2188]

### TERTIARY PHOSPHINE COMPLEXES HAVING FORMALLY ZEROVALENT METAL

A number of tertiary phosphine–metal complexes have been made in which the metal exhibits a formal valency of zero. Tetraethyl-*o*-phenylenediphosphine dissolves cobalt and palladium at about 200° giving the complexes $[M(o\text{-}C_6H_4(PEt_2)_2)_2]$ (M = Co, Pd); iron, ruthenium, rhodium and platinum do not react but iron, in the presence of hydrogen, gives a *trans* dihydro complex $[FeH_2,o\text{-}C_6H_4(PEt_2)_2]$.[1827] Tetraphenylethylenediphosphine dissolves Raney nickel at about 160° giving $Ni[C_2H_4(PPh_2)_2]_2$.[1796] Various methods have been used to prepare phosphine complexes of other zerovalent metals. Octahedral $M[C_2H_4(PMe_2)_2]_3$ (M = V, Cr, Mo, W),[1829] tetrahedral $M[C_2H_4(PMe_2)_2]_2$ (M = Fe, Co),[1829] and other complexes of the type $ML_2$ (M = Ni, Pd; L = $C_2H_4(PMe_2)_2$, $MeC(CH_2PPh_2)_3$),[1830] have been obtained by reduction of higher valent complexes. Zerovalent phosphine molybdenum compounds can be obtained by heating dibenzenemolybdenum with three equivalents of $C_2H_4(PMe_2)_2$ or $o\text{-}C_6H_4(PR_2)_2$ (R = Et, Ph).[1828] Triphenylphosphine–platinum complexes, $Pt(PPh_3)_4$ and $Pt(PPh_3)_3$, are reported by Malatesta.[1797,1832] They react with carbon monoxide eliminating one equivalent of $Ph_3P$ to give the complexes $PtCO(PPh_3)_3$ and $PtCO(PPh_3)_2$ respectively.

Reppe and Sweckendiek[1793] showed that triphenylphosphine and tributylphosphine would react with metal (Fe, Ni, Co) carbonyls, replacing one or two of the carbon monoxide ligands to form tertiary phosphine–metal carbonyl complexes such as $Ph_3P,Ni(CO)_3$, $(Bu_3P)_2,Ni(CO)_2$, $(Ph_3P)_2,Fe(CO)_3$, $Ph_3P,Co(CO)_3$. More recent work has resulted in the isolation of tertiary phosphine–metal carbonyl complexes from the following metals, Cr,[1794,1815] Mo,[1794,1815] W,[1794,1815] Fe,[1793,1800] Co,[1793,1809] Ni,[1793,1795,1804] Mn,[1745,1798,1810–1] Pt[1797] and V.[1808] Tertiary phosphine–manganese carbonyl salts $[Mn(CO)_4,PR_3]^-M^+$ (R = Et, Ph; M = Na, Li) are prepared by reduction of the corresponding dimeric carbonyls $[Mn(CO)_4,PR_3]_2$ with metal amalgams.[1811] Tertiary phosphine manganese carbonyl halides,[1811–2,1860] hydride,[1811] and methyl[1811] [$XMn(CO)_3,PR_3$] ($X = Cl, H, CH_3$) are described. Acylcobalttricarbonyl–triphenylphosphine complexes can be prepared by the reaction of $Ph_3P$ with $RCo(CO)_4$ or with $NaCo(CO)_4$ and alkyl halide[1813-4]; they react with trimethyl phosphite to eliminate first one carbon monoxide and then the triphenylphosphine ligand[1814, 1859]:

$$Ph_3P + RCo(CO)_4 \rightarrow RCO{-}Co(CO)_3,PPh_3$$

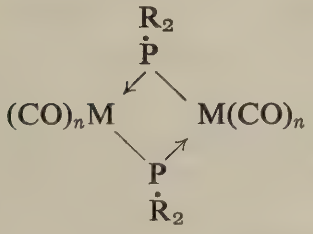
$$RCO{-}Co(CO)_3,PPh_3 \xrightarrow[-CO]{(MeO)_3P} RCO{-}Co(CO)_2,PPh_3,P(OMe)_3 \xrightarrow[-PPh_3]{(MeO)_3P} RCO{-}Co(CO)_2,(P(OMe)_3)_2$$

Rhenium pentacarbonyl chloride and $Ph_3P$ react to give $Re(CO)_4,PPh_3,Cl$.[1902]

Chelating ditertiary phosphines such as $(CF_3)_2PCH_2CH_2P(CF_3)_2$[1771] and [$C_2H_4(PR_2)_2$] ($R = Et$,[1796] $CH_2CH_2CN$[270]) react with nickel carbonyl displacing two carbon monoxide ligands to form the complexes $Ni(CO)_2$,(diphosphine); more powerful chelating ditertiary phosphines such as $C_2H_4(PPh_2)_2$ and [$o$-$C_6H_4(PR_2)_2$] ($R = Et, Ph$) replace all four carbon monoxide ligands giving Ni(diphosphine)$_2$ complexes.[1796] Ditertiary phosphines react with hexacarbonyls of chromium, molybdenun and tungsten to replace either 2 or 4 CO groups; tritertiary phosphines replace 3 CO groups.[1816]

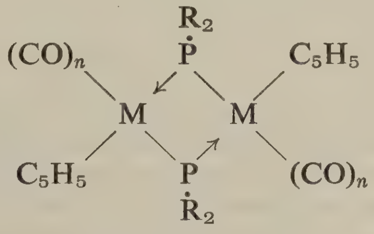
Tetrasubstituted diphosphines react with dimeric metal carbonyls of cobalt and manganese[1848] and with *cyclo*pentadienyl metal carbonyls of iron, nickel, molybdenum and tungsten,[1846-7] giving dimeric phosphorus-bridged complexes, **XXXV** and **XXXVI** respectively, e.g.,

$$Mn_2(CO)_{10} + R_2P{-}PR_2 \rightarrow [R_2P,Mn(CO)_4]_2 + 2CO$$



$M = Co$, $n = 3$
$M = Mn$, $n = 4$

**XXXV**



$M = Mo, W$; $n = 2$
$M = Fe$; $n = 1$
$M = Ni$; $n = 0$

**XXXVI**

The same complexes are obtained from phosphinous chlorides by the reactions:

$$2R_2PCl + 2NaMn(CO)_5 \rightarrow [R_2PMn(CO)_4]_2 + 2CO + 2NaCl^{1848}$$
$$2R_2PCl + 2Na[C_5H_5,Fe(CO)_2] \rightarrow [C_5H_5,Fe(PR_2)CO]_2 + 2CO + 2NaCl^{1847}$$

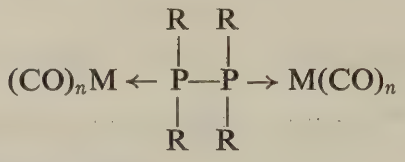
Vanadium compounds of structure **XXXV** ($R = Ph$ or/and H; $n = 4$) are obtained by treating vanadium hexacarbonyl with $PH_3$, $PhPH_2$ or $Ph_2PH$ in hexane solution[1808]:

$$2V(CO)_6 + 2PhPH_2 \rightarrow [V(CO)_4(PhPH)]_2 + 4CO + H_2$$

In the absence of solvent simple replacement of CO ligands occurs to give complexes such as $V(CO)_4(Ph_2PH)_2$.[1808]

Monomeric metal carbonyls of iron, chromium, nickel, molybdenum and tungsten[1795, 1850, 1862–4] react with tetrasubstituted diphosphines giving binuclear complexes, **XXXVII**, of the uncleaved diphosphine, e.g.,

$$2Cr(CO)_6 + R_4P_2 \rightarrow 2CO + [R_4P_2.Cr_2(CO)_{10}]$$



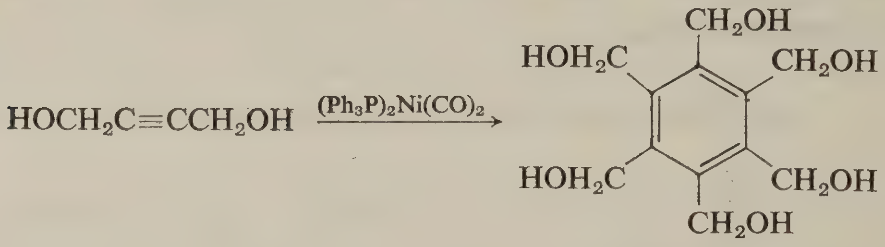
$$(CO)_nM \leftarrow \underset{R}{\overset{R}{P}}\text{—}\underset{R}{\overset{R}{P}} \rightarrow M(CO)_n$$

$M = Ni;\quad n = 3$
$M = Fe;\quad n = 4$
$M = Cr, Mo, W;\quad n = 5$

**XXXVII**

The Cr, Mn, and W complexes of $Me_4P_2$ undergo rearrangement on being heated, losing CO, to give complexes of type **XXXV**.[1863–4]

The polymerization of acetylenic compounds to benzene derivatives in the presence of tertiary phosphine–metal halide or metal carbonyl complexes, particularly $(Ph_3P)_2Ni(CO)_2$, which was discovered by Reppe and Sweckendiek,[1793] has been extensively investigated.[1799, 1801–7] Typical examples are the polymerization of 2-butyne-1,4-diol to hexamethylolbenzene,[1803] of phenylacetylene to 1,2,4-triphenylbenzene,[1801] and vinylacetylene to 1,2,4-trivinylbenzene[1799]:



α-ω Acetylenic hydrocarbons yield polymeric products.[1805] Kinetics of the polymerizations and the effects of the phosphine–metal carbonyl catalyst, acetylene structure and solvent are reported by Meriwether *et al.*,[1805–6] who showed that for complexes of the type $Ni(CO)_2,(PR_3)_2$ the catalytic activity varies as:

$$R = \text{—}CH_2CH_2CN > Ph > H > OEt > n\text{-alkyl} \gg \text{—}OPh \sim \text{zero}$$

### TERTIARY PHOSPHINE–ORGANOMETAL AND METAL HYDRIDE COMPLEXES

Organo and hydrido complexes of a number of metals having metal–carbon or metal–hydrogen bonds stabilized by tertiary phosphines have been prepared. Copper(I), silver(I) and gold(I) form ethynyl complexes of the type $PhC{\equiv}CM.PR_3$ ($M = Cu, Ag, Au$).[1817–8] A number of organogold compounds form tertiary phosphine complexes, $RAu.PR'_3$ ($R =$ alkyl, aryl); trimethylgold complexes, $Me_3Au.PR_3$ ($R = Me, Ph$), can be obtained by direct combination of $Me_3Au$ with the phosphine at −70°.[1852] Organonickel(II) and *cis-trans* planar platinum(II) compounds of the type $(R_3P)_2MR'X$ and $(R_3P)_2MR'_2$ ($M = Ni, Pt$; $R =$ alkyl, aryl, ethynyl; $X =$ halogen) can be obtained by treating the tertiary phosphine metal halide complexes $(R_3P)_2MX_2$ with Grignard or organolithium reagents.[1820–2, 1866, 1874] Platinum(IV) compounds $(Et_3P)_2Pt(Ph)_2X_2$ ($X = Cl, I$) are reported.[1821] Hydride complexes have been isolated in the cases of: planar platinum, $(R_3P)_2PtXH$ ($X = Cl, Br, CN, CNS$)[1819, 1824, 1831, 1866] and $[(Ph_3P)_3PtH]^+X^-$ ($X = Cl, NO_3, ClO_4, BF_4, BPh_4$)[1831]; iron, FeXH(diphosphine)$_2$ ($X = H$ or halogen)[1875–6]; nickel,[1865] ruthenium and osmium, *trans*-MXH(diphosphine)$_2$ ($X = Cl, Br, I, H, CNS, NO_2$)[1823, 1875]; iridium, $(Ph_3P)IrHCl_2$,[1825] $(Ph_3P)_3IrH_2Cl$[1825] and $(Ph_3P)_3IrH_3$.[1826]

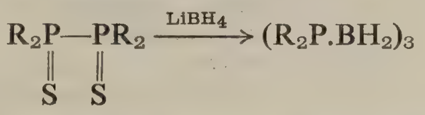
### PHOSPHINE–BORON HYDRIDE COMPLEXES

Boron hydrides react with primary and secondary phosphines to give 1 : 1 adducts which lose hydrogen, when heated, to form stable B–P polymers.[1388, 1780–1, 1867] The dimethylphosphine–borane complex, $Me_2PH,BH_3$, loses hydrogen at about 150° giving a mixture of a very stable and chemically inert trimeric dimethylphosphinoborane $(Me_2PBH_2)_3$, m.p. 86°, a somewhat less stable tetramer, m.p. 161°, and a trace of high polymer. The trimer is stable to heat below 350° and is hydrolyzed only slowly when heated at 300° with hydrochloric acid[1388, 1778, 1780]:

$$Me_2PH.BH_3 \xrightarrow[-H_2]{150°} (Me_2P.BH_2)_3 \xrightarrow{H_2O} 3Me_2PO_2H + 3H_3PO_4 + 12H_2$$

An *X*-ray diffraction study of the trimer indicates a *cyclo*hexane-like structure.[1755] The fully methylated phosphinoborane $(Me_2PBMe_2)_3$, m.p. 333°, is almost as stable to acid hydrolysis as $(Me_2P.BH_2)_3$; in contrast, $(H_2P.BMe_2)_3$ is rather unstable. Monomethylphosphine–borane complex is a volatile oil.[1388]

A number of other dialkylphosphinoboranes are described; they have been prepared by thermal decomposition of the dialkylphosphine–borane adduct,[1781] by reduction of $Me_2POCl$ or $Et_2PCl$ with $LiBH_4$[1780] and by reduction of tetra-alkyldiphosphine disulphides with alkali metal borohydrides[1870–1]:



$$\underset{\underset{S}{\|}}{R_2P}—\underset{\underset{S}{\|}}{PR_2} \xrightarrow{LiBH_4} (R_2P.BH_2)_3$$

Trimethylphosphine–borane, $Me_3P,BH_3$, is formed by direct reaction of trimethylphosphine with the borane, $B_2H_6$.[1388, 1872] A number of tertiary phosphine–borane adducts have been prepared by the exchange reaction[1868]:

$$Et_3N,BH_3 + R_3P \rightarrow R_3P,BH_3 + Et_3N\uparrow \qquad (R = \text{alkyl, aryl})$$

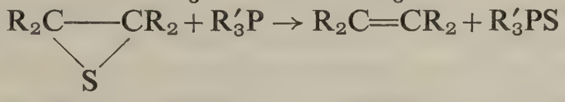
The reaction of phosphines with penta- and deca-borane are reported.[1867, 1869, 1873]

Enthalpies of reaction, in benzene solution, of diborane with mono-, di-, and triphenylphosphine have been determined calorimetrically and hence the enthalpies of the addition of these donors to $BH_3$ evaluated.[488]

### REDUCTION OF ORGANIC COMPOUNDS BY TERTIARY PHOSPHINES

The oxidation of trivalent phosphorus compounds has been reviewed by Cadogan.[355] Hydrogen peroxide, organic peroxides and disulphides, and many other oxygen and sulphur-containing compounds, are reduced by tertiary phosphines. In these reactions the phosphine is oxidized to the phosphine oxide or sulphide, e.g.

$$RO—OR + R'_3P \rightarrow ROR + R'_3PO$$



$$R_2C\underset{S}{\diagdown\!\diagup}CR_2 + R'_3P \rightarrow R_2C{=}CR_2 + R'_3PS$$

Some examples of the types of reductions which have been carried out, generally using triphenylphosphine, are shown in Table V.

## Derivatives of $P_2H_4$

Although the first organic derivative of diphosphine, $P_2H_4$, tetraphenyldiphosphine, was prepared in 1888 by Dörken[1883] by the interaction of diphenylphosphine and diphenylchlorophosphine, the chemical and physical properties of this compound remained largely unknown until the work of Kuchen and Buchwald[1884] was described in 1958. This work, together with that of Issleib and Seidel[68] who in 1959 described a number of tetra-alkyldiphosphines, forms the foundation for the recent rapid

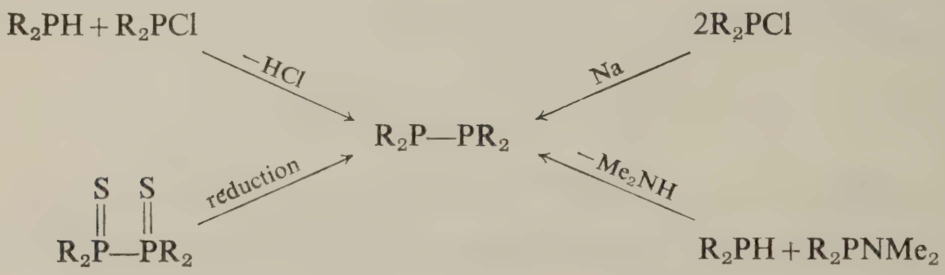
Refs. p. 1082

developments in this field. The chemistry of compounds with a P–P bond is reviewed by Cowley.[2171]

*Table V.—Reduction by Tertiary Phosphines*

| Class of organic compound | Product | Reference |
|---|---|---|
| Hydroperoxide | alcohol | 117, 118 |
| Dialkyl peroxide | ether | 117, 118 |
| Ozonide | ketone or aldehyde | 117, 119 |
| Peracid | carboxylic acid | 118, 122 |
| Perester | ester | 115, 118 |
| Diaryl peroxide | acid anhydride | 119–122 |
| Epoxides | olefine | 125, 185, 2003 |
| Episulphide | olefine | 126–128, 185 |
| Disulphide | thio ether | 110, 123, 178, 259, 261 |
| Tetrasulphide | disulphide | 260 |
| Arylsulphonyl chloride | mercaptan + disulphide | 128, 129 |
| Arylsulphinic acid | mercaptan | 129 |
| Arylsulphinyl chloride | mercaptan | 129 |
| Bis(*O*,*O*-dialkylthiophosphoryl) disulphide | trithiopyrophosphate | — |
| Amine oxide | amine | 124 |
| Nitroso compound | azoxy compound | 117, 868 |
| Aryl isocyanate | aryl isocyanide | 1693 |
| Oxazirane | imines | 262 |

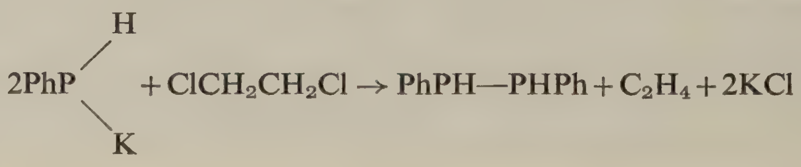
Tetrasubstituted diphosphines are generally prepared by the reaction of a secondary phosphine or its metal salt with a phosphinous chloride,[1884, 2172] by reduction of tetra-alkyldiphosphine disulphide with reagents such as zinc dust,[1903] sodium,[25] metals such as iron or calcium[30] or with tributylphosphine,[323, 1937] by reduction of phosphinous chlorides with metals,[26, 65, 68, 1884, 2173] and by reaction of secondary phosphine with *N*,*N*-dialkylphosphinous amides[296]:



Metal salts of certain secondary phosphines, particularly di*cyclo*hexylphosphine, react with alkyl halides such as ethylene dichloride,[85, 1879] ethyl iodoacetate[86] or triphenylmethyl chloride[212] to give tetrasubstituted diphosphines as the major product rather than the expected tertiary or ditertiary phosphine:

$$R_2PLi + ClCH_2CH_2Cl \rightarrow R_2PCl + LiCH_2CH_2Cl$$
$$LiCH_2CH_2Cl \rightarrow C_2H_4 + LiCl$$
$$R_2PLi + R_2PCl \rightarrow R_2P—PR_2 + LiCl$$

1,2-Diphenyldiphosphine results from the action of monopotassium phenylphosphine on ethylene dichloride or methylene dichloride,[76] the overall reaction being:



$$2PhP\begin{smallmatrix}H\\ \\K\end{smallmatrix} + ClCH_2CH_2Cl \rightarrow PhPH—PHPh + C_2H_4 + 2KCl$$

Diethylphosphinothionic chloride is reduced in good yield to $Et_4P_2$ by copper bronze.[30]

Reduction of asymmetric diphosphine disulphides $[RMePS]_2$ (R = Et, Ph) with two equivalents of tributylphosphine gives a 1 : 1 mixture of the two isomeric *cis-trans* diphosphines RMeP–PMeR.[1888]

Tetraphenyldiphosphine is formed by the thermal decomposition of diphenylphenylcarbamoylphosphine[168]; analogously phenylbis(phenylcarbamoyl)phosphine yields tetraphenyl*cyclo*tetraphosphine[168] and tris(phenylcarbamoyl)phosphine yields elemental phosphorus[156]:

$$2Ph_2PCONHPh \xrightarrow{\Delta} Ph_4P_2 + (PhNH)_2CO + CO$$
$$4PhP(CONHPh)_2 \xrightarrow{\Delta} (PhP)_4 + 4(PhNH)_2CO + 4CO$$
$$4P(CONHPh)_3 \xrightarrow{\Delta} P_4 + 6(PhNH)_2CO + 6CO$$

The same phosphorus-containing products are formed together with tributyldichlorophosphorane by the reaction of the halogen compounds $Ph_2PCl$, $PhPCl_2$, and $PCl_3$ with tributylphosphine[213]:

$$Bu_3P + 2Ph_2PCl \rightarrow Ph_4P_2 + Bu_3PCl_2$$
$$4Bu_3P + 4PhPCl_2 \rightarrow (PhP)_4 + 4Bu_3PCl_2$$
$$3Bu_3P + 2PCl_3 \rightarrow 2P + 3Bu_3PCl_2$$

The Raman spectra of $Et_4P_2$ and $Cu_4P_2$ show the phosphorus–phosphorus emission band at 424 and 419 cm.$^{-1}$ respectively.[1890]

### REACTIONS OF DIPHOSPHINES

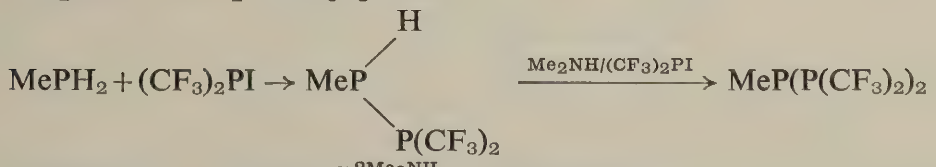
Like phosphines, tetrasubstituted diphosphines are extremely reactive compounds. The P–P bond is easily broken in reactions such as oxidation, reduction and halogenation. Reactions are shown in outline on Chart III.

## Derivatives of Linear Polyphosphines

The preparation and chemistry of organic polyphosphines to 1963 has been reviewed by Wiberg *et al.*[1881]

Various derivatives of $P_3H_5$ are reported, e.g., $Ph_5P_3$,[1884] $Et_5P_3$,[1881] $MeP(P(CF_3)_2)_2$,[1887] $P_3(CF_3)_5$,[1887] and $MeP(P(Ph)_2)_2$.[1900] Methods of preparation which are generally similar to those for diphosphine derivatives are indicated below:

$$2Ph_2PH + PhPCl_2 \rightarrow Ph_5P_3 + 2HCl$$



$$MePH_2 + (CF_3)_2PI \rightarrow MeP\begin{matrix} H \\ P(CF_3)_2 \end{matrix} \xrightarrow{Me_2NH/(CF_3)_2PI} MeP(P(CF_3)_2)_2$$

$$MeP(NMe_2)_2 + Ph_2PH \xrightarrow[\Delta]{-2Me_2NH} MeP(P(Ph)_2)_2$$

## *cyclo*Polyphosphines

Köhler and Michaelis in 1877 showed that phenylphosphine and phenyldichlorophosphine react with elimination of hydrogen chloride to give a compound of empirical formula PhP which was originally designated as phosphorobenzene, Ph–P=P–Ph, by analogy with azobenzene.[1891] The exact nature of the various polymeric forms of $(PhP)_n$ has been a matter of considerable controversy and it was not until the work of Daly and Maier was published that some light was shed on the subject.[1900, 2179–80, 2325, 2332] Crystalline compounds having the following melting

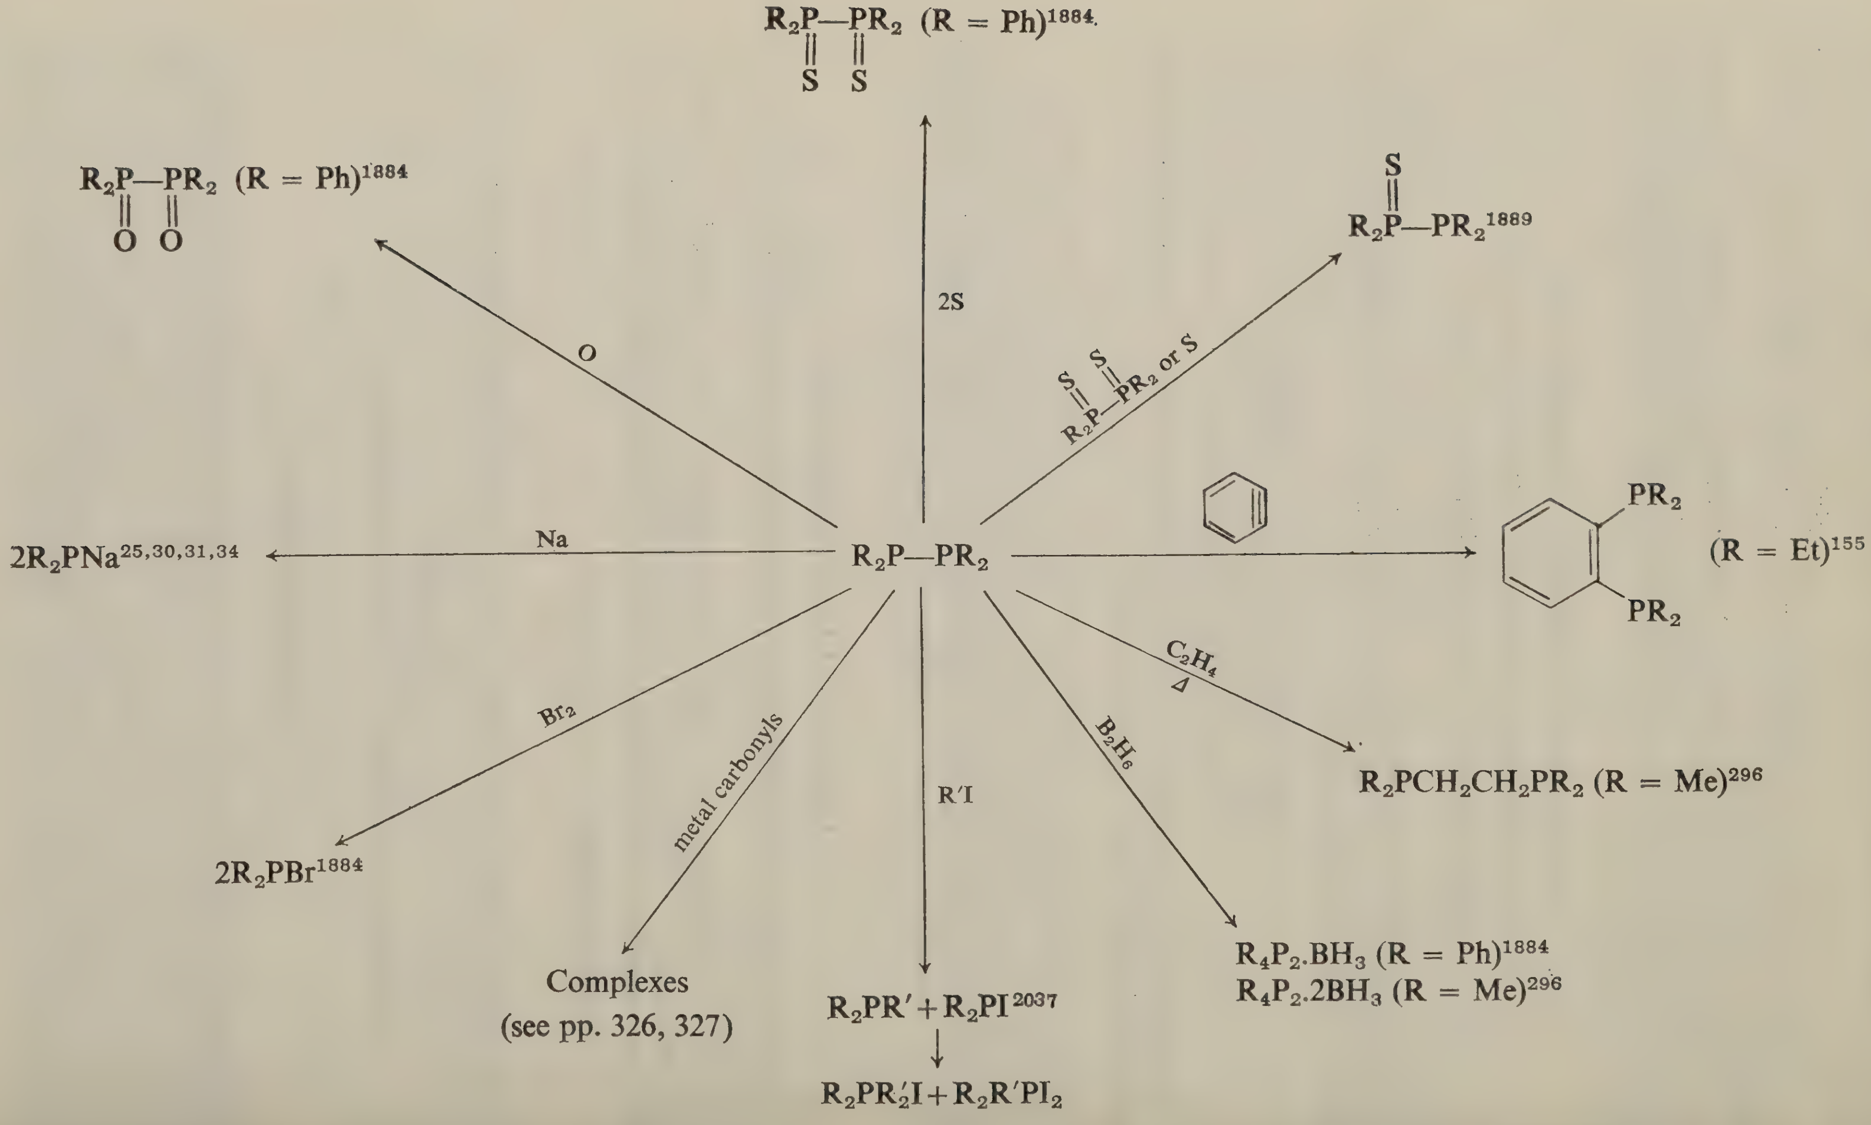


CHART III.—Some reactions of diphosphines points have been isolated: *A*, 149–150°[27,38,50,310,1881,1891,1894–5,1900,1905]; *B*, 154–156°[1900] (*A* recrystallized from methyl cyanide); *C*, 190°[310,1905]; *D*, 189–193°[1900] (*C* recrystallized from tetrahydrofuran, THF) together with amorphous, presumably polymeric, compounds having higher melting points which are insoluble in organic solvents.[1894,1900,1905]

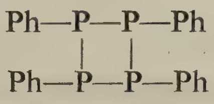
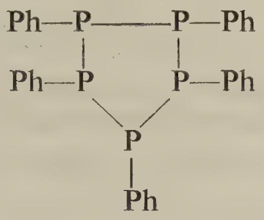
On the basis of molecular weight measurements of *A* and *C* in solution the following structures have been proposed: (i) *A*=*C*=**XXXVIII**[310]; (ii) *A*=**XXXVIII**, *C*=**XXXIX**[1905]; (iii) *A*=*C*=**XXXIX**[1894,1898]; and (iv) *A*=**XXXIX**[38,50,1881,1900,1907]

Ph—P=P—Ph

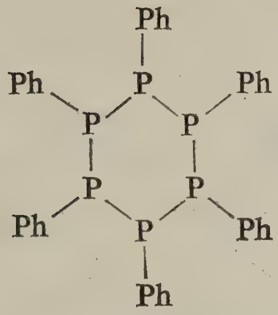
**XXXVIII**



**XXXIX**



**XL**



**XLI**

Henderson *et al.* concluded from cryoscopic, mass spectra and nuclear magnetic resonance data that *A* and *C*, both in the solid state and in solution, are stereoconformers of tetraphenyl*cyclo*tetraphosphine **XXXIX**[1894,1898] and found no evidence for the existence of **XXXVIII**. Daly and Maier determined the molecular weights, from cell dimensions and density of the crystalline compounds *B* and *D*, and determined their structure by *X*-ray crystal analysis. Compound *B* was shown to be pentaphenyl*cyclo*pentaphosphine, **XXXVIII**. Compound *D* crystallizes in at least four forms, all of which are crystalline modifications of hexaphenyl*cyclo*hexaphosphine, **XLI**. The *X*-ray powder patterns of the high-melting compounds, m.p. 252°–256° and 260°–285°, show these to be highly crystalline. The pentamer reacts with nickel carbonyl to form a complex and is cleaved by sulphur to form $(PhPS)_3$; the hexamer reacts with neither nickel carbonyl nor sulphur.[2325]

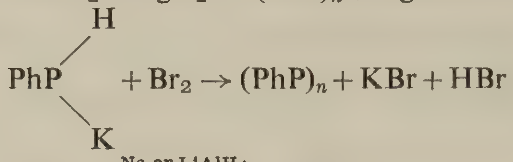
It is reported that whereas phosphorobenzene, $(PhP)_4$, reacts with $Ni(CO)_4$ or $[Fe(CO)_4]_2$ giving carbonyl derivatives $(PhP)_4,Ni(CO)_3$ and $(PhP)_4,[Fe(CO)_4]_2$ respectively, carbonyls of molybdenum and tungsten form complexes of the type $(PhP)_5,M(CO)_5$.[1901] Expansion of a 4-membered to a 5-membered phosphorus ring was postulated.[1901] Daly and Maier point out that preparation of compound B in two ways and crystallization from three different solvents, benzene/ethanol, acetonitrile or tetrahydrofuran, always gave crystals of the pentamer and suggest that synthesis of $(PhP)_4,NiCO_3$ could be equally well explained by postulating a ring contraction of $(PhP)_5$.[2332] At 160° phosphobenzene decomposes giving phenylphosphindene, PhP, a reactive intermediate which can be trapped by reaction with disulphides to form a phenyl phosphonodithioite[194]:

$$(PhP)_n \rightarrow PhP \xrightarrow{Et_2S_2} PhP(SEt)_2$$

Other methods of preparing phosphorobenzene are the reaction of phenylphosphine with tetramethylphenylphosphonous diamide[1900,2325] or with an organo-mercury compound,[1895] by the action of bromine on monopotassiumphenylphosphine,[76] and by reduction of phenylphosphonous dichloride[50]:

$$2PhP(NMe_2)_2+2PhPH_2 \xrightarrow{170°/1\ hr.} (PhP)_5+4Me_2NH$$

$$PhPH_2+HgR_2 \rightarrow (PhP)_n+Hg+2RH$$

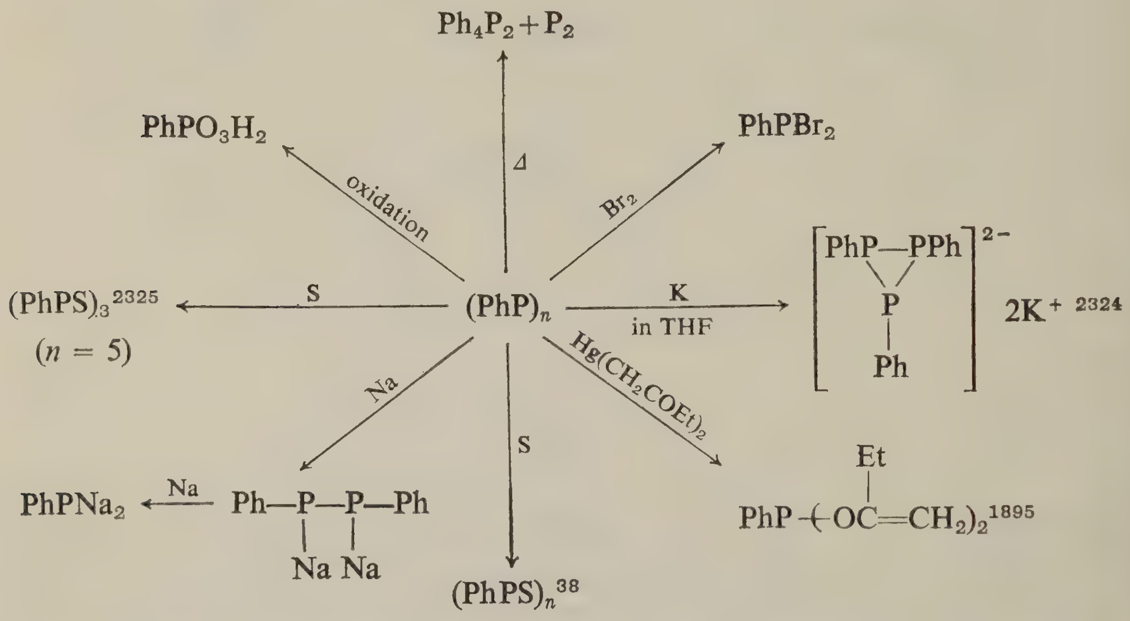


$$PhP\begin{smallmatrix}H\\K\end{smallmatrix} + Br_2 \rightarrow (PhP)_n + KBr + HBr$$

$$PhPCl_2 \xrightarrow{Na\ or\ LiAlH_4} (PhP)_n$$

The fluorinated pentameric *cyclo*polyphosphine $(C_6F_5P)_5$ is made by reaction of pentafluorophenylphosphonous dibromide or di-iodide with elemental mercury.[2326]

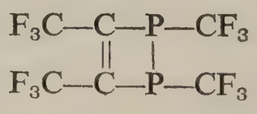
Some reactions of $(PhP)_n$ are indicated below:



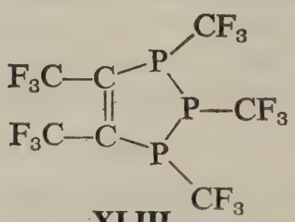
The first alkyl*cyclo*polyphosphines, tetrameric and pentameric trifluoromethyl compounds $(CF_3P)_4$ and $(CF_3P)_5$, were prepared in 1958 by Mahler and Burg[1892] by the reduction of trifluoromethylphosphonous di-iodide with elemental mercury at room temperature:

$$CF_3PI_2+Hg \rightarrow (CF_3P)_4 \quad \text{m.p. } 66{\cdot}4°,\ \text{b.p. } 145°$$
$$(CF_3P)_5 \quad \text{m.p. } -33°,\ \text{b.p. } 190°$$

*X*-Ray crystal analysis of the tetramer shows a puckered 4-membered phosphorus ring.[1897] The two compounds react easily and reversibly with trimethylphosphine or trimethylamine to form the complexes $Me_3P–PCF_3$ and $Me_3N–PCF_3$ respectively. These dissociate at room temperature to a mixture of $(CF_3P)_4$ and $(CF_3P)_5$.[1907] Catalytic amounts of trimethylphosphine suffice to convert $(CF_3P)_5$ to $(CF_3P)_4$ at room temperature; in the absence of this catalyst interconversion takes place at 260°.[1907] Reaction of the tetramer and pentamer with bistrifluoromethylacetylene yields 1,2,3,4-tetrakis(trifluoromethyl)-3,4-diphospha*cyclo*butene, **XLII**, and 1,2,3,4,5-pentakis(trifluoromethyl)- 3,4,5-triphospha*cyclo*pentane **XLIII**[1899]:



**XLII**

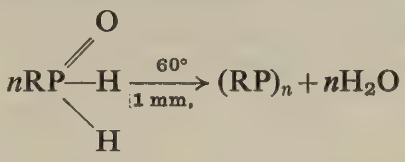


**XLIII**

Pentamethyl*cyclo*pentaphosphine has been synthesized by the thermal decomposition of methyl phosphonodifluoridite,[302]

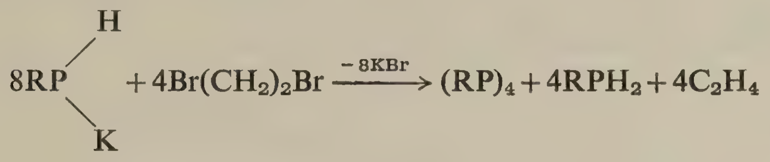
$$(\mathrm{MePF_2} \xrightarrow{\Delta} (\mathrm{MeP})_5)$$

A number of alkyl *cyclo*polyphosphines $(RP)_4$ and $(RP)_5$ have been synthesized by the condensation of monoalkylphosphine with alkylphosphonous dichloride,[1886] by reduction of the phosphonous dichloride with magnesium or lithium and by dehydration of primary phosphine oxides[1894, 1896]:

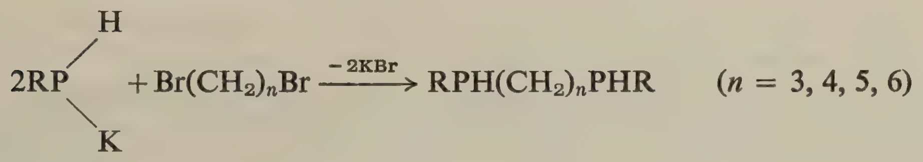


$$n\mathrm{RP}(=\mathrm{O})(\mathrm{H})\mathrm{-H} \xrightarrow[1\ \mathrm{mm.}]{60^\circ} (\mathrm{RP})_n + n\mathrm{H_2O}$$

Tetrabutyl*cyclo*tetraphosphine is obtained in 42% yield by the reaction of white phosphorus with butyl magnesium bromide and butyl bromide.[18] Tetra*cyclo*hexyltetraphosphine, $(RP)_4$, is formed by the action of potassium *cyclo*hexyl phosphide on methylene dichloride or ethylene dibromide[79]; the 1,3-, 1,4-, 1,5- and 1,6-dihalides yield the expected disecondary phosphines:

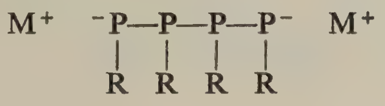


$$8\mathrm{RP}(\mathrm{H})(\mathrm{K}) + 4\mathrm{Br(CH_2)_2Br} \xrightarrow{-8\mathrm{KBr}} (\mathrm{RP})_4 + 4\mathrm{RPH_2} + 4\mathrm{C_2H_4}$$



$$2\mathrm{RP}(\mathrm{H})(\mathrm{K}) + \mathrm{Br(CH_2)}_n\mathrm{Br} \xrightarrow{-2\mathrm{KBr}} \mathrm{RPH(CH_2)}_n\mathrm{PHR} \qquad (n = 3, 4, 5, 6)$$

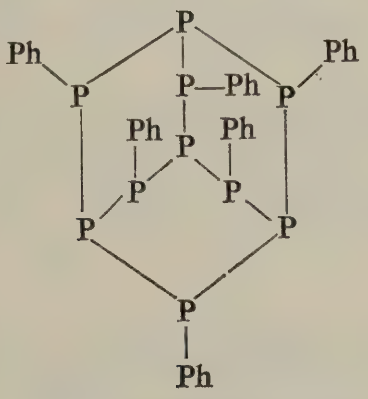
Metal phosphides of the type:



$$\mathrm{M^+}\quad {}^-\underset{\mathrm{R}}{\mathrm{P}}-\underset{\mathrm{R}}{\mathrm{P}}-\underset{\mathrm{R}}{\mathrm{P}}-\underset{\mathrm{R}}{\mathrm{P}}^-\quad \mathrm{M^+}$$

(R = ethyl, methyl; M = Li, Na, K; R = *cyclo*hexyl; M = K) are formed by the action of the metals on the *cyclo*tetraphosphines $(RP)_4$ in tetrahydrofuran solution. They react with alkyl halides giving linear tetraphosphines.[2327] Complexes of *cyclo*polyphosphines with boron halides[2328] and with copper halides[2329] are reported.

A compound $Ph_6P_{10}$, believed to have an adamantane-like structure, **XLIV**, has been obtained by the interaction of dilithiumphenylphosphine with phosphorus trichloride[1881].

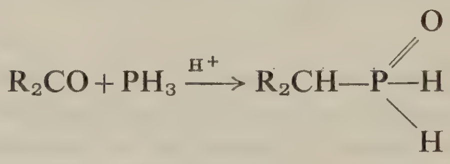


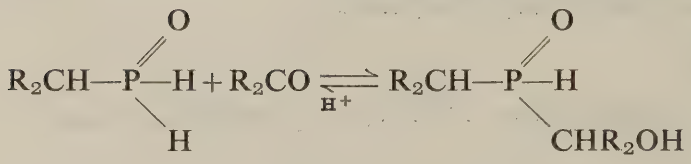
**XLIV**

## PHOSPHINE OXIDES AND RELATED COMPOUNDS

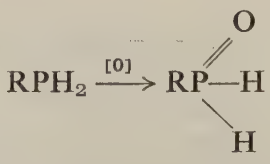
### Primary Phosphine Oxides, $RPOH_2$

Buckler and Epstein in 1960[102] showed that phosphine reacts with ketones in concentrated hydrochloric acid solution to form a mixture of the corresponding primary phosphine oxide and α-hydroxyalkyl secondary phosphine oxide. The primary oxide is formed initially by a reaction which involves migration of an oxygen atom from carbon to phosphorus; the secondary oxide is formed subsequently by a normal carbonyl addition to the primary oxide:





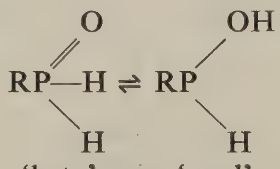
The relative amounts of the two products formed are determined by steric factors which influence the extent to which the carbonyl addition occurs.[102, 1909–10] Primary phosphine oxides may also be prepared by the controlled oxidation of primary phosphines with hydrogen peroxide in ethyl alcohol under an atmosphere of nitrogen,[102–3, 1909] by *tert*-butyl hydroperoxide[103] or by nitrogen dioxide[103]:



Although stable in hydrochloric acid solution or at low temperature, primary phosphine oxides readily disproportionate in alcohol solution or in concentrated form at room temperature to form a mixture of primary phosphine and phosphonous acid.[1909] They are also readily dehydrated giving *cyclo*polyphosphines[1894, 1896]:

$$2RPO.H_2 \rightarrow RPH_2 + RPO_2H_2$$
$$nRPO.H_2 \xrightarrow[1\text{ mm.}]{60^\circ} (RP)_n + nH_2O$$

For this reason primary phosphine oxides have generally been characterized by infra-red and nuclear magnetic resonance spectroscopy and by conversion to derivatives (see Chart IV). Spectroscopic data show the compounds to exist mainly in their ‘keto’ rather than their ‘enol’ forms[1909]:



'keto' 'enol'

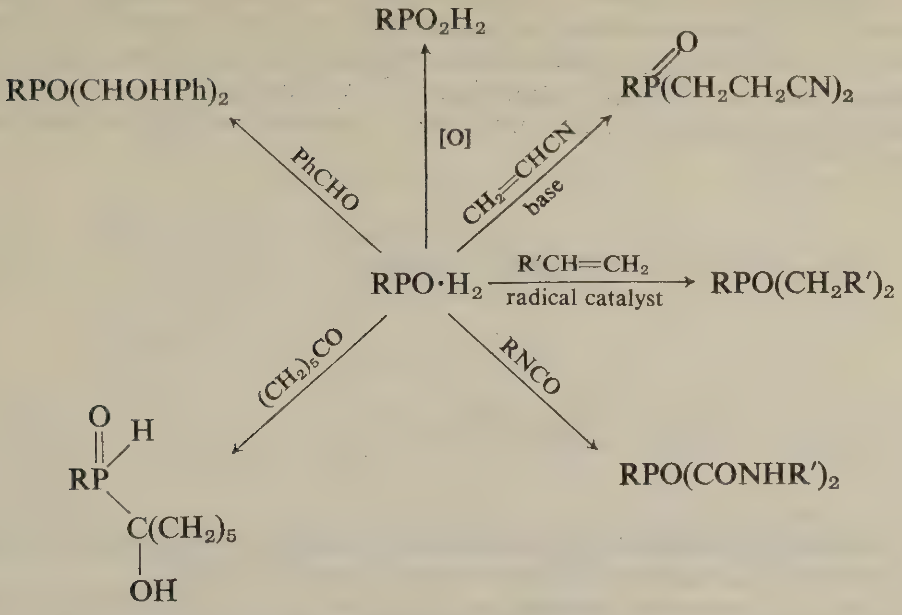


CHART IV.—Some reactions of primary phosphine oxides

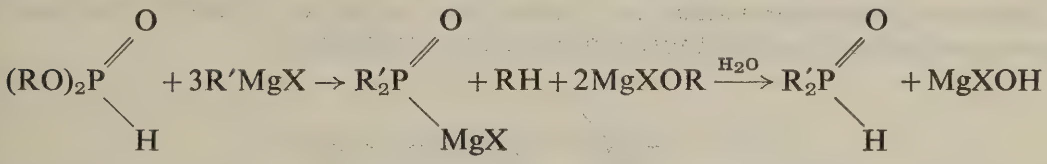
## Secondary Phosphine Oxides, $R_2\overset{O}{\underset{H}{P}}$

Dialkyl phosphine oxides were first obtained by Williams and Hamilton in 1952 by the reaction of dialkyl hydrogen phosphonates with Grignard reagents.[1911] A number of other routes to these compounds are now well established but the Grignard synthesis, owing to the availability of starting compounds and high yields, remains the most convenient laboratory method for dialkylphosphine oxides in which the alkyl groups are unsubstituted butyl or higher alkyls (lower dialkyl compounds have not been isolated):

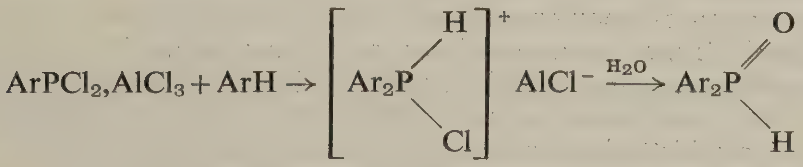


$$(RO)_2\overset{O}{\underset{H}{P}} + 3R'MgX \rightarrow R'_2\overset{O}{\underset{MgX}{P}} + RH + 2MgXOR \xrightarrow{H_2O} R'_2\overset{O}{\underset{H}{P}} + MgXOH$$

(R = ethyl, butyl; R' = butyl,[282] higher alkyl,[444, 1911] phenyl[1913, 1915]).

Organolithium compounds have been used in place of the Grignard reagents.[1914] Diarylphosphine oxides are best prepared by the Friedel–Crafts reaction of phosphorus trichloride with an excess of an aromatic hydrocarbon[1918]:

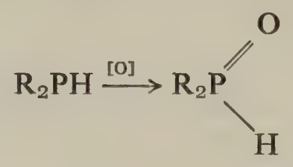
$$PCl_3 + ArH + AlCl_3 \rightarrow ArPCl_2,AlCl_3 + HCl \uparrow$$



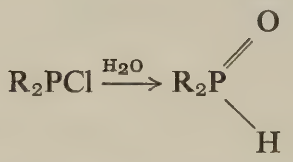
$$ArPCl_2,AlCl_3 + ArH \rightarrow \left[Ar_2\overset{H}{\underset{Cl}{P}}\right]^+ AlCl^- \xrightarrow{H_2O} Ar_2\overset{O}{\underset{H}{P}}$$

Small yields of diarylphosphine oxides have been reported as by-products in the conventional Friedel–Crafts synthesis of arylphosphonous dichlorides when the aromatic function was mesityl, durenyl, and pentamethylphenyl.[1914]

Other methods of preparation are the carefully controlled oxidation of secondary phosphines,[104-6] the hydrolysis of dialkyl[284,1914] or diaryl[424,532] phosphinyl chlorides, the reduction of phosphinyl chlorides with reagents such as lithium aluminium hydride, $LiAlH_4$, magnesium[1916] or sodium[1916] and the reaction of ketones with phosphine in the presence of concentrated hydrochloric acid (see p. 916).[102,1909-10]



$$R_2PH \xrightarrow{[O]} R_2P(=O)H$$



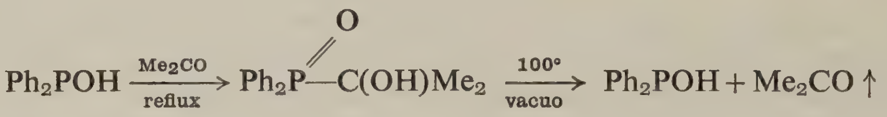
$$R_2PCl \xrightarrow{H_2O} R_2P(=O)H$$

Sodium diphenylphosphine oxide results from the action of sodium hydroxide,[36] sodium hydride[1926] or sodium[1928] on triphenylphosphine oxide.

The majority of secondary phosphine oxides are colourless crystalline solids. The diaryl compounds are unstable on storage or during attempted distillation, disproportionating to a mixture of secondary phosphine and phosphinic acid:

$$2R_2POH \rightarrow R_2PH + R_2PO_2H$$

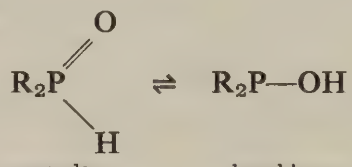
They are conveniently isolated as their crystalline acetone[1918] or chloral[532] adducts. Diphenylphosphine oxide may be stored as its acetone complex which dissociates on heating to regenerate the phosphine oxide:



$$Ph_2POH \xrightarrow[\text{reflux}]{Me_2CO} Ph_2P(=O)\text{—}C(OH)Me_2 \xrightarrow[\text{vacuo}]{100^\circ} Ph_2POH + Me_2CO\uparrow$$

Dialkylphosphine oxides disproportionate less readily than the aryl compounds. Di-*n*-butylphosphine oxide disproportionates at 220° to dibutylphosphine and dibutyl phosphinic acid[282]; dioctylphosphine oxide is reported to be stable for several hours at 200°–250°, but disproportionates in the presence of sodium hydroxide.[284]

Secondary phosphine oxides and phosphinous acids are isomeric; they may be represented as keto and enol forms of the same compound:



$$R_2P(=O)H \rightleftharpoons R_2P\text{—}OH$$

secondary phosphine oxide    phosphinous acide

The structure of secondary alkyl and arylphosphine oxides is indicated from potentiometric titrations which show them to be neutral compounds,[444,1911] and by their infra-red spectra, which show the presence of P=O and P–H bonds but no P–OH bond.[1924] Equilibrium with the phosphinous acid structure is indicated by the preparation of silver diphenylphosphinate from diphenylphosphine oxide and silver nitrate solution[1913]; the formation of this salt is slow, suggesting a slow rearrangement of phosphine oxide to phosphinous acid. Although many esters of phosphinous acids, $R_2P\text{–}OR'$, have been prepared,[329,411,413,525-7,544,576-7,1919] the only true acids reported are bis(trifluoromethyl)phosphinous acid, $(CF_3)_2P\text{–}OH$,[1923] and its sulphur analogue bis-(trifluoromethyl)thiophosphinous acid, $(CF_3)_2PSH$.[583] The oxygen compound forms salts such as $(CF_3)_2PO^-\ Me_3\overset{+}{N}H$; its infra-red spectrum shows the presence of a P–OH bond but no P=O or P–H bonds.

Secondary phosphine oxides undergo numerous reactions characteristic of compounds having a P–H bond, such as base-catalyzed addition to carbonyl compounds, negatively substituted olefins and isocyanates and free-radical catalyzed addition to olefins to form unsymmetrical tertiary phosphine oxides.

$$R_2PO.H \xrightarrow{R'_2CO + \text{Base}} R_2PO.CH(OH)R'_2{}^{105,1915}$$

$$R_2PO.H \xrightarrow{CH_2{=\!=}CHX + \text{Base}} R_2PO.CH_2CH_2X \quad (X = CN, CO_2R, COCH_3, CONH_2)^{104-5,1917}$$

$$R_2PO.H \xrightarrow{ArNCO + \text{Base}} R_2PO.CONHAr^{105}$$

$$R_2PO.H \xrightarrow{R'CH{=\!=}CH_2 + R^{\cdot}} R_2PO.CH_2CH_2R'$$

Active aldehydes such as chloral and formaldehyde react readily in the absence of base catalysts[104-5] particularly with the more 'acidic' secondary phosphine oxides such as diarylphosphine oxides[532,1918] and bis(-2-cyanoethyl)phosphine oxide.[105]

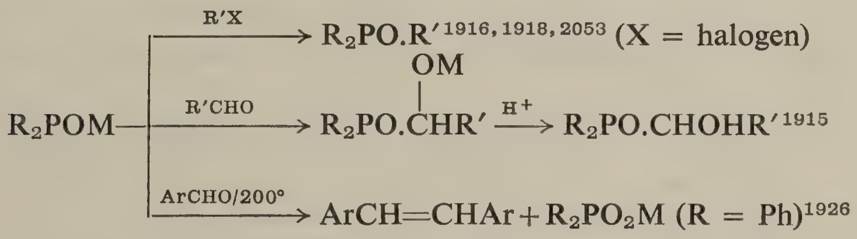
The compounds may be halogenated giving phosphinyl halides, undergo the Mannich reaction to form $\beta$-dialkylaminomethyl tertiary phosphine oxides and react with carbon tetrachloride and alcohols in the presence of tertiary organic amines to form alkyl phosphinates (cf. the Todd reaction p. 991).

$$R_2PO.H \xrightarrow{N\text{-chlorosuccinimide}/SOCl_2} R_2PO.Cl^{284,1913}$$

$$R_2PO.H \xrightarrow{CH_2O + R_2NH} R_2PO.CH_2NR_2{}^{105}$$

$$R_2PO.H \xrightarrow{CCl_4,\ R'OH,\ R_3N} R_2PO.OR'^{105}$$

Metal salts of secondary phosphine oxides are alkylated by alkyl halides to unsymmetrical tertiary phosphine oxides; they react with carbonyl compounds to form salts of $\alpha$-hydroxyphosphine oxides. Aromatic aldehydes and salts of diphenylphosphine oxide react at 200° in a Wittig-type reaction to form stilbene derivatives:



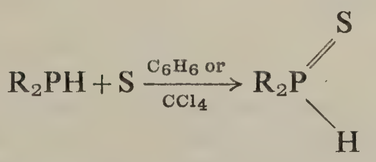
$$R_2POM \xrightarrow{R'X} R_2PO.R'^{1916,1918,2053} \quad (X = \text{halogen})$$

$$R_2POM \xrightarrow{R'CHO} R_2PO.\overset{\overset{OM}{|}}{C}HR' \xrightarrow{H^+} R_2PO.CHOHR'^{1915}$$

$$R_2POM \xrightarrow{ArCHO/200^\circ} ArCH{=}CHAr + R_2PO_2M \quad (R = Ph)^{1926}$$

## Secondary Phosphine Sulphides, $R_2PS.H$

These compounds were first prepared by Peters in 1960[131]; they are obtained by the careful addition of sulphur to secondary phosphines in inert solvent solution[66,131,1747]:



$$R_2PH + S \xrightarrow[CCl_4]{C_6H_6 \text{ or}} R_2P(S)H$$

Two new routes to secondary phosphine sulphides are the reaction of *N*,*N*-dimethyl phosphinamides with hydrogen sulphide and the action of organo-lithium compounds on diethyl hydrogen phosphonothionate[2330]

$$RR'PNMe_2 \xrightarrow[\text{in benzene at } 80^\circ]{H_2S} RR'P(S)H$$

$$(EtO)_2P(S)H \xrightarrow{RLi} Et_2P(S)H$$

**Refs. p. 1082**

The thiono structure has been confirmed by nuclear magnetic resonance and infrared spectroscopy. They undergo base catalyzed addition to carbonyl compounds forming α-hydroxyalkyl tertiary phosphine sulphides, are chlorinated to form phosphinochloridothionates, react with sulphur to form phosphinodithioic acids, and add to olefins in the presence of radical catalysts giving tertiary phosphine sulphides.

Secondary phosphine selenides, $R_2P(Se)H$ ($R = Ph$, $Me_2CHCH_2^-$), have been made by adding red selenium to the secondary phosphines in benzene solution. They have the same structure as the corresponding oxides and sulphides but are less reactive and do not add to acetone in the presence of basic catalysts.[2177]

### Tertiary Phosphine Oxides, $R_3PO$

The chemistry of secondary and tertiary phosphine oxides to 1960 has been reviewed by Berlin and Butler.[1908]

As a class, tertiary phosphine oxides are the most stable organophosphorus compounds. The carbon–phosphorus bonds are comparable in strength with C–C bonds[456] and will remain intact under quite vigorous reaction conditions. For example, $Ph_3PO$ may be nitrated with nitric-sulphuric acid mixtures to form $(m\text{-}NO_2\text{-}C_6H_4)_3PO$[1]; methyl substituents on the aryl groups of compounds of the type $RPO.(C_6H_4Me)_2$ ($R = Me$, Et, Ph) may be oxidized to carboxyl groups using alkaline permanganate in aqueous pyridine[1882,1956] without cleaving the C–P bond. Tertiary phosphine oxides generally possess a high degree of thermal stability, the temperatures required for decomposition being approximately 300°C. above those required for decomposition of the corresponding amine oxides.[1700] Oxides having alkyl groups with an available β-hydrogen atom cleave to olefin and secondary phosphine oxides; oxides having no β-hydrogen atom are more stable. The secondary phosphine oxide formed by thermal decomposition of the lower members undergoes disproportionation, e.g., ethyldimethylphosphine oxide decomposes:

$$\begin{array}{l} Me_2EtPO \xrightarrow{330^\circ\text{–}670^\circ} Me_2POH + C_2H_4 \\ \qquad\qquad\qquad\qquad \downarrow \\ \qquad\qquad\qquad\quad Me_2PH + Me_2PO_2H \end{array}$$

Relative stabilities of several phosphine oxides are shown in Table VI.[1700]

*Table VI.—Relative Stabilities of Several Phosphine Oxides*

| R in RR′R″PO | Temperature for 50% decomposition |
|---|---|
| $Me_3$ | stable to 700° |
| $Ph_3$ | slight discoloration at 690° |
| Et, Me, Ph | 665° |
| $Me_2$, Et | 525° |
| $Et_3$ | 510° |
| Et, Me, pentyl | 490° |
| $Bu_3$ | 490° |

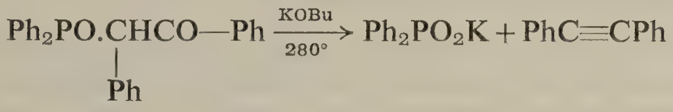
Notable exceptions to the general stability are (a) α-hydroxyalkyl substituted phosphine oxides, which undergo C–P fission with aqueous bases[36,273,1915] and dissociate on heating,[424,1915] (b) tris-(2-pyrryl)phosphine oxide which, gives pyrrole on cleavage with aqueous base,[1986] and (c) tris-(trifluoromethyl)phosphine oxide which, in turn, is decomposed by water to bis-(trifluoromethyl)phosphinic acid or by aqueous base to trifluoromethylphosphonic acid.[1962] Benzyl[1968] and aryl[36,1970] substituted phosphine oxides undergo C–P bond fission on fusion with sodium hydroxide to yield sodium phosphinate and hydrocarbon, e.g.,

$$Ph_3PO \xrightarrow[\Delta]{NaOH} Ph_2PO_2Na + PhH$$

In this reaction the ease of substituent fission in unsymmetrical tertiary phosphine oxides decreases in the series: benzyl > phenyl > alkyl, and naphthyl > phenyl > *p*-tolyl.[1970] Alkali metal salts of secondary phosphine oxides are formed by fusion of aryl-substituted phosphine oxides with alkali metals[1928] or with sodium hydride,[1926] e.g.,

$$Ph_3PO \xrightarrow{NaH} Ph_2PONa + PhH$$

*β*-Keto substituted alkylphosphine oxides are decomposed by bases at high temperatures giving phosphinate and acetylene[1920]:



$$\underset{\displaystyle Ph}{Ph_2PO.\underset{|}{C}HCO—Ph} \xrightarrow[280°]{KOBu} Ph_2PO_2K + PhC{\equiv}CPh$$

Attempts to reduce tertiary phosphine oxides to tertiary phosphines, except by the use of metal hydrides (see p. 895), have been unsuccessful. Recently reported reduction techniques involve the use of silicon hydrides such as polymethyl siloxane[40] or silicochloroform[1982] and boranes or trialkylamine boranes[2179] as reducing agents:

$$R_3PO + 2SiCl_3H \rightarrow R_3P + SiCl_4 + H_2 + (Cl_2SiO)_n$$
$$R_3PO + SiCl_3H + R_3N \rightarrow R_3P + R_3N,HCl + (Cl_2SiO)_n$$
$$Ph_3PO + (R_2BH)_2 \rightarrow Ph_3P + (R_2B)_2O + H_2$$

The atomic refractions of phosphorus in tertiary phosphine oxides are given by Razumov and Zabusova.[1977]

Electron diffraction of trimethylphosphine oxide in the gas phase shows bond lengths P–O 1·48 A., P–C 1·81 A., and bond angles C–P–C 106°, C–P–O 112·3°.[2333]

### TERTIARY PHOSPHINE OXIDE COMPLEXES

Phosphine oxides readily form hydrates, generally monohydrates, $R_3PO,H_2O$ and less frequently the hemihydrate $(R_3PO)_2,H_2O$. Triphenylphosphine oxide forms a hydrate, m.p. 132°, and a hemihydrate, m.p. 154–157°. A hydrogen peroxide adduct $(Ph_3PO)_2,H_2O_2$ is reported to be formed when triphenylphosphine is oxidized by aqueous hydrogen peroxide.[1992] Using $^{18}O$-labelled $Ph_3PO$ it has been demonstrated that no oxygen exchange occurs with water even at the boiling point.[1973] Tertiary phosphine oxides are weakly basic[1972]; they form adducts with many simple and complex inorganic acids[265, 1972] and with strong organic acids such as trichloroacetic acid,[1991] many of which are stable crystalline compounds having characteristic melting points. Spectrophotometric studies of $R_3PX$ ($X = O, S, Se$) complexes with halogens, such as iodine, iodine chloride and bromide, show that in cases where the 1:1 complex is the principal one, and when the substituents on phosphorus are identical, there is a considerable increase in the formation constant which follows the sequence $Se > S > 0$.[1985, 1993] Alkali metals are reported to form highly coloured adducts with tertiary phosphine oxides.[1974]

Co-ordination compounds having tertiary phosphine oxide ligands have been prepared from many metal salts particularly those of the transition metals. Complexes are reported of the types: $(R_3PO)_2,Y$ (where $Y = SnCl_4$, $SnBr_4$, $FeBr_2$, $TiCl_4$,[1965] $SbCl_5$,[1684] $FeCl_2$, $InCl_3$, $SiCl_4$, $SnI_4$, $AsCl_3$, $SbCl_3$, $BiCl_3$, $BiBr_3$, $BiI_3$[1930]); $Ph_3PO,X$ (where $X = MgCl_2$, $BF_3$, $BBr_3$, $AlCl_3$, $GaCl_3$, $InCl_3$, $TiCl_4$, $PCl_5$[1930]); $(R_3PO)_2,MX_2$ (where M = Zn,[1925,1953,1972] Cd,[1953,1972] Cu,[1925,1944] Fe,[1953] Co,[67,88,1936,1953,1966,1972] Ni,[67, 88, 1932, 1966] Hg,[1684, 1972] Mn,[1938, 1953] Cr,[1967] and X = univalent anion); $(alkyl_3PO)_3,Cr(CNS)_3$[1967]; $(Ph_3PO)_3,CrCl_3$[1930]; $3R_3PO,Fe_2Cl_6$[1925]; and $[(R_3PO)_4M]^{n+}X_n^-$ ($M = Mn^{2+}$, $Fe^{3+}$, $Co^{2+}$, $Cu^{2+}$, $Zn^{2+}$ and $X = ClO_4$).[1958]

This property has been utilized in a number of analytical methods which involve the separation of metals by solvent extraction.[1964] The use of tertiary phosphine oxides as extractants for uranium and thorium has been extensively investigated.[1521, 1647, 1927, 1929]

Although numerous tertiary phosphine oxide–metal halide complexes are known, only a few complexes of tertiary phosphine sulphides and selenides are described; these are: $(Ph_3PS)_2,PdCl_2$,[1307] $(R_3PS)_2,SnX_4$ (R = alkyl, X = Cl, Br),[1301] $(Ph_3PSe)_2,PdCl_2$,[1307] $(Ph_3PSe)_2,SnCl_4$,[1307] and $Ph_3PS,Y$ (where Y = $HgCl_2$, $AlCl_3$, $AlBr_3$, $SnCl_4$, $TiCl_4$, $TiBr_4$, $SbCl_5$, $NbCl_5$, $TaCl_5$, $FeCl_3$).[2331]

## PREPARATION OF TERTIARY PHOSPHINE OXIDES

Tertiary phosphine oxides are generally prepared either by direct oxidation of the corresponding phosphine or by reaction of a pentavalent phosphoryl halide or ester with an organometallic compound such as a Grignard reagent. The halogen atoms of phosphoryl halides and the alkoxyl (or aryloxy) groups of phosphate esters may be replaced with moderate success in a stepwise manner by Grignard reagents and to obtain tertiary phosphine oxide it is general to use a slight excess of the reagent. The following phosphorus-containing starting materials may be used: phosphorus oxyhalides,[95, 1946–50, 1972] phosphonyl halides,[1951, 1956] phosphinyl halides,[1951–2, 1978] dialkyl phosphorochloridates,[465] tertiary phosphates,[1955] phosphonates,[1954, 1956] and phosphinates.[1957] Organolithium compounds have been used to prepare tertiary phosphine oxides from phosphorus oxyhalides,[219] trialkyl phosphates,[1959] and diethyl phosphorochloridate[1960]:

$$POX_3 \xrightarrow[3RLi]{3RMgX} R_3PO + 3MgX_2 \text{ (or LiX)}$$

Pyrophosphoryl chloride reacts with phenyl magnesium halides to give a mixture of triphenylphosphine oxide and diphenylphosphinic acid.[1975] Phosphorus pentachloride (see p. 891) gives a mixture of products.

### *Miscellaneous Methods*

Tertiary phosphine oxides are formed as the isolable products after hydrolysis from the reaction of elemental phosphorus[20, 22] or phosphorus and $P_2I_4$[23, 238] or $P_2I_4$[2294] with alkyl iodides (p. 885), and by the alkaline decomposition of many quaternary phosphonium salts (p. 937). Good yields of tris-($\beta$-substituted)phosphine oxides result from the action of aqueous alkali on white phosphorus in the presence of negatively substituted olefines such as acrylonitrile or acrylamide and tetrafluoroethylene[1671, 1922]:

$$P_4 + KOH + CH_2{=}CHX \xrightarrow{H_2O} OP(CH_2CH_2X)_3$$
$$(X = CN, CONH_2, CO_2R, SO_2Me)$$

Tris(dialkylaminomethyl)phosphine oxides are formed in high yield by the reaction of white phosphorus with *N*-hydroxymethyldialkylamines in water–alcohol mixture at 80°C.[2002]

Dihalogenophosphoranes react readily with water, alcohols[22, 1987] or anhydrous oxalic acid[1962] to form the phosphine oxide:

$$R_3PX_2 \xrightarrow{R'OH} R_3PO + R'X + HX \qquad (R' = H, \text{alkyl})$$

Dihalogenophosphoranes have been proposed as reagents for the preparation of optically pure, inverted, alkyl halides from optically active alcohols, and neopentyl halides which are free of isomeric halide from neopentyl alcohol[1988–9]:

$$Ph_3PX_2 + ROH \rightarrow [Ph_3\overset{+}{P}OR\,X^- + HX] \rightarrow Ph_3PO + RX + HX$$

A related reaction is that of a tertiary phosphine with monobromocyanoacetamide and a reactive alcohol such as benzyl or allyl alcohol, the overall reaction being[1990]:

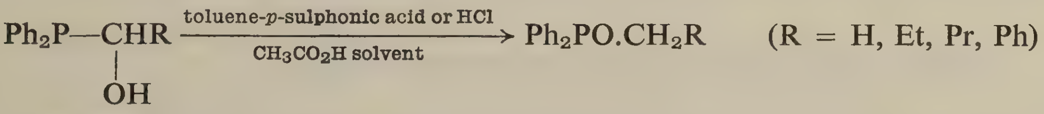
$$R_3P + CNCH(Br)CONH_2 + ROH \rightarrow R_3PO + RBr + CNCH_2CONH_2$$

Hydrolysis of tris-(trifluoromethyl)dichlorophosphorane gives an intermediate pentavalent hydrolysis product of unique structure, namely $(CF_3)_3POH.Cl$.[1963]

Esters of phosphinous acids undergo the Arbuzov reaction (pp. 1006, 1007) when heated with alkyl halide[1919] or alone:

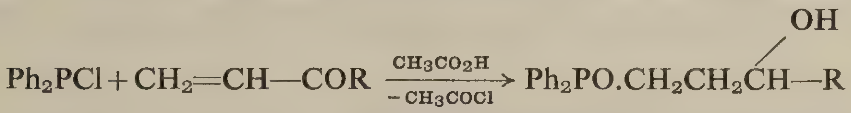
$$R_2P-OR' + R''X \rightarrow R_2PO.R'' + R'X$$

α-Hydroxyalkyldiphenylphosphines rearrange to alkyldiphenylphosphine oxides under strongly acidic conditions[1910, 1961]:

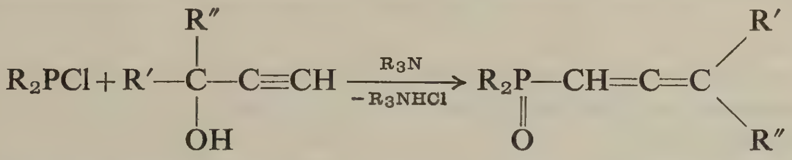


$$Ph_2P-\underset{\underset{OH}{|}}{C}HR \xrightarrow[CH_3CO_2H\ \text{solvent}]{\text{toluene-}p\text{-sulphonic acid or HCl}} Ph_2PO.CH_2R \qquad (R = H, Et, Pr, Ph)$$

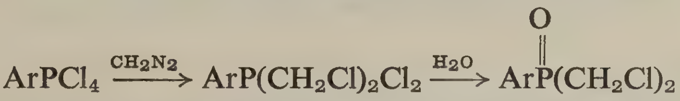
Diphenylphosphinyl chloride reacts with aldehydes and α-β unsaturated ketones giving α- and γ-hydroxysubstituted diphenylphosphine oxides respectively[451]:



Tertiary phosphine oxides having allenic substituents are formed from phosphinous halide and α-acetylenic alcohols in the presence of a base[791]:

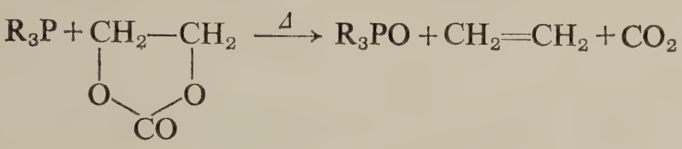


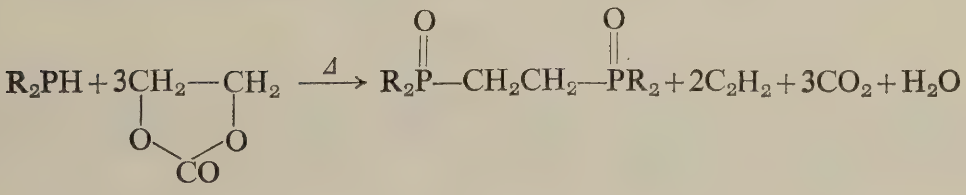
Chloromethylsubstituted phosphine oxides can be obtained from diazomethane and phosphorus pentachloride or aryltetrachlorophosphoranes[535]:

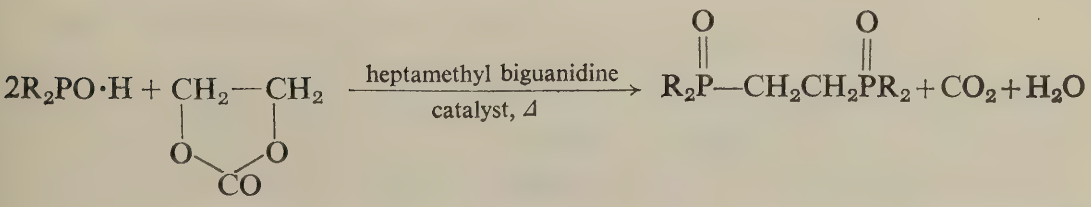


$$ArPCl_4 \xrightarrow{CH_2N_2} ArP(CH_2Cl)_2Cl_2 \xrightarrow{H_2O} Ar\overset{\overset{O}{\|}}{P}(CH_2Cl)_2$$

Ethylene and substituted ethylene carbonates react with tertiary phosphines, alone or with copper powder catalyst, giving tertiary phosphine oxide and the olefine corresponding to the carbonate used.[1984] Secondary phosphines and secondary phosphine oxides are converted to ethylenebisphosphine oxides or 2-hydroxyalkylphosphine oxides depending on the choice of the carbonate, catalyst, and reaction conditions[1983–4]:







Unsymmetrical phosphine oxides are conveniently obtained by the addition of alkyl halides to the reaction product of dialkyl phosphite and Grignard reagents[2053–4]:

$$(RO)_2PO.H + 3RMgX \rightarrow R_2PO.MgX + RH + 2ROMgX$$
$$R_2PO.MgX + R'X \rightarrow R_2R'PO + MgX_2$$

Phosphinous chlorides form phosphonium-like solid addition compounds with reactive alkyl halides such as α-chloroethers, α-chlorosulphides and benzyl chloride but do not react with simple alkyl chlorides. The complexes are decomposed on treatment with an alcohol and a base to form tertiary phosphine oxide and with hydrogen sulphide to form tertiary phosphine sulphide[2423–6]:

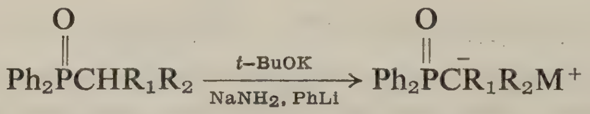
$$Et_2PCl + ClCH_2SEt \rightarrow [Et_2P(Cl)CH_2SEt]^+Cl^- \rightarrow \left[\begin{array}{l} \xrightarrow{EtOH} Et_2P(O)CH_2SEt \\ \xrightarrow{H_2S} Et_2P(S)CH_2SEt \end{array}\right.$$

1,2-Dichloroethyl ethers afford 1-alkoxyvinylphosphine sulphides:

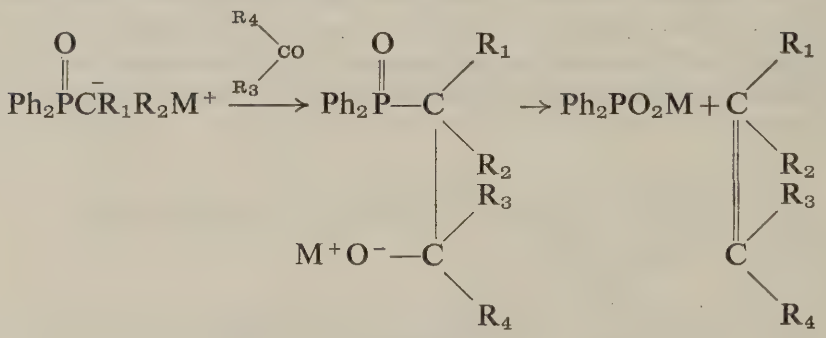
$$Ph_2PCl + BuOCH(Cl)CH_2Cl \rightarrow [\text{complex}] \xrightarrow{H_2S} Ph_2P(S)CH(OBu){=}CH_2$$

SOME REACTIONS OF TERTIARY PHOSPHINE OXIDES

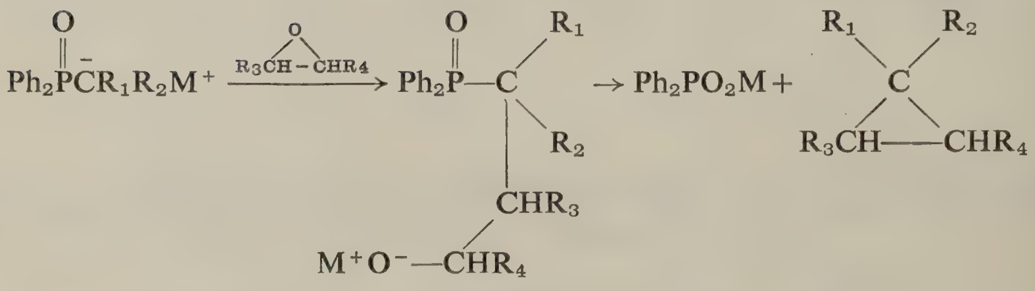
In a variation of the well-known Wittig reaction (p. 946), Horner and co-workers[1916, 1970–1] showed that phosphine oxide anions, formed by reaction of a phosphine oxide having at least one α-hydrogen atom with potassium *tert*-butoxide or $NaNH_2$, would react with aldehydes to form intermediates which decompose to phosphinate anion and olefine; reaction with epoxides leads to the formation of *cyclo*propane derivatives.[1976] When lithium salts of the phosphine oxide anion are used the intermediates (**XLV** and **XLVI**, M = Li) do not eliminate phosphinate anion, and the products isolated from the carbonyl or epoxide reaction after hydrolysis are β-hydroxy and γ-hydroxy phosphine oxide respectively:



$$Ph_2\overset{O}{\overset{\|}{P}}CHR_1R_2 \xrightarrow[NaNH_2,\ PhLi]{t\text{-}BuOK} Ph_2\overset{O}{\overset{\|}{P}}\bar{C}R_1R_2M^+ \qquad (M = Li, Na, K)$$

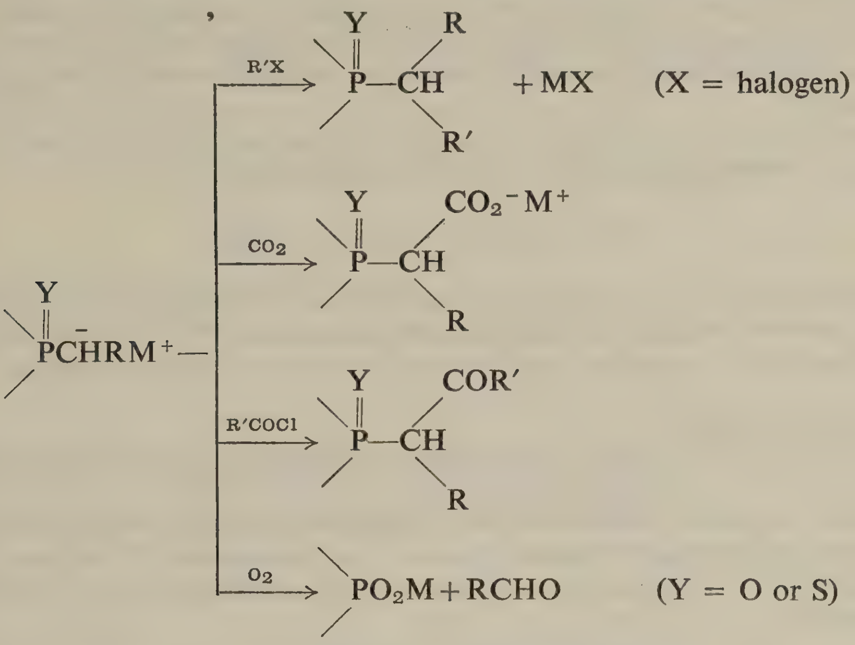


**XLV**



**XLVI**

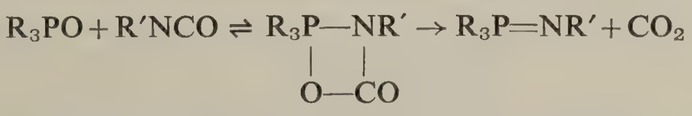
Salts of phosphine oxide/sulphide anions undergo many reactions which are typical of organoalkali compounds, introducing a new substituent (e.g., alkyl,[1928] carboxyl,[1981] acyl[1970-1]) on the $\alpha$-carbon atom; reaction with oxygen causes P–C bond fission to give a phosphinate anion and a carbonyl compound[1916]:



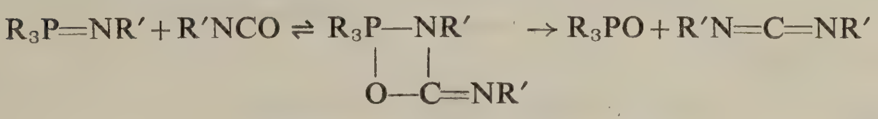
Triphenylphosphine oxide or sulphide and organo-alkali compounds such as benzylsodium,[1928] benzyllithium[1979-80] or methyllithium[1981] undergo rapid exchange followed by a slower but still rapid metalation to form $\alpha$-metallated alkyldiphenylphosphine oxide/sulphide, e.g.,

$$Ph_3PO + RCH_2Li \rightarrow Ph_2PO.CH_2R + PhLi$$
$$Ph_2PO.CH_2R + PhLi \rightarrow Ph_2PO.CHRLi + PhH$$

A number of phosphoryl compounds, phosphine oxides, phosphate esters, and phosphoramidates act as catalysts for the conversion of organic isocyanates and even isothiocyanates to carbodi-imides.[236-7,1878] The best catalysts are tertiary phosphine oxides, the most efficient of these being phospholene oxides such as 1-ethyl-3-methyl-3-phospholene-1-oxide[237,1904,1912] which is effective at a level of 0·1 part by weight of the isocyanate. The proposed catalytic process is indicated below[1878,1893]:



$$R_3PO + R'NCO \rightleftharpoons \underset{\displaystyle |\quad\ \ |\atop \displaystyle O—CO}{R_3P—NR'} \rightarrow R_3P{=}NR' + CO_2$$



$$R_3P{=}NR' + R'NCO \rightleftharpoons \underset{\displaystyle |\quad\ \ |\atop \displaystyle O—C{=}NR'}{R_3P—NR'} \rightarrow R_3PO + R'N{=}C{=}NR'$$

Tertiary phosphines and phosphine sulphides exert a similar catalytic effect and are converted during the reaction to the corresponding tertiary phosphine oxide.[236,1749,1904]

### Tertiary Phosphine Sulphides, Selenides and Tellurides

Tertiary phosphine sulphides and selenides are generally prepared by the direct addition of elemental sulphur or selenium to the corresponding tertiary phosphine under an atmosphere of nitrogen and generally in an inert solvent.[1,2,133,141,200,1779] The reaction of triarylphosphines with sulphur has been studied kinetically[132,135-7];

in benzene solution the reaction of triphenylphosphine with $S_8$ is slow and is believed to proceed by an initial nucleophilic attack by triphenylphosphine on the $S_8$ ring; the reaction rate is strongly accelerated by small amounts of phenol, methanol or acetonitrile. Other forms of sulphur, e.g., $S_2$, react very rapidly with triphenylphosphine. Triphenylphosphine is readily converted to triphenylphosphine sulphide by reaction with organic disulphides,[123, 259, 261] tetrasulphides,[260] diacoyl disulphides or bis(*O*,*O*-dialkylthiophosphoryl)disulphides; dibenzoyl disulphide is reported to be unreactive.[1]

Tertiary phosphine selenides are conveniently obtained from potassium selenocyanate and tertiary phosphine in acetonitrile solution[2334]:

$$R_3P + KSeCN \rightarrow R_3PSe + KCN$$

Few tertiary phosphine tellurides are reported; they are made by direct combination in boiling toluene solution under a nitrogen atmosphere.[140, 2349] The compounds are pale golden-yellow crystalline solids which deposit tellurium on storage:

$$RR'_2P + Te \rightarrow RR'_2PTe$$

$$(R,R' = \text{Et, Bu, Pr or cyclohexyl; if } R = \text{Ph}, R' = \text{Pr or Bu})$$

Phosphorus pentasulphide reacts with Grignard reagents giving many products; a large excess of Grignard reagent favours the formation of tertiary phosphine sulphides.[134, 1764] Thiophosphoryl chloride may be alkylated using organolithium compounds[200]:

$$3MeLi + PSCl_3 \rightarrow Me_3PS + 3LiCl$$

The aluminium halide catalysed reaction of a thiophosphoryl chloride or bromide with benzene affords a mixture of phenylphosphonothionic dihalide, diphenylphosphinothionic halide, and triphenylphosphine sulphide, the proportions of which depend on the proportions of reagents used. Unsymmetrical tertiary phosphines may be obtained by starting with the appropriate phosphonothionic dihalide or phosphinothionic halide[1749]:

$$PSCl_3 + AlCl_3 + PhH(\text{excess}) \xrightarrow[\text{reflux}]{\text{8 hours}} Ph_3PS(85\%) + Ph_2PSCl + PhPSCl_2$$
$$RPSBr_2 + AlBr_3 + PhH \rightarrow Ph_2PS.R$$
$$R_1R_2PSBr + AlBr_3 + PhH \rightarrow PhPS.R_1R_2$$

Some reactions of tertiary phosphine sulphides are shown in Chart V.

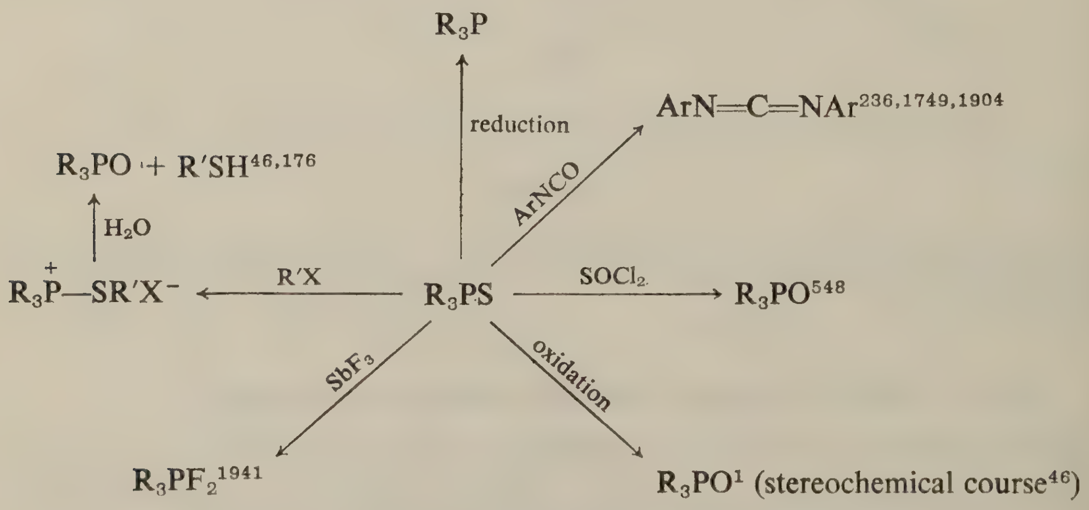


CHART V.—Reactions of tertiary phosphine sulphides

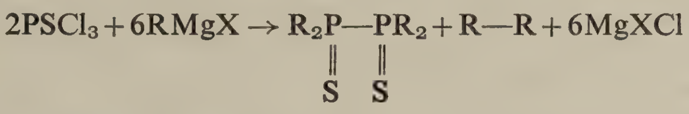
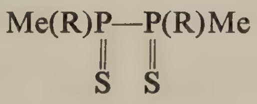
### Diphosphine Disulphides

In 1949 Kabachnik and Shepeleva[1931] showed that the reaction of thiophosphoryl chloride with methyl magnesium bromide formed, not the expected trimethylphosphine sulphide, but a new class of compound, tetramethyldiphosphine disulphide, $Me_2PS–PSMe_2$, in good yield. The generality of this reaction, which for some years was considered anomalous, has been demonstrated by several groups of workers in recent years.[25, 30, 34, 68, 323, 1885, 1903, 1933–4] Yields of up to 90% of tetra-alkyldiphosphine disulphide are reported[30] from the reaction:



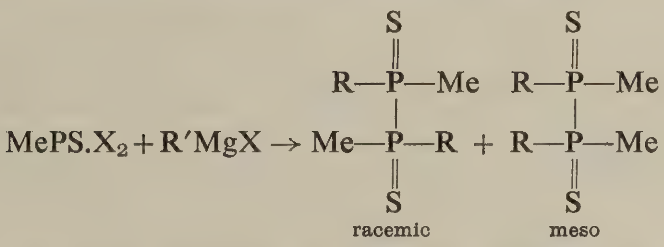
$$2PSCl_3 + 6RMgX \rightarrow \underset{\underset{S}{\|}}{R_2P}—\underset{\underset{S}{\|}}{PR_2} + R—R + 6MgXCl$$

Symmetrical disulphides of the type



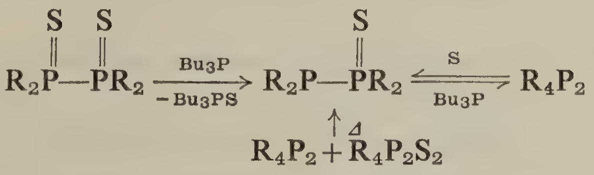
$$\underset{\underset{S}{\|}}{Me(R)P}—\underset{\underset{S}{\|}}{P(R)Me}$$

(where R = ethyl, propyl, butyl, hexyl, and benzyl) have been obtained by the action of the appropriate Grignard reagent on methylphosphorothionodihalides, and were shown to exist in both racemic and meso forms[323, 1935, 2422]:



$$MePS.X_2 + R'MgX \rightarrow \begin{array}{c} S \\ \| \\ R—P—Me \\ | \\ Me—P—R \\ \| \\ S \\ \text{racemic} \end{array} + \begin{array}{c} S \\ \| \\ R—P—Me \\ | \\ R—P—Me \\ \| \\ S \\ \text{meso} \end{array}$$

Tetra-alkyldiphosphine monosulphides have been prepared by the partial reduction of the disulphides with tributylphosphine, by partial sulphuration of tetra-alkyldiphosphine and by equilibration of a diphosphine with the corresponding diphosphine disulphide[323, 1888–9, 1937]:



$$\overset{\overset{S}{\|}}{R_2P}—\overset{\overset{S}{\|}}{PR_2} \xrightarrow[-Bu_3PS]{Bu_3P} R_2P—\overset{\overset{S}{\|}}{PR_2} \underset{Bu_3P}{\overset{S}{\rightleftharpoons}} R_4P_2$$

$$\uparrow \Delta$$

$$R_4P_2 + R_4P_2S_2$$

Tetra-alkyldiphosphine disulphides have proved to be extremely versatile intermediates for the preparation of dialkyl substituted organophosphorus compounds in good yields. Reactions are indicated in Chart VI.

Acetylenic Grignard reagents are reported to react normally with thiophosphoryl chloride to form trialkynylphosphine sulphides.[2335]

## PHOSPHONIUM COMPOUNDS

These compounds have the general formula $R_1R_2R_3R_4P^+X^-$, where $R_1$, etc., represent organic radicals bonded to the phosphorus atom by a P–C bond and X is an acid radical.

### Preparation

#### REACTION OF TERTIARY PHOSPHINES WITH ALKYL HALIDES

The simplest and most widely used method of preparing quaternary phosphonium halides is the reaction of tertiary phosphines with alkyl halides.[1, 2004] Polar solvents

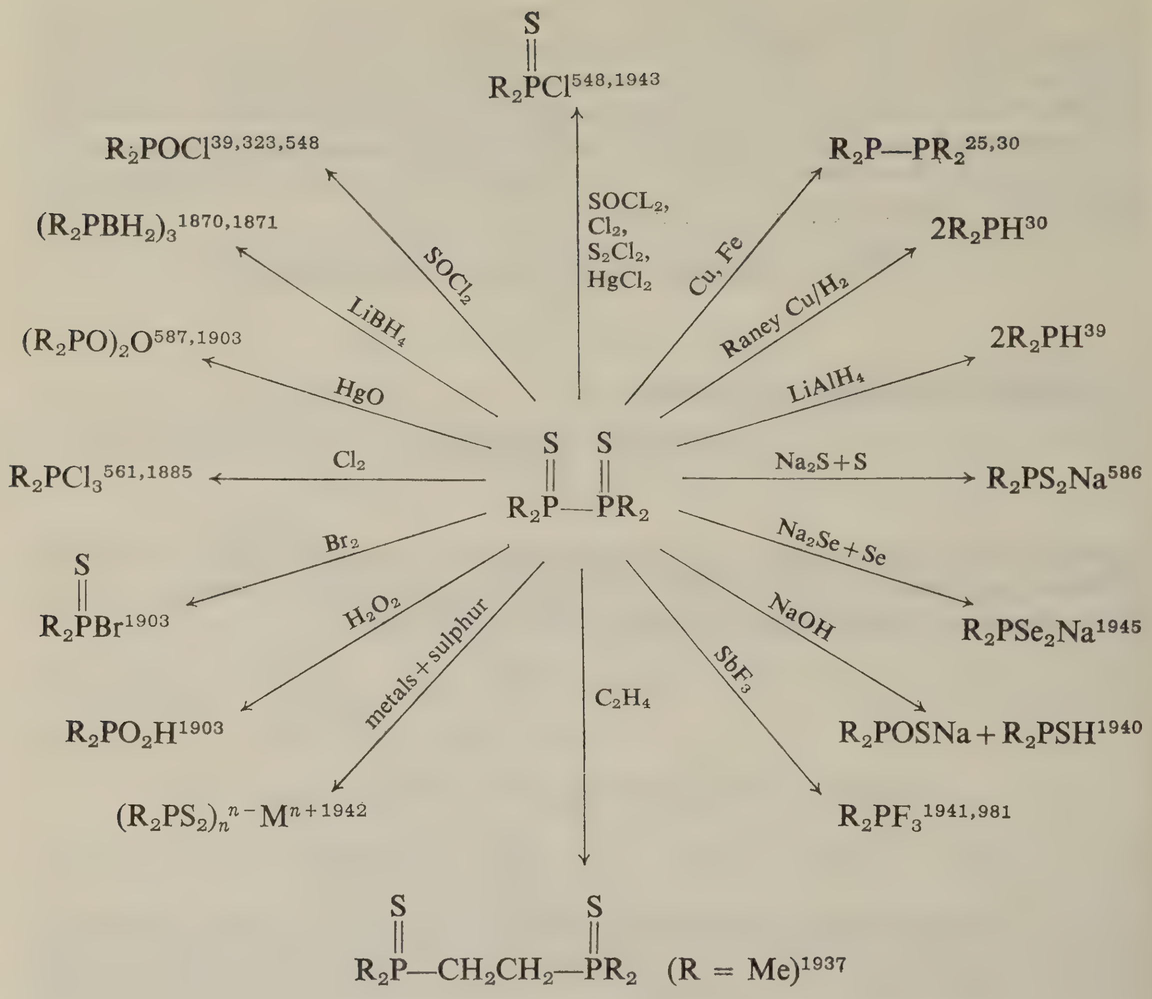


CHART VI.—Reactions of tetra-alkyl diphosphine disulphides

such as acetonitrile, formic acid and nitromethane are frequently used to facilitate reaction[41]:

$$R_1R_2R_3P + R_4X \rightarrow R_1R_2R_3R_4P^+X^-$$

Studies of the reaction show that the reaction rate decreases rather rapidly with increasing bulk of both constituents and, unlike the basicity of phosphines, is affected by steric and conjugative effects as well as by polar factors. Early work showed that in reactions of alkyl halides with phosphines of the type $ArPEt_2$ in acetone solution[1748] the reaction rates are faster, and the effect of substituents in the aryl ring is less than in the corresponding arsines and amines, $ArAsEt_2$ and $ArNEt_2$ respectively. The effect of substituents in the *para*-position of the benzene ring on the reaction rate was:

methoxy > methyl > hydrogen > phenoxy > chlorine > bromine

More recently the nucleophilic order of a number of secondary and tertiary phosphines has been determined from the kinetics of the reaction of the phosphines with ethyl iodide in acetone solution[1739]:

$$R_3P + EtI \rightarrow R_3\overset{+}{P}EtI^-$$
$$R_2PH + EtI \rightarrow R_2\overset{+}{P}HEtI^-$$

The reactions were bimolecular and the reaction rates of various phosphines decreased in the order: trialkyl > $PhPEt_2 > Ph_2PEt > (p\text{-}CH_3OC_6H_4)_3P > (alkyl)_2PH > Ph_3P > (CNCH_2CH_2)_3P$. The reaction rates in this series varied by a factor of more than $10^3$. For a number of phosphines, e.g., trialkyl-, triaryl- and arylethylphosphines, the reaction rate, $k$, could be expressed in the form of an equation:

$$\log_{10} k = a - b \sum \sigma^*$$

where $\sum \sigma^*$ is the sum of the Taft values for the substituted groups of the phosphine and $a$ and $b$ are constants. Thus, for these phosphines, the nucleophilic character, like the basicity, is determined largely by the inductive effect as measured by $\sum \sigma^*$. The reaction rates of phosphines which contain one or more methyl groups, tri-*iso*butylphosphine, and tris-(2-cyanoethyl)phosphine deviated from the above equation by amounts sufficient to indicate the operation of steric and/or conjugative effects.

The relative reactivities of various primary alkyl iodides with tri-*n*-butylphosphine in acetone are similar to those found on varying the substituent in other $S_N2$ reactions.[2007] The reactions proceed faster in polar than in non-polar solvents.[1739, 1748] Relative reaction rates of *n*-propyl halides with tri-*n*-butylphosphine are I:Br:Cl = 2660:248:1.[1739] The enthalpy and entropy of activation of tributyl- and triphenylphosphine with ethyl iodide in acetone are 12·5 ± 0·1, 14·2 ± 0·1 kcal./mole and −31 ± 1, −33 ± 1 e.u. respectively.[1739]

$\alpha$-$\omega$-Primary dihalides generally react normally with tertiary phosphines to form bis-quaternary phosphonium salts. Methylene dihalides can react anomalously (see p. 934). Quaternization of tertiary phosphines, e.g., triphenylphosphine with secondary and tertiary alkyl halides, is complicated by olefine formation.[1998] Triphenyl-*tert*-butylphosphonium chloride has been obtained by heating triphenylphosphine with an excess of *tert*-butyl chloride in formic acid at 130° under pressure.[41] When the reaction is conducted under reflux the products are triphenylphosphine hydrochloride and 2-methylpropene.[1998]

Allylic rearrangement occurs in the reaction of triphenylphosphine with 1-bromo-2-methylene*cyclo*hexyl compounds.[1997]

### THE REACTION OF PHOSPHINES WITH CARBONYL COMPOUNDS

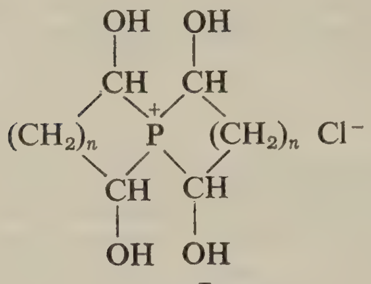
Early work in this field showed that aliphatic aldehydes and $\alpha$-chloroaldehydes condense with phosphonium iodide[1720] or with phosphine in ether solution in the presence of hydrochloric or hydrobromic acid catalyst.[1706] Crystalline tetrakis-($\alpha$-hydroxyalkyl)-phosphonium salts were isolated from the lower aliphatic aldehydes.

Phosphine[273–4, 832] and substituted phosphines[275–7, 279, 282, 1290, 1784] react in concentrated aqueous hydrochloric acid with aqueous formaldehyde to give excellent yields of hydroxymethylphosphonium chlorides:

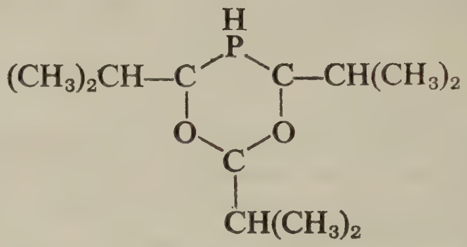
$$PH_3 + 4CH_2O + HCl \rightarrow (HOCH_2)_4\overset{+}{P}Cl^-$$
$$PhPH_2 + 3CH_2O + HCl \rightarrow Ph\overset{+}{P}(CH_2OH)_3Cl^-$$
$$Bu_2PH + 2CH_2O + HCl \rightarrow Bu_2\overset{+}{P}(CH_2OH)_2Cl^-$$
$$Ph_3P + CH_2O + HCl \rightarrow Ph_3\overset{+}{P}CH_2OHCl^-$$

Under similar conditions phosphine and *n*-alkyl aldehydes form tetrakis-($\alpha$-hydroxyalkyl)-phosphonium chlorides[1300, 2073] while dialdehydes which can form relatively stable 5- or 6-membered rings, such as succindialdehyde and glutaraldehyde, form spirocyclic phosphonium compounds **I**.[856, 1300] Secondary phosphines react with these dialdehydes giving monocyclic phosphonium salts.[575, 1034] $\alpha$-Branched aldehydes and phosphine form novel heterocyclic compounds, e.g., *iso*butyraldehyde gives

2,4,6-tri-*iso*propyl-1,3-dioxa-5-phosphine, **II**.[856, 1300] Chloral forms bis-(2,2,2-trichloro-1-hydroxyethyl)phosphine.[1300, 2124]



**I**



**II**

Benzaldehyde has been reported to react with phosphine in a mixture of concentrated hydrochloric acid and an alcohol to give tris- and bis-(α-alkoxybenzyl)phosphine.[2070, 2123–4] In concentrated hydrochloric acid solution and in organic solutions of hydrochloric acid the products are bis-(α-hydroxybenzyl)-benzylphosphine oxides[1290, 2123]:

$$3ArCHO + PH_3 \xrightarrow{H^+} (ArCHOH)_2PO.CH_2Ar$$

Phosphine and formaldehyde solution readily form trishydroxymethylphosphine in the presence of many metal salts[1284]; similar catalyzed reactions are reported for acetaldehyde, crotonaldehyde, butyraldehyde, glyoxal and chloroacetaldehyde[2119]:

$$PH_3 + 3RCHO \xrightarrow{PtCl_4} (RCHOH)_3P$$

Primary and secondary phosphines such as phenylphosphine and dibutylphosphine will form the hydroxymethyl tertiary phosphine by reaction with commercial formalin solution without added catalyst.[280, 282, 1217] At 100° phosphine, primary and secondary alkyl phosphines react with paraformaldehyde giving similar products[1268, 2318]:

$$RPH_2 \rightarrow RP(CH_2OH)_2$$
$$R_2PH \rightarrow R_2PCH_2OH$$

Kinetics and activation energies for the reaction of $PH_3$, $MePH_2$, $EtPH_2$ and MeEtPH with paraformaldehyde have been evaluated.[1237] Phosphine and aqueous formaldehyde are reported to form tetrakis-(hydroxymethyl)phosphonium hydroxide.[1257]

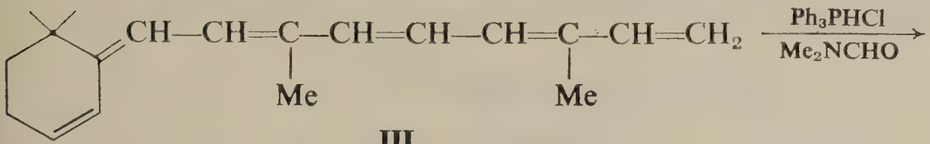
Primary phosphines and dienones react by addition of the phosphine to the C=C double bond rather than to the carbonyl group to form 4-phosphorinanones.[2072] Hexafluoroacetone and phosphine readily form $(CF_3)_2CH(OH)PH_2$ at 60° but acetone and phosphine fail to react at 100°.[2340] The reactions of phosphines with carbonyl compounds have been reviewed.[1909–10]

### ADDITION OF TERTIARY PHOSPHINES TO OLEFINS

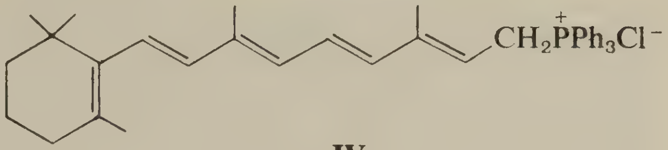
Sarnecki and Pommer[2014–5] have shown that phosphonium salts may be obtained by the action of triphenylphosphonium halides (preferably the bromide) on alcohols:

$$2Ph_3\overset{+}{P}HBr^- + HO(CH_2)_4OH \rightarrow Ph_3\overset{+}{P}(CH_2)_4\overset{+}{P}Ph_3Br_2{}^-$$

Triphenylphosphonium salts add $\alpha$–$\omega$ to conjugated olefins; for example, the hexaene **III** adds triphenylphosphonium chloride to give the phosphonium salt **IV.**[2015]

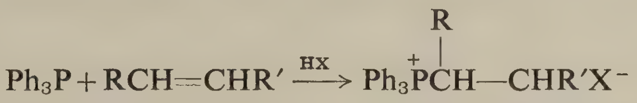


**III**



**IV**

Phosphonium salts have also been prepared by the addition of triphenylphosphine to compounds having a polarized carbon–carbon double bond[2010]:



$$Ph_3P + RCH{=}CHR' \xrightarrow{HX} Ph_3\overset{+}{P}\overset{\overset{R}{|}}{C}H{-}CHR'X^-$$

$$(R = H, Me, Ph, CO_2H, CO_2R;\ R' = CO_2H, CO_2Et, CONH_2, CN, NO_2)$$

Trishydroxymethylphosphine and acrylic acid form $\beta$-(trishydroxymethylphosphonio)propionic acid $\beta$-lactone[2017]:

$$(HOCH_2)_3P + CH_2{=}CHCO_2H \rightarrow (HOCH_2)_3\overset{+}{P}CH_2CH_2CO_2^-$$

ADDITIONS TO ALKYLIDENEPHOSPHORANES

Alkylidenephosphoranes add halogen acids to form phosphonium halides[2018, 2021] and add halogens to form $\alpha$-halogenoalkylphosphonium halides[2024, 2026–7]:

$$Ph_3P{=}CH_2 + XBr \rightarrow Ph_3\overset{+}{P}{-}CH_2XBr^- \qquad (X = H, Br)$$

Alkyl halides effect $\alpha$-carbon alkylation[2024] affording a valuable route to secondary and tertiary alkyl-substituted phosphonium salts. Thus, *iso*propyltriphenylphosphonium iodide may be converted to *tert*-butyltriphenylphosphonium iodide[2016]:

$$Ph_3\overset{+}{P}CHMe_2I^- \xrightarrow{BuLi} Ph_3P{=}CMe_2 \xrightarrow{MeI} Ph_3\overset{+}{P}CMe_3I^-$$

Acyl halides and alkylidenephosphoranes form a mixture of phosphonium salt and acylated phosphorane, the overall reaction being [2012]:

$$2Ph_3P{=}CHR + RCOCl \rightarrow Ph_3P{=}CR.CO.R + Ph_3\overset{+}{P}CH_2RCl^-$$

Many metallic and non-metallic halides (e.g., $HgBr_2$, $Me_3SiBr$, $Ph_3GeBr$, $Me_3SnBr$, $Me_2SnBr_2$, $Ph_2PBr$, $PhPBr_2$) have been shown to react with alkylidenephosphoranes forming phosphonium salts in which the respective hetero-atom is linked to phosphorus through a methylene group[2022–3, 2341, 2427]:

$$Ph_3P{=}CH_2 + Me_3SiBr \rightarrow Ph_3\overset{+}{P}CH_2SiMe_3Br^-$$

$$2Ph_3P{=}CH_2 + PhPBr_2 \rightarrow (Ph_3\overset{+}{P}CH_2)_2PPhBr_2^-$$

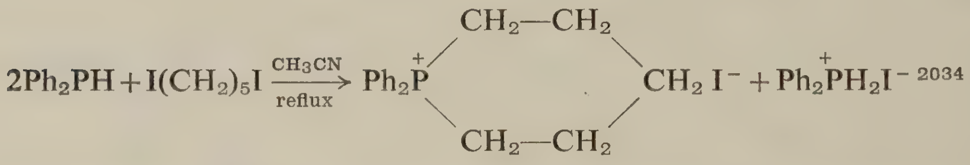
Boron compounds (hydrides, halides and triphenyl boron) give adducts which may be represented formally as zwitter-ionic phosphonium salts[2020, 2022]:

$$Ph_3P{=}CH_2 \xrightarrow{B_2H_6} Ph_3\overset{+}{P}{-}CH_2BH_3^-$$

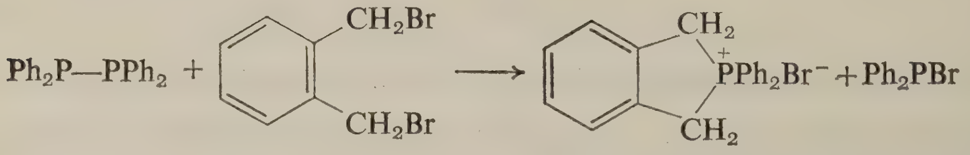
MISCELLANEOUS REACTIONS

Phosphonium salts are formed when phosphonium iodide, primary or secondary phosphines, metal phosphides, halogenophosphines and halogenophosphoranes are heated with alkyl halides:

$$EtPLi_2 + MeI \rightarrow Et\overset{+}{P}Me_3I^{-}\ ^{24}$$



Tetraphenyldiphosphine undergoes P–P bond fission when heated with alkyl halides to form a mixture of diphenylalkylphosphine, which is further alkylated to a diphenyldialkylphosphonium halide, and a diphenylphosphinyl halide.[2037] A novel route to diphenyl cyclic phosphonium salts involves reaction of the diphosphine with $\alpha$-$\delta$ dibromides such as 1,4-dibromobutene-2 and 1,2-dibromomethyl benzene.[2036]



Tertiary phosphines quaternize with the lower alkyl and benzyltoluenesulphonic esters[2029] giving phosphonium tosylates, and with triethyloxonium fluoroborate[2038] or triethoxycarbonium fluoroborate[2030] giving phosphonium fluoroborates:

$$R_3P + R'OTs \rightarrow R_3R'\overset{+}{P}OTs^{-} \qquad (Ts = p\text{-}CH_3.C_6H_4SO_2\text{–})$$
$$PhP(CH_2Cl)_2 + Et_3\overset{+}{O}BF_4^{-} \rightarrow PhEt\overset{+}{P}(CH_2Cl)_2BF_4^{-} + Et_2O$$
$$R_3P + (EtO)_3\overset{+}{C}BF_4^{-} \rightarrow EtR_3\overset{+}{P}BF_4^{-} + (EtO)_2CO \qquad (R = Et, Ph)$$

The reaction of quaternary ammonium salts of Mannich bases,[2031] and of aromatic carbonium ion salts[2030, 2342] with tertiary phosphines affords a route to many phosphonium salts which are difficult to obtain by other methods:

$$Ph_3P + RCH_2NMe_3X \rightarrow Ph_3\overset{+}{P}CH_2RX^{-} + Me_3N$$
$$Ph_3P + Ar_2\overset{+}{C}OEt.BF_4^{-} \rightarrow Ar_2C(OEt)\overset{+}{P}Ph_3.BF_4^{-} \qquad (Ar = p\text{-}MeOC_6H_4CH{=}CH\text{—})$$

Trishydroxymethylphosphine and epoxides react readily in the absence of acids to form strongly basic phosphonium hydroxides; with acids the product is a 2-hydroxyalkyltrishydroxymethylphosphonium salt.[2032] The same phosphine and *N*-methylolurea afford ureidomethyltrishydroxymethylphosphonium hydroxide which can be isolated as the picrolonate salt[2033]:

$$P(CH_2OH)_3 + NH_2CONHCH_2OH \xrightarrow{50^\circ} NH_2CONHCH_2\overset{+}{P}(CH_2OH)_3OH^{-}$$

Low yields of phosphonium salts have been obtained by the cuprous halide catalyzed decomposition of aliphatic diazonium compounds in the presence of tertiary phosphines and acids.[2035]

The conditions under which methyl chloride or methyl bromide and white phosphorus react to form high yields of tetramethylphosphonium halides have been established.[2343]

## THE REACTION OF PHOSPHINES WITH ORGANIC COMPOUNDS CONTAINING A HIGHLY REACTIVE (POSITIVE) HALOGEN ATOM

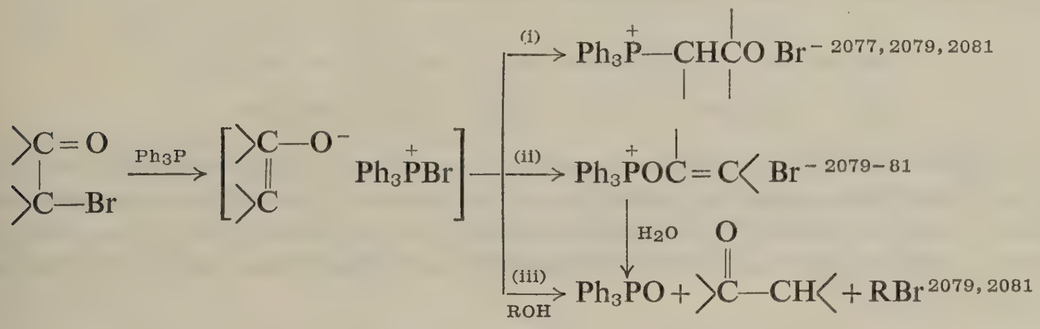
Trivalent phosphorus compounds and simple primary alkyl halides generally react by nucleophilic attack of phosphorus on carbon to form a P–C bond:

$$>P + >C—X \rightarrow >\overset{+}{P}—C< + X^-$$

In recent years a considerable amount of evidence has accumulated which indicates that with a highly reactive (positive) halogen compound the initial nucleophilic attack by phosphorus can occur on the halogen atom to form a halogenophosphonium or halogenoquasiphosphonium ion-pair intermediate which undergoes further reactions to give the ultimate reaction products (see reviews by Hoffmann & Diehr[2075] and Miller[2076]):

$$>P + X—Y \rightarrow \left[>\overset{+}{P}—X.Y^-\right] \rightarrow \text{Products}$$

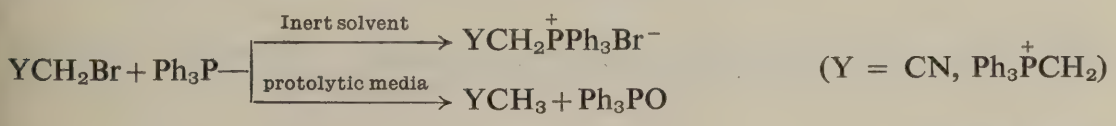
The ultimate fate of halogenophosphonium carbanion ion-pairs derived from tertiary phosphines and highly reactive (positive) halogen compounds (e.g., α-bromosulphones, α-bromonitriles, bromoacetylenes, α-bromoketones, halogenoamides and α-halogenoalkylphosphonium salts) depends on the reaction medium and the structure of the halogen compound. In inert media the ion pair can rearrange to form a normal phosphonium salt (route i) or, if the anion is mesomeric, to form an isomeric quasiphosphonium compound (route ii). In protolytic media the ultimate products are tertiary phosphine oxide and a reduced halogen compound (route iii). All three types of reaction have been observed in the reaction of triphenylphosphine with α-halogenoketones and are illustrated below:



Recombination of the intermediate phosphonium-enolate ion-pair according to either route (i) or (ii) has been shown to be determined by the frontier electron densities (cf. Fukui *et al.*[2434]) of the carbon and oxygen atoms in the enolate ion.[2083]

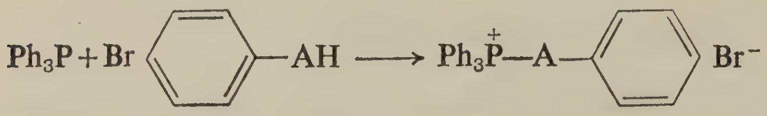
Enol phosphonium salts formed by the reaction of triphenylphosphine with chloral[2080] and α-halogenoketones such as α-bromo*cyclo*hexanone[2079, 2083] and $Ph_2CCl.CO.Ph$[2082] are extremely hygroscopic. They are rapidly decomposed by water, alcohol and protolytic reagents.

Two well-established examples of the effect of solvent on the ultimate reaction products are the reactions of bromoacetonitrile and bromoethyltriphenylphosphonium bromide with triphenylphosphine. In inert media the products are cyanomethyltriphenylphosphonium bromide[2084] and methylenebis(triphenylphosphonium) dibromide[2028] respectively. In protolytic media the solvents and products are respectively: moist chloroform, methyl cyanide[2084]; methanol, triphenylmethylphosphonium bromide,[2085] together with triphenylphosphine oxide:



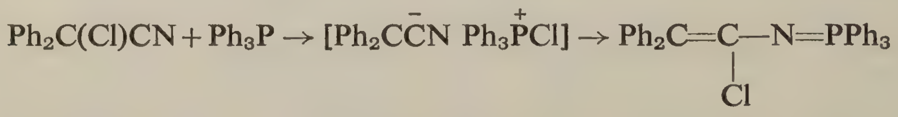
$$YCH_2Br + Ph_3P — \begin{cases} \xrightarrow{\text{Inert solvent}} YCH_2\overset{+}{P}Ph_3Br^- \\ \xrightarrow{\text{protolytic media}} YCH_3 + Ph_3PO \end{cases} \qquad (Y = CN, Ph_3\overset{+}{P}CH_2)$$

*ortho-* and *para*-Bromo-aromatic amines and phenols react with triphenylphosphine to form phosphinimidium salts (*N*-quasiphosphonium salts) and aryloxytriphenylphosphonium salts respectively.[2088] Reaction of the amines is acid-catalyzed and is inhibited by aliphatic amines.[2089]



(A = O or NH)

In the reaction of triphenylphosphine with chlorodiphenyl acetonitrile in the absence of a protic solvent the initially formed ion-pair forms a halogenovinyl phosphine imine.[2252–3] In the presence of water the products are triphenylphosphine oxide, diphenylacetonitrile and hydrogen chloride.



$$Ph_2C(Cl)CN + Ph_3P \rightarrow [Ph_2C\overset{-}{C}N\ Ph_3\overset{+}{P}Cl] \rightarrow Ph_2C{=}\underset{\displaystyle Cl}{\underset{|}{C}}{-}N{=}PPh_3$$

$$Ph_2C(Cl)CN + Ph_3P \rightarrow [Ph_2C\overset{-}{C}N\ Ph_3\overset{+}{P}Cl] \xrightarrow{H_2O} Ph_2CHCN + Ph_3PO + HCl$$

### REACTION OF POLYHALOGENOMETHANES

In inert media triphenylphosphine and methylene dibromide form the expected methylenebis(triphenylphosphonium) dibromide.[2028] The reaction with bromoform is sluggish and proceeds readily only in the presence of a free-radical catalyst to form dibromomethyltriphenylphosphonium bromides.[2019, 2079] With carbon tetrachloride and carbon tetrabromide the final products are dihalogenomethylenetriphenylphosphorane and triphenyldihalogenophosphorane[2024–5]:

$$Ph_3P + CBr_4 \rightarrow [Ph_3\overset{+}{P}Br + CBr_3^-] \rightarrow [Ph_3\overset{+}{P}{-}CBr_3]Br^-$$
$$[Ph_3\overset{+}{P}{-}CBr_3]Br^- + Ph_3P \rightarrow Ph_3P{=}CBr_2 + Ph_3PBr_2$$

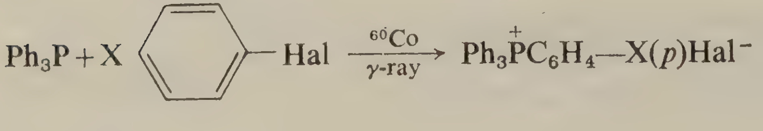
In alcoholic solution, bromoform and carbon tetrachloride afford high yields of triphenylphosphine oxide by hydrolysis of the initially formed halogenophosphonium-carbanion ion-pair.[2086] Trifluoroiodomethane and trimethylphosphine undergo a novel reaction giving tetramethylphosphonium iodide and trifluoromethyldimethylphosphine[2087]:

$$CF_3I + Me_3P \rightarrow [CF_3^-I\overset{+}{P}Me_3] \rightarrow Me_3\overset{+}{P}CF_3I^- \xrightarrow{Me_3P} Me_4\overset{+}{P}I^- + Me_2PCF_3$$

### ARYL PHOSPHONIUM COMPOUNDS

The thermally induced quaternization of triphenylphosphine with chlorobenzene and bromobenzene has not been realized. Moderate yields of tetra-arylphosphonium salts have been obtained by heating arylphosphines and aryl bromides in the presence of aluminium chloride,[1157, 2005] by ultra-violet light irradiation of mixtures of triphenylphosphine and aryl iodide in chlorobenzene solvent,[2006] and by $\gamma$-irradiation of mixtures of triphenylphosphine and aryl halides.[2337]

$$Ar_3P + ArBr \xrightarrow{AlCl_3} Ar_4\overset{+}{P}Br^- \qquad (Ar = p\text{-}/m\text{-}CH_3C_6H_4{-},\ C_6H_5)$$
$$Ph_3P + ArI \xrightarrow{uv} Ph_3\overset{+}{P}ArI^- \qquad (Ar = C_6H_5{-},\ p\text{-}HOC_6H_4{-})$$



(X = H, Cl, Br, $CH_3$)

Refs. p. 1082

Aryl polytriphenylphosphonium bromides are obtained by quaternization of di- and polyaryl bromides with triphenylphosphine in diethylene glycol diethyl ether solvent, e.g., 1,2,4,5-tetrabromobenzene gives benzene-1,2,4,5-tetrakis(triphenylphosphonium) tetrabromide.[1155, 1210]

Aromatic free-radicals, generated by the action of oxygen or cobalt chloride on Grignard reagents,[1106–7, 1071, 1113, 2339] by the decomposition of aryldiazonium salts and by the decomposition of arylnitrosodiazonium acetate,[1106, 1996] react with arylphosphines to give good yields of tetra-arylphosphonium salts:

$$\mathrm{Ph_3P + ArN_2Cl \xrightarrow[\text{buffer}]{\text{NaOAc}} Ph_3\overset{+}{P}ArCl^-}$$

$$\mathrm{Ph_3P + ArMgX \xrightarrow[\text{CoCl}_2]{\text{O}_2\text{ or}} Ph_3\overset{+}{P}ArX^-}$$

Dodonov and Medox showed that in the formation of $Ph_4PBr$ from triphenylphosphine and phenylmagnesium bromide in ether solution the yield was 13–14% in air, 72% in oxygen and only 5% in hydrogen.[1113]

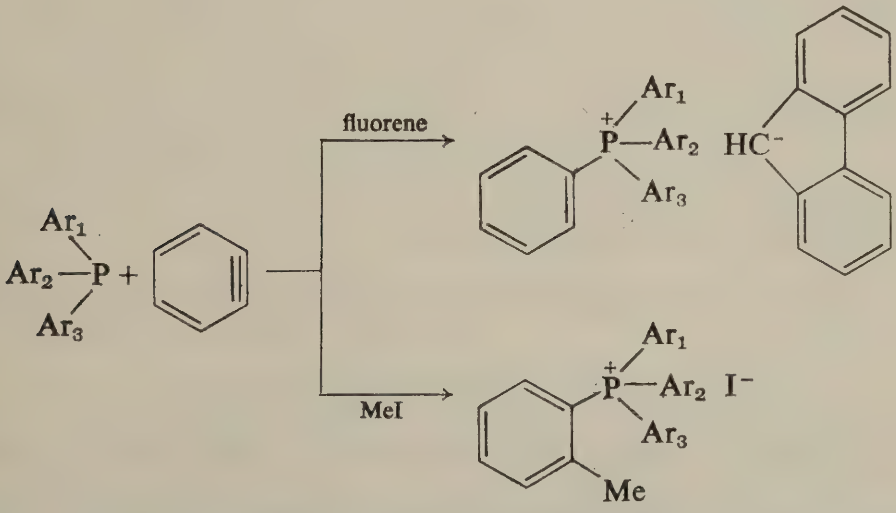
The photochemically or thermally induced reaction of diphenyliodonium chloride or borofluoride with triphenylphosphine in alcoholic media gives 40–50% yields of tetraphenylphosphonium chloride or borofluoride respectively.[2051–2, 2336]

Triarylphosphine complexes of cadmium and mercury halides, $(Ar_3P)_2MX_2$ ($M = Cd, Hg$; $X = Br, I$), react with alkyl bromides or iodides to form bis-(triarylalkylphosphonium)tetrahalogenometal compounds $[(Ar_3PR)^+]_2MX_4^{2-}$.[1754, 2428] This reaction has been extended by Horner and co-workers to the reaction of aryl halides with tertiary phosphine complexes of bromides and chlorides of $Ni^{II}$, $Co^{II}$, $Zn^{II}$, $Cu^{II}$, $Mn^{II}$ and $Fe^{II}$. The reactions are carried out in the melt or in boiling benzonitrile giving good yields of arylphosphonium salts[2338]:

$$\mathrm{2R_3P + MX_2 \xrightarrow{80^\circ} (R_3P)_2MX_2 \xrightarrow[120^\circ]{ArX} [R_3PAr]^+R_3P.MX_3^- \xrightarrow[180^\circ]{ArX} [(R_3PAr)^+]_2MX_4^{2-}}$$

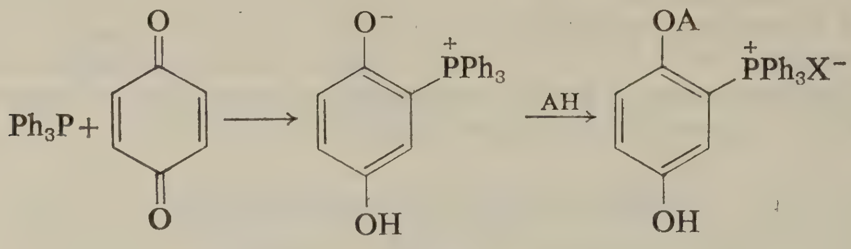
($R$ = alkyl, aryl; $X$ = Cl, Br; $M$ preferably Ni, Co)

Benzyne and triphenylphosphine give low yields of tetraphenylphosphonium salts.[298] At −40° in the presence of fluorene, arylphosphines and benzyne form tetra-arylphosphonium fluorenide from which phosphonium salts can be obtained in 67% yield by treatment with an acid. With methyl iodide[2009] or triphenyl boron[298] instead of fluorene the product is an *o*-substituted phenyltriphenylphosphonium compound:



($Ar_1 = Ar_2 = Ar_3 = Ph$; $Ar_1 = Ph$, $Ar_2 = p$-tolyl, $Ar_3 = p$-diphenyl)

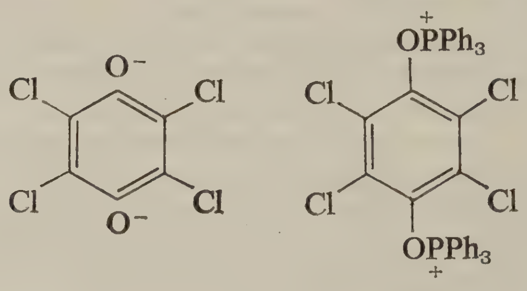
Benzoquinone and triphenylphosphine react to form the zwitter ion **V** which with hydrochloric acid or ethyl iodide may be converted to the normal phosphonium salt **VI**[182,186]:



**V** **VI**

(A = H, X = Cl; A = Et, X = I).

Chloranil reacts with difficulty to form the quasiphosphonium salt **VII**[2010]:



**VII**

## Properties of Phosphonium Compounds

Phosphonium salts, with the exception of hydroxides and alkoxides, are generally crystalline solids which dissolve in water without decomposition[1,2059] giving solutions having high electrical conductivity. They generally exhibit the properties of salts of strong bases with acids. The hydroxides and alkoxides are generally syrupy compounds which give strongly alkaline solutions.

Phosphonium compounds contain a 4-covalent tetrahedrally substituted phosphorus atom. Even so, it was not until 1947 that Mann and Holliman succeeded in resolving an asymmetric compound, the *P*-phenyl-*P*-*p*-hydroxyphenyl-*P*-*spiro*-1,2,3,4-tetrahydrophospholinium ion as its camphorsulphonate.[2060,2071] Since that time many asymmetric phosphonium salts have been resolved into their optical antipodes.[259,2042,2069] A useful review of the early attempts to resolve asymmetric phosphorus compounds is given by Mann.[2071] Reactions of optically active phosphorus compounds are reviewed by Hudson and Green,[574] and by Kamai and Usackeva.[2422] $^{31}P$ Chemical shifts in phosphonium salts are recorded.[2344]

### DECOMPOSITION OF PHOSPHONIUM HYDROXIDES

As a general rule, quaternary phosphonium hydroxides decompose when heated, either alone or in aqueous solution, to form a tertiary phosphine oxide and a hydrocarbon[141,269,271]:

$$R_1R_2R_3R_4P^+OH^- \rightarrow R_1R_2R_3PO + R_4H$$

Fenton and Ingold[269] studied the decomposition of phosphonium hydroxides of the type $R_3P^+R'OH^-$ ($R$=alkyl, phenyl; $R'$=arylalkyl, alkyl, phenyl) and from the observed order of preferential group elimination as hydrocarbon (benzyl > phenyl > methyl > 2-phenylethyl > ethyl > higher alkyl) concluded that the reaction involves the formation of an intermediate penta-covalent phosphonium hydroxide, $R_4P\text{–}OH$, which undergoes decomposition with elimination of the group having the greatest tolerance for a negative charge. This conclusion has been fully substantiated by more recent work on the decomposition of aryltriphenylphosphonium salts,[2039] alkyltriarylphosphonium salts[1956] and compounds of the type $\overset{\frown}{(\mathrm{CH_2})_n}\overset{+}{\mathrm{P}}(\mathrm{Ph})\mathrm{MeX}^-$ [2345] with strong aqueous alkali. The relative ease of elimination of aryl groups as aromatic hydrocarbons are: *o*-, *m*-, *p*-nitrophenyl > *p*-chlorophenyl > *p*-carbethoxyphenyl > *p*-diphenyl > α- and β-naphthyl > phenyl > *p*- and *m*-aminophenyl > *p*- and *m*-tolyl > *p*- and *m*-hydroxyphenyl.[2039]

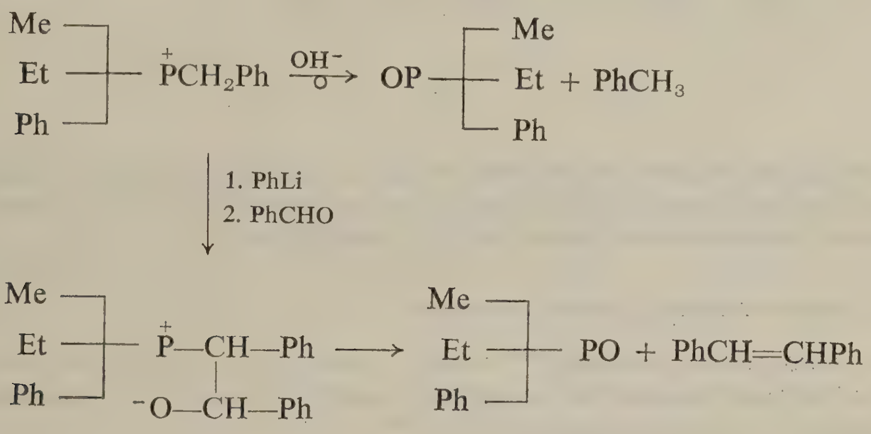
Kinetic studies of the decomposition of ethylmethylphenylbenzylphosphonium chloride[2044] and iodide[2040] and a number of *para*-substituted benzylphosphonium salts[2045] with aqueous alkali show that the reaction rates obey a third-order rate equation, $k \propto [R_4P^+][OH^-]^2$. It is generally accepted that the reaction proceeds by attack of hydroxide ion on a transient covalent adduct of the phosphonium cation and hydroxide ion[278, 2040, 2044]:

$$R_4P^+OH^- \overset{\text{fast}}{\rightleftharpoons} R_4P\text{—}OH \underset{\text{fast}}{\overset{OH^-}{\rightleftharpoons}} R_4P\text{—}O^- \xrightarrow{\text{slow}} R_3PO + R^-$$

and

$$R^- + H_2O \rightarrow RH + OH^-$$

The conversion of optically active ethylmethylphenylbenzylphosphonium chloride or iodide to ethylmethylphenylphosphine oxide with aqueous base is stereospecific and involves inversion of configuration at the phosphorus atom.[2041, 2043–4] The Wittig reaction of the phosphonium chloride with benzaldehyde to form stilbene and the same phosphine oxide is stereospecific and occurs with retention of configuration at phosphorus[2044]:



Further evidence which indicates inversion of configuration at the phosphorus atom in phosphonium salts on treatment with alkali has been advanced by Horner.[42, 44, 46]

The mechanism of the hydroxide cleavage of tetrakis(hydroxymethyl)phosphonium chloride to trishydroxymethylphosphine, formaldehyde and hydrogen has been examined.[279]

### *Exceptions to Normal Paraffinic Degradation*

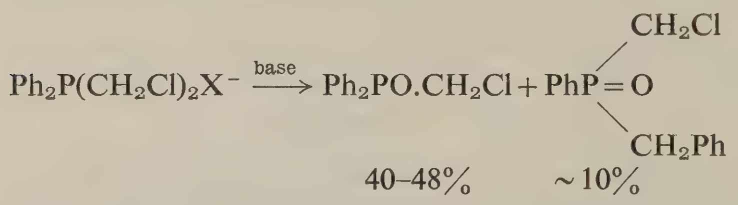
As indicated on page 896, phosphonium compounds having a 2-cyanoethyl substituent, a hydroxymethyl substituent, three or four chloromethyl substituents or a β,β-diphenylethyl substituent are decomposed by inorganic bases to form tertiary phosphine.

Tracer studies using tritium-labelled phosphonium salts of the type $R'CH_2CHR.P^+Ph_3X^-$ show that when R is a strongly electronegative substituent the compound first formed with hydroxide ion is not a pentavalent hydroxide adduct but the methylene phosphorane $R'CH_2CR{=}PPh_3$; this can form the phosphonium hydroxide and hence the tertiary phosphine oxide by addition of a water molecule:

$$R'CH_2C(R){=}PPh_3 \xrightarrow{H_2O} R'CH_2CHR.\overset{+}{P}Ph_3OH^- \rightarrow R'CH_2CH_2R + Ph_3PO$$

Compounds of the type $R_2P(CH_2Cl)_2Cl$ (R = ethyl, *cyclo*hexyl) and $Ph_3PCH_2Cl$[276, 2050] undergo normal paraffinic degradation with base to form methyl chloride and tertiary phosphine oxide, but diphenylbis(chloromethyl)phosphonium chloride gives a mixture of the expected product chloromethyldiphenylphosphine oxide and a product of rearrangement, benzylchloromethylphenylphosphine oxide.[276] Similar group migrations occur in bromomethyltriphenylphosphonium, methylmercaptomethyltriphenylphosphonium salts[2050] and phenyl tris(chloromethyl)phosphonium salts[2038]:

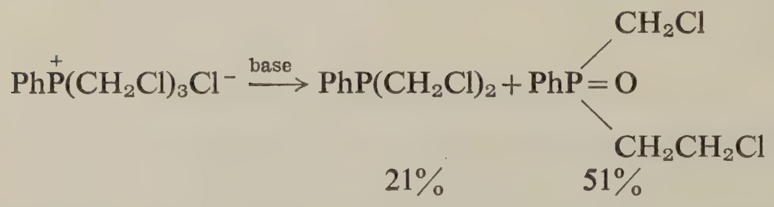
$$R_2\overset{+}{P}(CH_2Cl)_2X^- \xrightarrow{\text{base}} R_2PO.CH_2Cl + CH_3Cl \qquad (R = Et, Cy)$$



$$Ph_2P(CH_2Cl)_2X^- \xrightarrow{\text{base}} \underset{40\text{–}48\%}{Ph_2PO.CH_2Cl} + \underset{\sim 10\%}{PhP(CH_2Cl)(CH_2Ph){=}O}$$

$$Ph_3\overset{+}{P}CH_2YX^- \xrightarrow{\text{base}} Ph_3PO + Ph_2PO.CH_2Ph$$

$$17\%,\ Y = SMe$$
$$33\%,\ Y = Br$$



$$Ph\overset{+}{P}(CH_2Cl)_3Cl^- \xrightarrow{\text{base}} \underset{21\%}{PhP(CH_2Cl)_2} + \underset{51\%}{PhP(CH_2Cl)(CH_2CH_2Cl){=}O}$$

The ethynyl-substituted phosphonium compound $(C_6H_5)_2PC{\equiv}C\overset{+}{P}(C_6H_5)_2MeI^-$ is reported to undergo facile cleavage in warm water or ethanol giving diphenylmethylphosphine oxide and diphenylethynylphosphine.[94]

### DECOMPOSITION OF PHOSPHONIUM ALKOXIDES

There is no recent evidence[2016] which supports the claim that phosphonium alkoxides thermally decompose to tertiary phosphine oxide and hydrocarbon which was suggested by Hey and Ingold in 1933[268]:

$$R_4P^+OR' \xrightarrow{\Delta} R_3PO + R{-}R' \qquad (R = \text{methyl, benzyl, 2-phenylethyl})$$

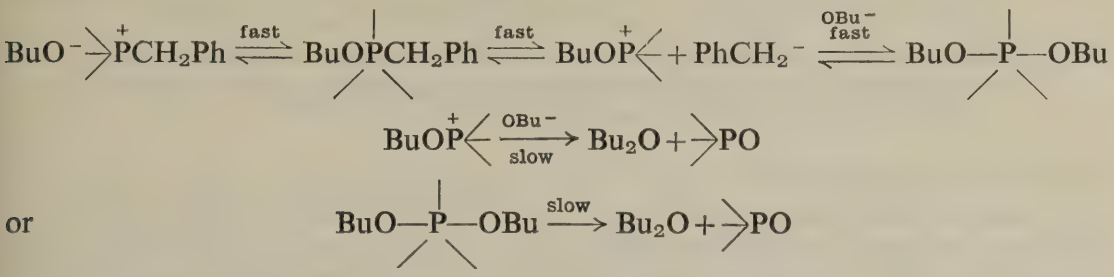
Grayson and Keough showed that benzyl-substituted phosphonium alkoxides are decomposed by heating in alcoholic solvent to tertiary phosphine oxide, a toluene and an ether[2046]:

$$R_3P^+CH_2ArX^- + NaOR \xrightarrow{ROH} R_3PO + ArCH_3 + R_2O + NaX$$

The same products are obtained by heating the corresponding methylenephosphorane with alcohol[2046]:

$$R_3P{=}CHAr + ROH \rightarrow R_3P^+CH_2ArOR^- \rightarrow R_3PO + ArCH_3 + R_2O$$

Under reflux in butanol solution optically active methylethylphenylbenzylphosphonium butoxide gives almost completely racemized methylethylphenylphosphine oxide (a slight net inversion of configuration occurs). The fact that, at room temperature, toluene is formed very much faster than dibutyl ether suggests the following reactions[2047]:



Tetra-alkyl- and phenyl-substituted phosphonium alkoxides behave differently from the benzyl compounds. Tetrabutylphosphonium butoxide shows no dissociation in butanol solution up to 200°C.[2046] With dry sodium ethoxide, tetrabutylphosphonium bromide decomposes at 240° to tributylphosphine and butene; no hexane is formed.[2016] Under similar conditions primary alkyltriphenylphosphonium salts decompose to *n*-alkyldiphenylphosphine and alkylphenyl ethers, but *iso*-propyltriphenylphosphonium iodide decomposes by the classical 'onium' route to triphenylphosphine and propene[2016, 2048]:

$$Ph_3\overset{+}{P}RX^- \xrightarrow{NaOR'} Ph_2PR + PhOR'$$

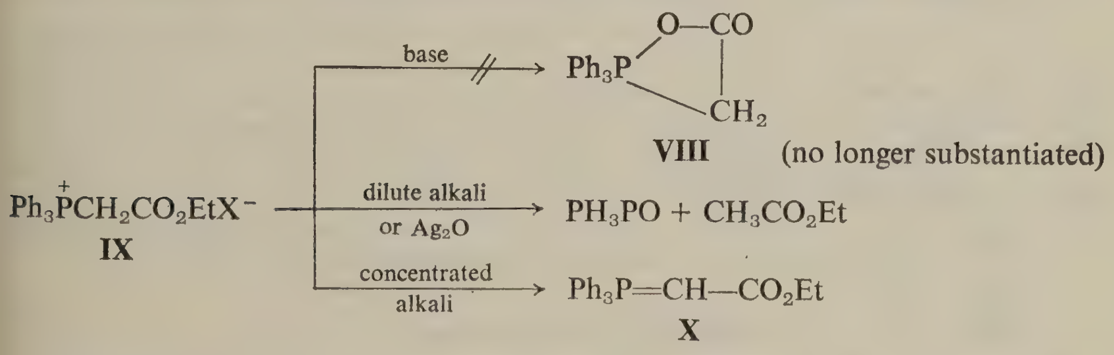
$$Ph_3P^+CHMe_3I^- \xrightarrow{NaOMe} Ph_3P + CH_3CH=CH_2$$

2-Hydroxyethyltriphenylphosphonium iodide is decomposed by alcoholic sodium alkoxide to 2-alkoxyethyldiphenylphosphine oxide and benzene; in aqueous solvents decomposition with hydroxide ion proceeds normally to give 2-hydroxyethyldiphenylphosphine oxide[2049]:

$$Ph_3\overset{+}{P}CH_2CH_2OH - \left| \begin{array}{l} \xrightarrow{RO^-/ROH} Ph_2PO.CH_2CH_2OR + PhH \\ \xrightarrow{OH^-/H_2O} Ph_2PO.CH_2CH_2OH + PhH \end{array} \right.$$

BETAINES

A number of early workers claimed the preparation of phosphonobetaines, **VIII**, by the action of alkali on phosphonoacetic ester, **IX**. More recent work shows that carbethoxymethyltriphenylphosphonium salts can react with alkali to form either a stable triphenylcarbethoxymethylene phosphorane **X** or the products of normal paraffinic degradation, depending on the concentration of the alkali used[2116–7]:



**VIII**

**IX**

**X**

Chloroacetic, $\beta$-chloropropionic and $\gamma$-chlorobutyric acids react with triphenylphosphine giving the corresponding carboxyalkyltriphenylphosphonium chlorides **XI.**[2118] The salt from chloroacetic acid undergoes decarboxylation on treatment with aqueous base; the other two salts form stable phosphonobetaines **XII**. There is no evidence that these phosphonobetaines have a pentacovalent structure.[2118] In contrast to chloroacetic acid, bromoacetic acid reacts like a typically positive halogen compound with triphenylphosphine to form the phosphine oxide and acetyl bromide.[2117-8] Triphenylphosphine and acrylic acid form triphenylphosphinopropionic betaine.[2346]

$$\underset{\textbf{XI}}{Ph_3\overset{+}{P}(CH_2)_nCO_2HCl^-} \xrightarrow[\text{aq}]{\text{NaOH}} \underset{\textbf{XII}}{Ph_3\overset{+}{P}(CH_2)_nCO_2^-} \qquad (n = 2, 3)$$

$$Ph_3P + BrCH_2CO_2H \xrightarrow[\text{no solvent}]{\text{benzene or}} Ph_3PO + CH_3COBr$$

MESOMERIC PHOSPHONIUM SALTS

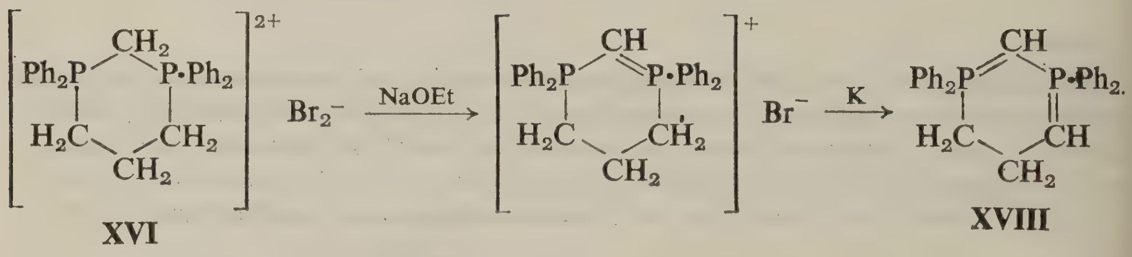
The reaction of triphenylphosphine and methylene dibromide to form methylenebistriphenylphosphonium dibromide[2028] led to the discovery of stable salts containing the stable triphenylphosphoniummethylenetriphenylphosphorane cation **XIII**.[2114] This cation is mesomeric as evidenced by a single $^{31}P$ n.m.r. absorption peak. Treatment with potassium gives the novel phosphorane hexaphenylcarbodiphosphorane **XIV** which reacts with hydrochloric acid to reform the mesomeric phosphonium salt and with bromine to form triphenylphosphoniumbromomethylenetriphenylphosphorane **XV**:

$$Ph_3\overset{+}{P}CH_2\overset{+}{P}Ph_3Br_2^- \xrightarrow{Na_2CO_3} \underset{\textbf{XIII}}{[Ph_3P\text{—}CH{=}PPh_3]^+Br^-} \xrightarrow[\text{diglyme}]{K} \underset{\textbf{XIV}}{Ph_3P{=}C{=}PPh_3}$$

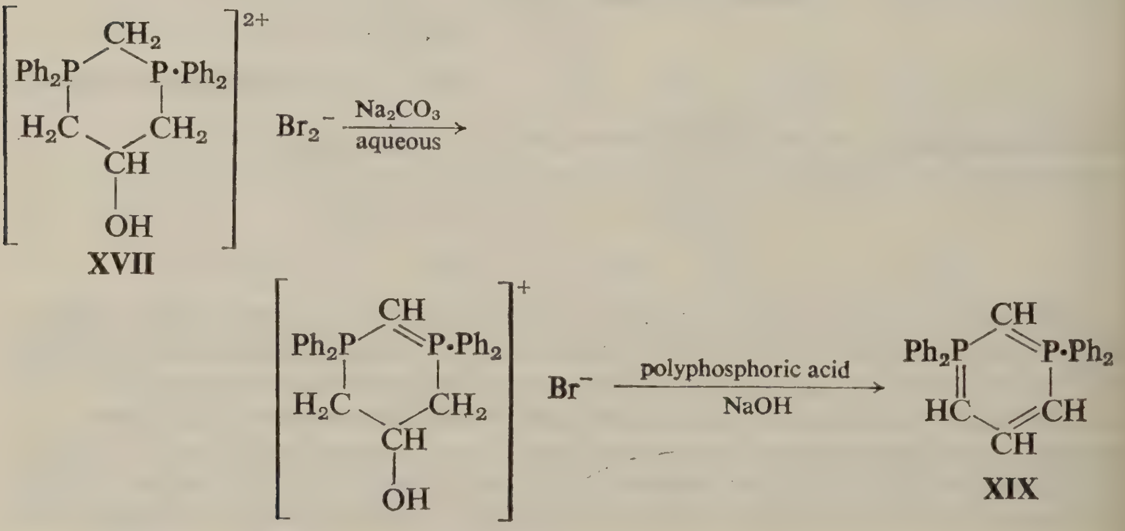
$$\downarrow Br_2$$

$$\underset{\textbf{XV}}{[Ph_3P\text{—}CBr{=}PPh_3]^+Br^-}$$

Similar mesomeric phosphonium compounds have been obtained from 1,1,3,3-tetraphenyl-1,3-diphosphonia*cyclo*hexane dibromide **XVI** and 1,1,3,3-tetraphenyl-1,3-diphosphonia-5-hydroxy*cyclo*hexane dibromide **XVII** which are themselves converted by base to yellow amorphous cyclic phosphoranes, 1,1,3,3-tetraphenyl-1,3-diphospha-4,5-dihydro*cyclo*hexane **XVIII** and 1,1,3,3-tetraphenyl-1,3-diphosphabenzene **XIX** respectively.[2115]



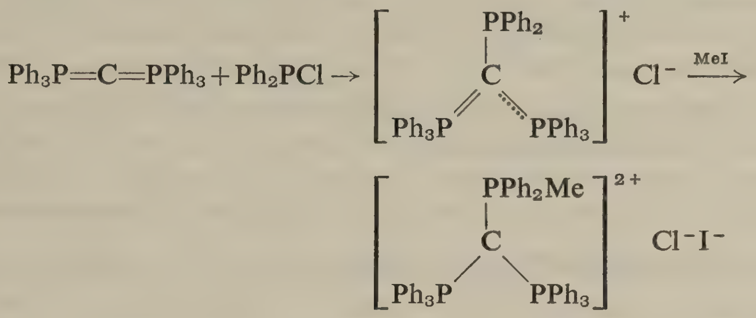
**XVI** **XVIII**



**XVII** **XIX**

1,1-Diphenyl-1-phosphabenzene,[2093] a yellow powder and 1,1-diphenylphosphanaphthalene[2095] have been obtained by similar routes by Märkl who has reviewed the chemistry of heterocyclic compounds of phosphorus.[2092] Heterocyclic phosphonium salts have been obtained by a number of workers.[218, 272, 2000, 2008]

A novel mesomeric phosphonium salt having three phosphorus atoms attached to one carbon atom is obtained from methylene bistriphenyl phosphorane[2347]:



### Applications of Phosphonium Compounds

The phosphonium salts have attained little commercial importance. The only compound which is at present produced in commercial quantities is tetrakishydroxymethylphosphonium chloride which is used in the flameproofing of cellulosic fibres. Compounds such as 3,4-dichlorobenzyltriphenylphosphonium chloride are substantive to wool and have been used as moth-proofing agents.[2091] Compounds of the type $R\overset{+}{P}Me_3X^-$ (where R is a long-chain alkyl group and X is a halogen), like the analogous nitrogen compounds, exhibit disinfectant properties.[2110] Tetrabutylphosphonium hydroxide has been used as a catalyst to bring about rearrangement and polymerization of siloxanes.[2125] Diquaternary phosphonium salts derived from tris(2,4,6-trimethoxyphenyl)phosphine are reported to show a high order of activity against influenza virus *in vitro*.[99] The antimyotic action of triphenyldecylphosphonium pentachlorophenoxide is more powerful than that of pentachlorophenol alone.[2128] Tetraphenylphosphonium chloride forms insoluble crystalline salts with the following anions: $BF_4^-$, $MnO_4^-$, $ReO_4^-$, $TeO_4^-$, $ClO_4^-$, $IO_4^-$ and the chloride complexes of a number of multiply charged metals; it has found some application in analytical chemistry.[2126] Benzyltriphenylphosphonium chloride has been used for the determination and extraction of rhenium.[2127]

## QUASIPHOSPHONIUM COMPOUNDS

Widely occurring in organophosphorus chemistry are four-covalent positively charged phosphorus compounds in which one or more of the atoms attached to phosphorus is oxygen, nitrogen, sulphur or halogen. Probably the only true phosphonium compounds in this class, i.e., those having an anion which is essentially ionic and metathetically replaceable in aqueous solution, are the *N*-quasi and *S*-quasi compounds. *O*-Quasiphosphonium salts and halogenophosphonium compounds are unstable to water, and are frequently formed as intermediates in the reactions of trivalent phosphorus compounds.[2075–6]

The first water-stable *O*-quasiphosphonium salt was isolated recently.[2351]

### *N*-Quasiphosphonium Compounds

PREPARATION

*From Phosphorous Amides*

Nitrogen analogues of the tertiary phosphines, i.e., phosphorous amides, $(R_2N)_3P$, phosphonous amides, $R'P(NR_2)_2$, and phosphinous amides, $R'_2PNR_2$, react readily with alkyl halides to form salt-like *N*-quasiphosphonium salts:

$$R'_2PNR_2 + R''X \rightarrow R'_2R''\overset{+}{P}NR_2X^- \qquad (R' = \text{alkyl, aryl, } NR_2)$$

Following the early work of Michaelis who demonstrated the quaternization of phosphorous tripiperidide,[2090] phosphorous tri-tetrahydroquinolide[446] and arylphosphonous dipiperidide[446] with alkyl and benzyl halides, a considerable number of *N*-quasiphosphonium compounds have been prepared by this route.[295,306,384,434,436,539,588,767,2094,2096]

The location of the methyl group on phosphorus in methylphenylbisdiethylaminophosphonium iodide, prepared from phenylphosphonous bisdiethylamide and methyl iodide, has been established by nuclear magnetic resonance.[384] Bis-(diphenylphosphino)methylamine, $(Ph_2P)_2NMe$, and methyl iodide form a monomethiodide shown by infra-red spectroscopy to be the phosphonium salt $Ph_2P.NMe.\overset{+}{P}Ph_2MeI^-$.[588] Halogens react with trisdimethylaminophosphine in inert solvents to form trisdimethylaminohalogenophosphonium halides. The salt-like character of these compounds has been demonstrated by conductimetric measurements in nitrobenzene, by the infra-red spectrum of the cation $(Me_2N)_3\overset{+}{P}Cl$ and by the preparation of complex salts such as $(Me_2N)_3\overset{+}{P}ClY^-$ (where $Y^- = NO_3^-, FeCl_4^-, BPh_4^-$).[2096] Solid compounds with well-defined melting points which may be regarded as *N,N,N,S*-quasiphosphonium halides are formed from hexa-*N*-alkylphosphorous triamides and alkyl/arylsulphenyl chlorides[2120] or by alkylation of phosphorotriamidothionates with *n*-alkyl iodides[2122]:

$$(R_2N)_3P + R'SCl \rightarrow (R_2N)_3P—SR'Cl$$
$$(RNH)_3PS + R'I \rightarrow (RNH)_3P—SR'I$$

Phenyl dimethylaminotrifluorophosphorane is reported to undergo rearrangement to phenylbis(dimethylamino)fluorophosphonium phenylpentafluorophosphate when allowed to stand at room temperature for several weeks. The anion represents one of the few hexa-coordinated species of phosphorus which have been reported.[1999]

### *From Halogenophosphoranes and Phosphorus Pentachloride*

*N*-Aryl substituted quasiphosphonium chlorides are formed by heating phosphorus pentachloride[2097-8] or aryl tetrachlorophosphoranes[2099] with primary aromatic amines:

$$PhPCl_4 + PhNH_2(\text{excess}) \rightarrow Ph\overset{+}{P}(NHPh)_3Cl^-$$

Alkylamino and dialkylaminotriphenylphosphonium salts are readily obtained from triphenyldihalogenophosphoranes and primary or secondary amines[2100-1]:

$$Ph_3PX_2 + RNH_2 \xrightarrow{Et_3N} Ph_3\overset{+}{P}NHRX^-$$

With phenylhydrazine the product is a triphenylphenylhydrazinophosphonium halide.

### *From Iminophosphoranes (Phosphine Imines)*

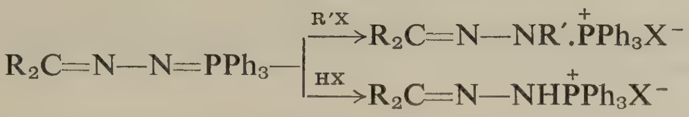
Iminophosphoranes may be regarded as the conjugate bases of *N*-quasiphosphonium salts, the relationship being formally similar to that between normal phosphonium salts and the methylenephosphoranes:

$$R_3P = NR' \underset{-HX}{\overset{+HX}{\rightleftharpoons}} R_3\overset{+}{P}—NHR'X^-$$

They have basic character,[110,2108] readily add hydrogen halides and react with alkyl halides to form the *N*-quasiphosphonium salts.[11,2100] Alkylaminotriphenylphosphonium salts have been converted to dialkylaminotriphenylphosphonium salts *via* the iminophosphorane:

$$Ph_3\overset{+}{P}NHRBr^- \xrightarrow[NH_3]{NaNH_2} Ph_3P{=}NR \xrightarrow{MeI} Ph_3\overset{+}{P}NRMeI^-$$

Phosphazines,[177] e.g., formaldehyde triphenylphosphazine $CH_2{=}N{-}N{=}PPh_3$, are alkylated by alkyl halides to form $N^{\beta}$-alkylidene-$N^{\alpha}$-alkylhydrazinotriphenylphosphonium salts; hydrogen halides give the $N^{\beta}$-alkylidenehydrazinophosphonium salts[2102]:



$$R_2C{=}N{-}N{=}PPh_3 \xrightarrow{R'X} R_2C{=}N{-}NR'.\overset{+}{P}Ph_3X^-$$
$$R_2C{=}N{-}N{=}PPh_3 \xrightarrow{HX} R_2C{=}N{-}NH\overset{+}{P}Ph_3X^-$$

In contrast the reaction of $\alpha$-ketophosphazines, $RCOCH{=}N{-}N{=}PPh_3$, with methyl iodide involves P–N bond fission to form a diazoketone and a normal phosphonium salt.[2103]

*From Tertiary Phosphines*

Tertiary phosphines react with solutions of chloramine forming aminophosphonium salts:

$$R_3P + ClNH_2 \rightarrow R_3\overset{+}{P}NH_2Cl^- \qquad (R = \text{alkyl, aryl, benzyl, 2-cyanoethyl})$$

The reactions proceed almost quantitatively based on the quantity of chloramine or phosphine consumed. Stable aminophosphonium salts such as the chloroplatinate, picrate, periodate and nitroprusside may be obtained from the chloride by double decomposition reactions.[2104-5, 2162] *N*-Substituted aminophosphonium salts are obtained using chloramines such as *N*-methylchloramine,[2104] *N*-benzylchloramine[2121] and *N*-chlorourea.[2161] Aminophosphines $(R_2N)_3P$, $(R_2N)_2PR'$, $R_2NPR'_2$, $RN(PPh_2)_2$ (where R = methyl, ethyl, R′ = methyl, butyl, phenyl) and hydrazinophosphines $RP(NHNMe_2)_2$ (where R = methyl, phenyl) react like tertiary phosphines with chloramine to form the corresponding aminosubstituted phosphonium salts.[2162, 2348, 2350] Triphenylaminophosphonium hydrogen sulphate can be prepared from triphenylphosphine and hydroxylamine-*O*-sulphonic acid.[2107]

The reaction of triphenylphosphine and hydrazoic acid was investigated by Staudinger and Hauser[110] who formulated the product as $Ph_3P{=}NH.N_3H$; recent work indicates the product to be triphenylaminophosphonium azide.[2106, 2109]

Salts of mesomerically stabilized bistriphenylphosphine nitride cation have been obtained by reaction of triphenylphosphine imine (iminotriphenylphosphorane) with dibromotriphenylphosphorane[2108] and by pyrolysis of triphenylaminophosphonium azide[2109]:

$$Ph_3P{=}NH + Ph_3PBr_2 \rightarrow [Ph_3P{=}N{-}P.Ph_3]^+Br^- + Ph_3\overset{+}{P}NH_2Br^-$$
$$Ph_3\overset{+}{P}NH_2N_3^- \rightarrow [Ph_3P{=}N{-}P.Ph_3]^+N_3^-$$

### GENERAL PROPERTIES OF *N*-QUASIPHOSPHONIUM COMPOUNDS

These compounds are frequently crystalline solids and are soluble in water without decomposition. Like the phosphonium salts, they undergo decomposition in hot alkaline solution to form an amine and a phosphoryl compound.[110, 903, 943, 2101]

$$R_3\overset{+}{P}NR'_2X^- \xrightarrow{H_2O/NaOH} R_3PO + R'_2NH$$
$$(R = \text{alkyl, aryl, } NR'_2;\ R' = \text{H, alkyl, aryl})$$

Hydroxides of tetra-(*N*-arylamino)phosphonium salts are reported to be syrupy neutral substances.[2099]

*N*-Quasiphosphonium compounds derived from hexa-*N*-substituted phosphorous triamide[295, 434] or tetra-*N*-substituted phenylphosphonous diamide[436] and methyl or benzyl halides undergo the Wittig reaction:

$$(R_2N)_2R'\overset{+}{P}CH_2Ph \xrightarrow[PhCHO]{NaOMe} (R_2N)_2R'PO + PhCH{=}CHPh \qquad (R' = \text{Ph or } R_2N)$$

*N*-Phenylaminotriphenylphosphonium chloride is readily decomposed by electrolysis to triphenylphosphine and aniline[2013]:

$$\mathrm{Ph_3\overset{+}{P}NHPhCl^- \rightarrow Ph_3P + PhNH_2 + HX}$$

Compounds such as di-(*tert*-butylamino)methylphenylphosphonium iodide are claimed to be fungicides.[306]

## *O*-Quasiphosphonium Compounds

Aryl esters of phosphorous,[813, 903, 916] phosphonous[421] and phosphinous[421, 920] acids react readily with alkyl halides such as methyl iodide or benzyl chloride to form *O*-quasiphosphonium compounds of the type $\mathrm{(ArO)_3\overset{+}{P}RX^-}$, $\mathrm{(ArO)_2\overset{+}{P}RR'X^-}$ and $\mathrm{ArO\overset{+}{P}RR'_2X^-}$ respectively. These compounds are readily hydrolyzed by water or dilute alkali to give a phosphoryl compound and a phenol.[421, 813, 916, 943] They react with alcohols to form the corresponding alkyl halide.[813, 2111] Thermal decomposition of the *O*-phenyl compounds at about 300° gives iodobenzene.[421] Reduction of methyltriphenoxyphosphonium iodide gives disodiummethylphosphine[36]:

$$\begin{array}{r}\mathrm{(PhO)_2PO.Me + PhI} \xleftarrow{\Delta} \\ \mathrm{MePNa_2} \xleftarrow{\mathrm{Na}}\end{array}\left|\mathrm{—(PhO)_3PMeI—}\right|\begin{array}{l}\xrightarrow{\mathrm{H_2O}} \mathrm{(PhO)_2PO.Me + PhOH + HI} \\ \xrightarrow{\mathrm{ROH}} \mathrm{(PhO)_2PO.Me + PhOH + RI}\end{array}$$

The reaction of triphenoxymethylphosphonium iodide with silver nitrate in alcoholic solution is reported to be slow.[813] With silver acetate or silver nitrate in acetonitrile solution there is an immediate precipitate of silver iodide, the reaction products being diphenyl methylphosphonate together with phenyl acetate or a mixture of *o*- and *p*-nitrophenols respectively. Under similar conditions but with silver nitrate and an alcohol an alkylphenylmethylphosphonate results[2112-3]:

$$\mathrm{MeP(OPh)_3I \xrightarrow[(AgNO_3)]{AgOAc} (PhO)_2PO.Me + AgI + PhOAc(HOC_6H_4NO_2)}$$

2,2,2-Triphenylethanol and tributyldibromophosphorane form 2,2,2-triphenylethoxytributylphosphonium bromide which, in contrast to other alkoxyphosphonium compounds,[920] is stable to water.[2351]

*O*-Quasiphosphonium fluoroborates having alkoxy and aryloxy substituents have been obtained by reaction of tertiary phosphites with oxonium and carbonium ion fluoroborates such as triethyloxonium fluoroborate and triphenylcarbonium fluoroborate. Ethyltriethyloxyphosphonium fluoroborate is readily decomposed by alcoholic alkoxide solution to form diethyl ethylphosphonate and an ether[921-2]:

$$\mathrm{(EtO)_3P + Et_3O^+BF_4^- \rightarrow (EtO)_3\overset{+}{P}EtBF_4^- + Et_2O}$$
$$\mathrm{(EtO)_3\overset{+}{P}EtBF_4^- \xrightarrow[PrO^-]{PrOH} EtPO(OEt)_2 + PrOEt}$$

*N*-Quasiphosphonium fluoroborates are obtained similarly using trisdialkylaminophosphines or by displacement of triphenyl phosphite from triphenylmethyltriphenoxyphosphonium fluoroborate.[921-2]

$$\mathrm{Ph_3C\overset{+}{P}(OPh)_3BF_4^- + (Me_2N)_3P \rightarrow Ph_3C\overset{+}{P}(NMe_2)_4BF_4^- + (PhO)_3P}$$

*O*-Aryl and *S*-aryl triphenylphosphonium bromides are obtained from triphenyldibromophosphorane and a phenol or mercaptan[1987]:

$$\mathrm{Ph_3PBr_2 + ArXH \xrightarrow{Et_3N} Ph_3\overset{+}{P}XArBr^-} \qquad (\mathrm{X = O, S})$$

### *S*-Quasiphosphonium Salts

Trialkylthioalkylphosphonium iodides result from the alkylation of trialkylphosphine sulphides with alkyl iodides.[176] They behave as normal dissociated salts in aqueous solution. Hydrolysis takes place slowly in hot water giving mercaptan and trialkylphosphine oxide; in alkaline solution hydrolysis is rapid giving the phosphine oxide with a predominant inversion of configuration[46]:

$$Et_3PS + MeI \rightarrow Et_3\overset{+}{P}SMeI^- \xrightarrow{H_2O} Et_3PO + MeSH + HI$$

## METHYLENEPHOSPHORANES

Methylenephosphoranes, **II**, are formed by the elimination of hydrogen halide from phosphonium compounds, **I**, having an $\alpha$-hydrogen atom. They add hydrogen halide, reforming the phosphonium salt. Bestmann considers that phosphonium salts can be regarded as Brønsted acids, and the alkylidenephosphoranes as their conjugate bases.[2011, 2129] The methylenephosphoranes themselves are best represented as resonance hybrids of contributing structures such as **II** and **III**:

$$\begin{array}{ccccc} R_3\overset{+}{P}CHR_1R_2X^- & \underset{+HX}{\overset{-HX}{\rightleftharpoons}} & R_3P{=}CR_1R_2 & \leftrightarrow & R_3\overset{+}{P}\overset{-}{C}HR_1R_2 \\ \textbf{I} & & \textbf{II} & & \textbf{III} \end{array}$$

The stability and reactivity of methylenephosphoranes vary widely, depending on the substituents attached to the phosphorus atom and to the $\alpha$-carbon atom. Generally the compounds may be isolated as red or yellow crystalline solids. The alkylidenetriphenylphosphoranes are highly reactive; they react with oxygen, hydrogen halides, water, alcohols and carbonyl compounds. Arylidenetriphenylphosphoranes are somewhat less reactive and the diarylidene compounds are stable to oxygen and carbonyl compounds but react with water and alcohols. In extreme cases the compounds may be prepared in aqueous solution and show remarkable stability.

Electron-attracting groups attached to the $\alpha$-carbon atom increase the acidity of the phosphonium salt and decrease the reactivity of the corresponding phosphorane. Thus, alkylidenetriphenylphosphoranes are difficult to isolate and can be prepared only by the action of bases such as phenyl lithium and butyl lithium in inert media on the appropriate phosphonium salts. On the other hand dilute aqueous base is sufficient to convert triphenyl-9-fluorenylphosphonium bromide,[2133] triphenyl-*cyclo*pentadienyl bromide,[2134] triphenyl-*p*-nitrobenzylphosphonium bromide[2135] and compounds of the type $Ph_3\overset{+}{P}CH_2YX^-$ ($Y = CN, COR, CO_2R$)[2116, 2131] to the corresponding phosphoranes.

Electron-attracting groups attached to phosphorus facilitate formation of the phosphorane from the phosphonium salt but increase the reactivity of the phosphorane to reagents such as water. Thus, in compounds $R_3PCH_2CO_2CH_3$, when $R = Ph$, deprotonation can be effected by dilute sodium carbonate solution[2129] but when R = *cyclo*hexyl, dilute sodium hydroxide is required.[2130] The *cyclo*hexyl compound is decomposed by cold water whereas the phenyl compound decomposes only on boiling.

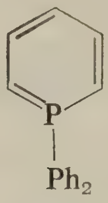
Transylidation reactions, e.g.,

$$Ph_3P{=}CH_2 + Ph_3\overset{+}{P}CH_2COR \rightleftharpoons Ph_3\overset{+}{P}CH_3 + Ph_3P{=}CHCOR$$

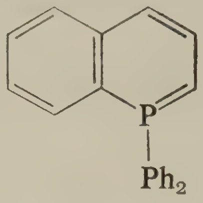
afford a useful method of comparing the strength of mesomeric and inductive effects of substituents on the acidity of the hydrogen atoms of the methylene group adjacent to phosphorus and on the basicity of the phosphorane. The acidity of the hydrogen atoms decreases in the series, substituent $= C_6H_5CO > CH_3CO_2 > C_6H_5 >$ alkyl.[2129]

Particularly interesting examples of stable phosphoranes are compounds such as

IV and V. These possess definite aromatic character, do not react with carbonyl compounds and are relatively stable to hydrolysis[2093, 2095]:



**IV**



**V**

## Preparation of Alkylidenephosphoranes

The first alkylidenephosphorane, diphenylmethylenetriphenylphosphorane, was made by Staudinger and Meyer[177] in 1919 by the thermal decomposition of the phosphazine obtained from triphenylphosphine and diphenylketen:

$$Ph_3P + Ph_2CN_2 \rightarrow Ph_3P{-}N{=}N{=}CPh_2 \xrightarrow{\Delta} Ph_3P{=}CPh_2 + N_2$$

In 1924 Isler[2136] obtained the same compound by treating the corresponding phosphonium compound with potassium:

$$Ph_3\overset{+}{P}CHPh_2Br^- \xrightarrow[-KBr]{K} Ph_3P{=}CPh_2$$

Of particular interest is the early work which showed that the above phosphorane would react with phenylisocyanate[177] or with diphenylketene[2137] giving diphenylketene isocyanate and tetraphenylallene respectively, together with triphenylphosphine oxide.

The potentialities of these reactions lay dormant for some 30 years until 1953 when Wittig and co-workers[5, 125, 2140] showed that triphenylalkylidenephosphoranes, formed by the action of bases such as phenyl lithium on $Ph_3\overset{+}{P}CH_2RX^-$, would react with aldehydes and ketones to form an intermediate betaine which decomposed to triphenylphosphine oxide and an olefin:

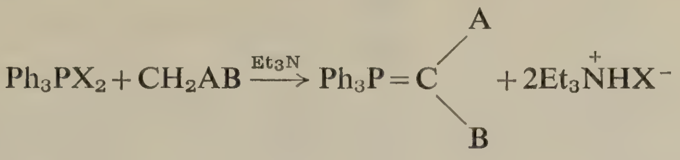
$$Ph_3P{=}CR_1R_2 + R_3R_4CO \rightarrow [\text{complex}] \rightarrow Ph_3PO + R_1R_2C{=}CR_3R_4$$

Wittig's work provided the stimulus to a considerable number of investigations and over the last 10 years there is little doubt that more papers have been published on the Wittig and related reactions than on any other branch of organophosphorus chemistry. A number of reviews of this work are available.[1998, 2004, 2011–3, 2138, 2143–6, 2158]

The most important method of preparation is by the action of suitable bases on alkylphosphonium salts:

$$R_3\overset{+}{P}CH_2R'X^- \xrightarrow[-BH]{B} R_3P{=}CHR'$$

As indicated earlier the strength of the base required depends on the acidity of the $\alpha$-hydrogen atom and can vary from aqueous sodium carbonate for compounds such as $(Ph_3\overset{+}{P})_2CH_2\,Br_2^-$ [2128] to alkali metals in non-polar solvents for compounds such as $Ph_3\overset{+}{P}CH_3Br^-$. Methods of lesser importance are the reaction of carbenes with triphenylphosphine to form halogenomethylenetriphenylphosphoranes,[2021] the formation of triphenylmethylenephosphorane by the reaction of diphenylmethylphosphine with benzyne[2148] or with diazomethane in the presence of copper,[2035] the reaction of triphenylphosphine with carbon tetrahalides to give compounds of the type $Ph_3P{=}CX_2$,[2024–5] and the formation of stable phosphoranes of the type $Ph_3P{=}CAB$ (A, B = CN, $CO_2R$, COR, $PhSO_2$, etc.) from triphenyldihalogenophosphoranes and active methylene compounds[582, 1000]:



$$Ph_3PX_2 + CH_2AB \xrightarrow{Et_3N} Ph_3P{=}C\begin{matrix}A\\ \\B\end{matrix} + 2Et_3\overset{+}{N}HX^-$$

### Reactions of Methylenephosphoranes

The importance of alkylidenephosphoranes stems from their use as intermediates for the preparation of a wide variety of organic compounds which may be obtained in high yield and purity by single-stage condensation reactions. Many of these compounds can be prepared in but poor yield by multi-stage classical organic chemical methods. Outstanding examples of the use of alkylidenephosphoranes as synthetic intermediates are in the following fields: naturally occurring polyenes and polyenic acids, Vitamin D, Vitamin A and carotenoids, *cyclo*propanes and acetylene derivatives. General reactions of phosphine methylenes are set out in Chart VII and on pages 927–931.

## ACID DERIVATIVES HAVING ONE OR TWO P–C BONDS

### Phosphonous Dihalides ($RPX_2$), Phosphinous Halides ($R_2PX$)

These compounds form an important class of intermediates for the preparation of acids and acid derivatives which contain one or two phosphorus–carbon bonds. The majority of the compounds recorded are chlorides. A few bromides and iodides are known and have usually been obtained from the corresponding chlorides by halide exchange reactions.

Relatively few phosphonous and phosphinous fluorides are reported. Halogenophosphines, in general, undergo both oxidation and fluorination with reagents such as antimony trifluoride or arsenic trifluoride, to form derivatives of phosphorus pentafluoride[302, 340, 556, 891, 991] (cf. page 958). Exceptions are halogenophosphines having negative substituents such as chloromethylphosphonous dichloride,[556, 2361–2] trifluoromethylphosphonous di-iodide,[302] bis(trifluoromethyl)phosphinous iodide, trifluorovinylphosphonous dichloride and bis(trifluorovinyl)phosphinous chloride[2432] which yield the corresponding fluorophosphines. Compounds such as phenylphosphonous dichloride may be converted to the corresponding fluorophosphines using sodium fluoride in tetramethylene sulphone solvent.[2431] Methyl phosphonous difluoride, formed from the chloro compound and potassium fluoride, decomposes slowly at room temperature to a mixture of methyl tetrafluorophosphorane and pentamethyl*cyclo*pentaphosphine. It reacts with nickel carbonyl giving a relatively stable complex $Ni(CH_3PF_2)_4$.[2360]

The more important general methods for preparing phosphonous and phosphinous halides are outlined below.

### Friedel–Crafts Synthesis

This method has been used extensively to prepare organophosphorus compounds and is one of the best for those in which phosphorus is linked to an aromatic nucleus[303]:

$$ArH + PCl_3 + AlCl_3 \rightarrow ArPCl_2{,}AlCl_3 + HCl$$

The complex of aluminium chloride and arylphosphonous dichloride may be broken by treatment with phosphorus oxychloride,[303] pyridine,[304] or water.[305] Treatment of

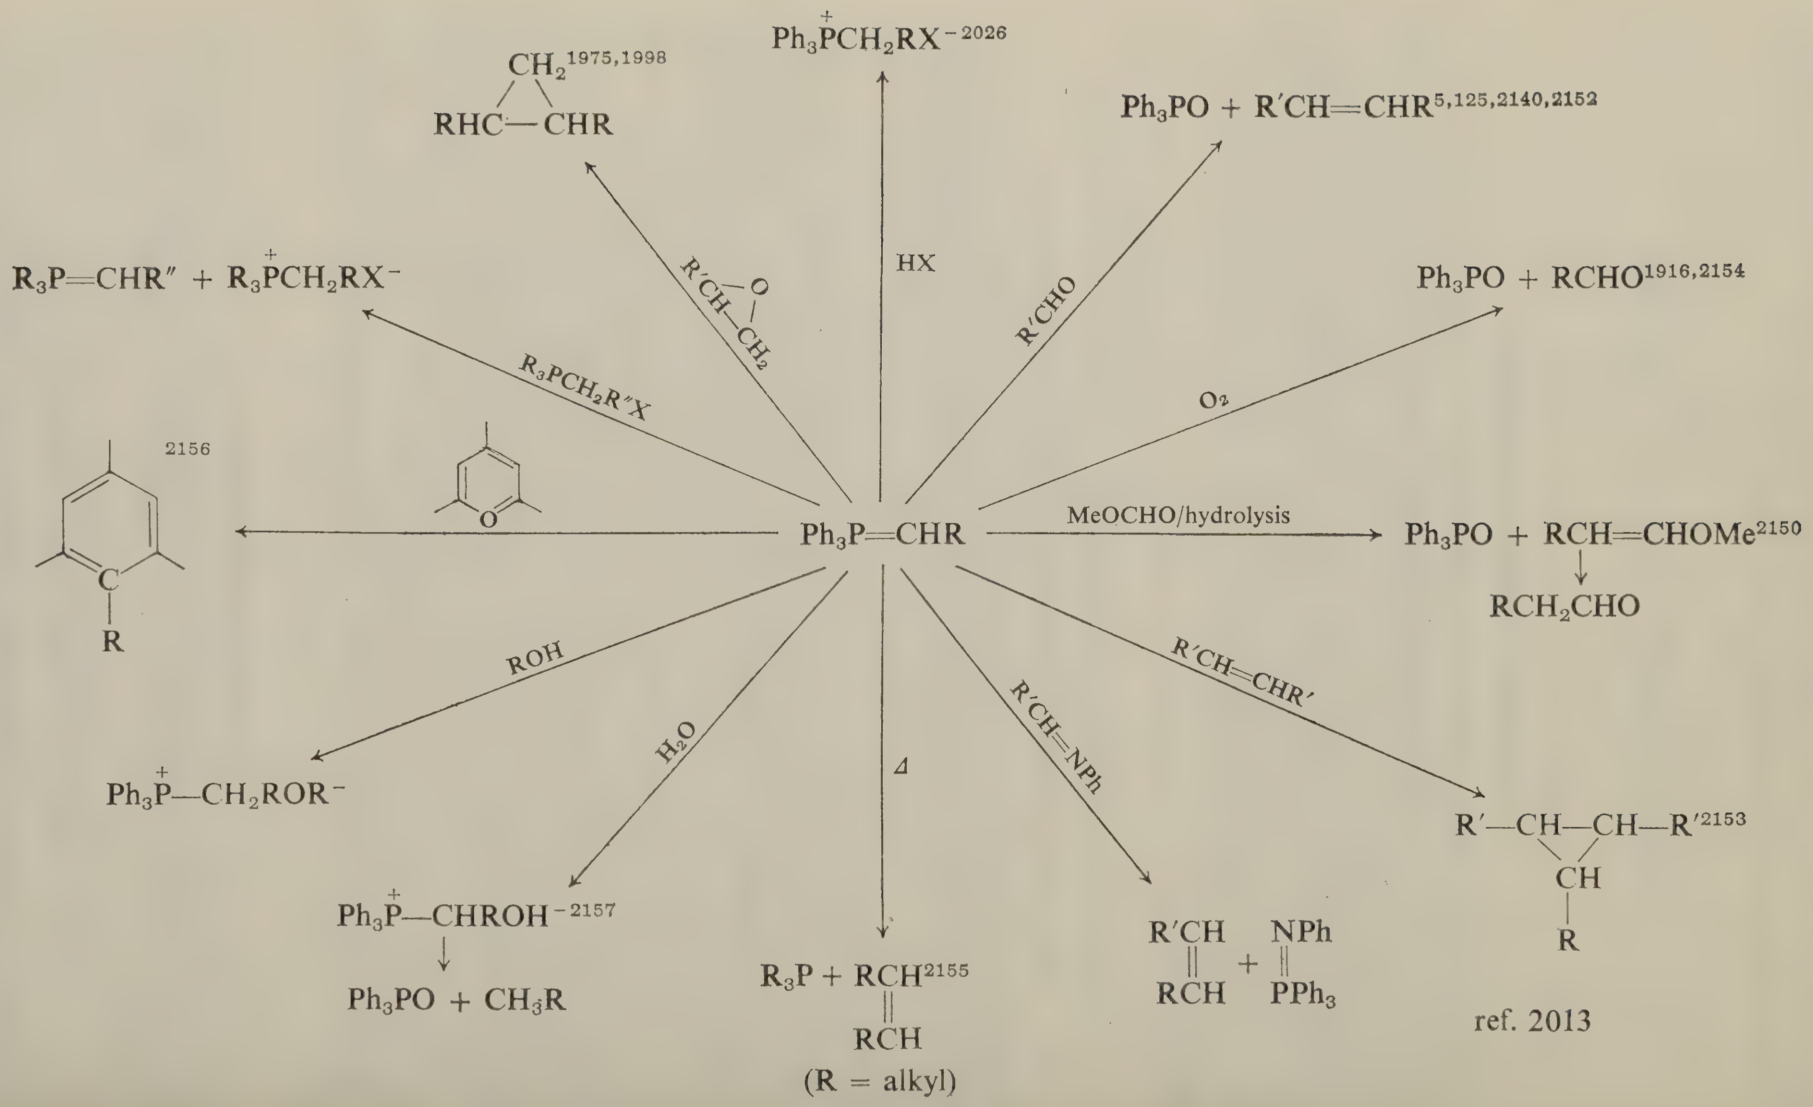


CHART VII.—General reactions of methylene phosphoranes the complex with an alcohol or phenol,[308] or with chlorine followed by an alcohol or phenol[309] gives the phosphonous and phosphonic ester respectively:

$$ArPCl_2,AlCl_3-\left|\begin{array}{l}\xrightarrow{POCl_3} ArPCl_2+POCl_3,AlCl_3\\ \xrightarrow{C_5H_5N} ArPCl_2+C_5H_5N,AlCl_3\end{array}\right.$$

A disadvantage of the Friedel–Crafts method is the formation of isomers; toluene gives *ortho*:*meta*:*para* isomers in the ratios 10:27:63.[307] Recent work throws doubt on the formation of the *ortho* compound. Toluene was found to yield two isomeric dichlorophosphines, *para* and *meta* in a ratio close to 2:1[547]; ethylbenzene[579] gave ethylphenyldichlorophosphines in a *para*:*meta* ratio of 1·63:1.

Isomer ratios of the products, $X–C_6H_4–PCl_2$, from $C_6H_5X$ and phosphorus trichloride (X = halogen, alkyl) have been investigated by Schindlbauer. Fluorobenzene gives the following isomer-percentage products: *ortho*- 5%, *meta*- 2%, *para*- 93%. The other halogenobenzenes give mainly *p*-isomer with little *ortho*- or *meta*-isomers; alkylbenzene gives little *ortho*-isomers, but *meta*-isomers in up to 40% yield.[2354] The Friedel–Crafts reaction of *o*-chlorotoluene and phosphorus trichloride followed by conversion of the products to phosphonic acids gives equal amounts of 3-chloro-4-tolylphosphonic acid and 4-chloro-3-tolylphosphonic acid.[2355]

Tertiary aromatic amines, such as dimethylaniline react with phosphorus trichloride (without catalyst or in the presence of aluminium chloride) giving, by successive replacement of the chlorine atoms, *p*-dialkylaminophenylphosphonous dichloride,[424, 1742–4] bis(*p*-dialkylaminophenyl)phosphinyl chloride,[424–5] and tris(*p*-dialkylaminophenyl)phosphine.[230, 424–5] Aqueous treatment of the chloro compounds gave the phosphonous acid and diarylphosphine oxide.[424] Anisole and phosphorus trichloride react under reflux with ferric chloride as catalyst to form isomeric methoxyphenylphosphonous dichlorides.[197]

### REACTION OF PHOSPHORUS TRICHLORIDE WITH ORGANOMETALLIC COMPOUNDS

Grignard reagents and organolithium compounds generally react with phosphorus trichloride giving exclusively tertiary phosphines.[310] By reverse addition, phosphinous chlorides have been obtained in good yield[528] from Grignard reagents. Organometallic compounds of mercury,[311] cadmium,[312, 2356] zinc,[310] aluminium,[313–4] and lead[315, 232] react with the trichloride giving phosphonous dichlorides:

$$\begin{array}{l}R_2Hg+PCl_3\rightarrow RPCl_2+RHgCl\\ RZnBr+PCl_3\rightarrow RPCl_2+ZnBrCl\\ R_3Al+3PCl_3\rightarrow 3RPCl_2+AlCl_3\\ Et_4Pb+3PCl_3\rightarrow 3EtPCl_2+PbCl_2+EtCl\end{array}$$

Phosphinous halides are often formed as by-products and under more vigorous conditions it is possible to prepare phosphinous chlorides from phosphorus trichloride or phosphonous chlorides using organic compounds of lead,[232, 316] zinc,[317] and mercury[318]:

$$R'PCl_2+HgR_2\rightarrow RR'PCl+RHgCl$$

Tetraethyl tin is reported to react with phosphorus tribromide but not with phosphorus trichloride.[319] Phosphorus trichloride will abstract a phenyl group from triphenyl bismuth and triphenyl stibine but not from triphenyl arsine.[529]

### REDUCTION OF COMPLEXES OF TYPE $R\overset{+}{P}Cl_3.A^-$ AND $R_2PX_2^+.A^-$

Alkyl phosphonous dichlorides are much more difficult to prepare than the aryl compounds. Recently it has been shown possible to reduce Kinnear–Perren complexes (see p. 954) with aluminium, phosphorus or sodium[321] or metal hydride[2357] in the presence of an alkali metal halide, with aluminium in methyl cyanide,[399] or with antimony powder in dibutyl phthalate[297, 332] to yield the phosphonous dichloride. Alkylarylphosphinous halides have been similarly prepared from the complex formed from aryldichlorophosphines[530]:

$$RCl + AlCl_3 + PCl_3 \rightarrow RPCl_3{,}AlCl_4 \xrightarrow{Al} RPCl_2{,}AlCl_3 + AlCl_3 \xrightarrow{KCl} RPCl_2 + 2KAlCl_4$$

$$RCl + AlCl_3 + ArPCl_2 \rightarrow RArPCl_2{,}AlCl_4 \xrightarrow{Al,\ KCl} R(Ar)PCl + KAlCl_4$$

Aryl dichlorophosphines are prepared by reducing aryl trichlorophosphonium fluoroborates (see p. 968) with magnesium,[531] or better, aluminium[532]:

$$Ar\overset{+}{P}Cl_3.BF_4^- \xrightarrow{Al} ArPCl_2$$

Diarylphosphinous chlorides are obtained by preparing the fluoroborate from an arylphosphonous dichloride rather than from phosphorus trichloride.[337, 532]

### REACTIONS OF ALKYL HALIDES WITH ELEMENTAL PHOSPHORUS

Elemental, especially white (P(w)), phosphorus and alkyl[205, 322] or aryl[322] halides and perfluoroalkyl iodides[154, 240] react at elevated temperature giving mixtures of organophosphorus compounds:

$$\begin{aligned}&CF_3I + P(w) \rightarrow CF_3PI_2 + (CF_3)_2PI + (CF_3)_3P\\&PhBr + P(w) \xrightarrow{300^\circ} PhBr_2 + Ph_2PBr \text{ [322, 2057]}\\&C_8H_{17}Br + P(w) \xrightarrow{250\text{–}270^\circ} C_8H_{17}PBr_2 + (C_8H_{17})_2PBr \text{ [322]}\end{aligned}$$

The phosphonous dihalides can be made to predominate.

Red phosphorus and alkyl or aryl halides react in the presence of copper powder giving mixtures of products in which the phosphonous dihalide predominates[323, 533, 2358]:

$$MeCl + P \xrightarrow{Cu} MePCl_2 + Me_2PCl$$

Carbon tetrachloride and white phosphorus react to form trichloromethylphosphonous dichloride, $CCl_3PCl_2$.[335]

### MISCELLANEOUS METHODS

Many methods have been described which give good yields of specific compounds. Phenylphosphonous dichloride is prepared[324-5] when a mixture of benzene and phosphorus trichloride is pyrolyzed at about 700°. Diphenylphosphinous chloride may be prepared by disproportionating the dichloride by pyrolysis[327] or by distillation with aluminium trichloride[326]:

$$\begin{aligned}PCl_3 + C_6H_6 &\rightarrow C_6H_5PCl_2 + HCl\\2C_6H_5PCl_2 &\rightarrow (C_6H_5)_2PCl + PCl_3\end{aligned}$$

An alternative route to this compound is from benzene and phosphorus pentasulphide *via* diphenylphosphinodithioic acid[328-9]:

$$P_2S_5 + C_6H_6 \xrightarrow{AlCl_3} (C_6H_5)_2PS_2H \xrightarrow{Cl_2} (C_6H_5)_2PCl_3 \xrightarrow{P} (C_6H_5)PCl$$

Dimethylphosphinous chloride can be obtained from tetramethyldiphosphine disulphide by reaction with phenyldichlorophosphine[1316]:

$$(Me_2PS)_2 + PhPCl_2 \rightarrow 2Me_2PCl + PhPS$$

The adducts formed by the addition of phosphorus pentachloride to olefines are reduced by elemental phosphorus giving $\alpha$-$\beta$-unsaturated phosphonous dichlorides.[331] Thermal decomposition of dihalogenophosphoranes has found limited application for the preparation of alkylarylphosphinous chlorides.[1] Reduction of tetrachlorophosphoranes with methyl phosphorodichloridite is reported[1504]:

$$CH_3PCl_4 + CH_3OPCl_2 \rightarrow CH_3PCl_2 + POCl_3 + CH_3Cl$$

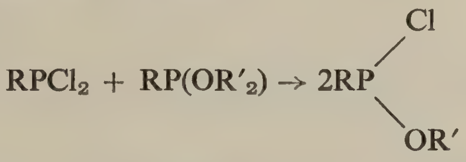
Halogenation, under carefully controlled conditions, of primary and secondary phosphines and phosphine derivatives which contain a P–P bond gives moderate yields of phosphonous and phosphinous halides. A method of potentially wide application involves chlorinating phosphines with phosgene[143, 333, 534]:

$$RPH_2 + 2COCl_2 \rightarrow RPCl_2 + 2CO + 2HCl$$
$$R_2PH + COCl_2 \rightarrow R_2PCl + CO + HCl$$

Grignard reagents and organoaluminium compounds[477] react with $Me_2NPCl_2$ and $(Me_2N)_2PCl$ giving dialkylphosphinous dimethylamide and monoalkylphosphonous tetramethyldiamide respectively. These compounds are cleaved by anhydrous hydrogen chloride[68, 334, 336] or with phosphorus trichloride[477] to the corresponding chlorides:

$$Me_2NPCl_2 \xrightarrow{2RMgX} Me_2NPR_2 \xrightarrow{HCl} R_2PCl + Me_2NH,HCl$$
$$(Me_2N)_2PCl \xrightarrow{RMgX} (Me_2N)_2PR \xrightarrow{HCl} RPCl_2 + 2Me_2NH,HCl$$
$$Et_2NPCl_2 \xrightarrow{AlEt_3} Et_2NPEt_2 \xrightarrow{PCl_3} Et_2PCl + Et_2NPCl_2$$

Diazoalkanes react with phosphorus trichloride giving by progressive substitution $RCH(Cl)PCl_2$, $[RCH(Cl)]_2PCl$ and $[RCH(Cl)]_3P$.[535] The use of diazo compounds in organophosphorus chemistry is reviewed briefly by Seyferth.[536] Esters of alkyl and aryl phosphonochloridous acid can be prepared in good yield by coproportionation of the diester and phosphonous dichloride[544]:



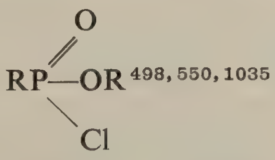
$$RPCl_2 + RP(OR'_2) \rightarrow 2RP\begin{matrix} Cl \\ OR' \end{matrix}$$

Typical reactions of phosphonous dihalides are shown in Chart VIII.

The photochemical or peroxide-catalyzed addition of phosphorus trichloride and phosphorus tribromide to olefines affords moderately good yields of 2-halogen substituted phosphonous dichloride.[2395–7] The peroxide catalyzed reaction of octene-1 and phosphorus trichloride is said to yield a single product, 2-chloro-octyl phosphonous dichloride.[2395] The ultra-violet catalyzed reaction of propylene and phosphorus tribromide gives almost pure $CH_3CH(PBr_2)CH_2Br$ but the thermal reaction at 150° gives a mixture of 70% $CH_3CH(PBr_2)CH_2Br$ and 30% $CH_3CHBr.CH_2PBr_2$.[2397]

### Phosphonyl Dihalides ($RPOX_2$) and Phosphinyl Halides ($R_2POX$)

These compounds are generally liquids or solids having low melting points. The chlorides, bromides, and iodides are readily hydrolyzed by water; in contrast, fluoro compounds are more stable and phenylphosphonic difluoride is reported not to be hydrolyzed in boiling water.[381] Compounds of the type $RPSF_2$ are more stable to hydrolysis than the corresponding oxygen compounds $RPOF_2$, whilst $R_2PA.F$ ($A = O, S$) are generally more stable than $RPA.F_2$.[547] The kinetics of hydrolysis of several phosphinyl chlorides[498, 550, 1035] and fluorides[438, 549, 1176] and of phosphonyl dichlorides[1035] have been determined, as have the kinetics of hydrolysis of *O*-alkyl phosphonochloridates:



$$RP\begin{matrix} O \\ —OR \\ Cl \end{matrix}$$ [498, 550, 1035]

and their reactions with amines to form *N*-substituted phosphonamidate esters.[551]

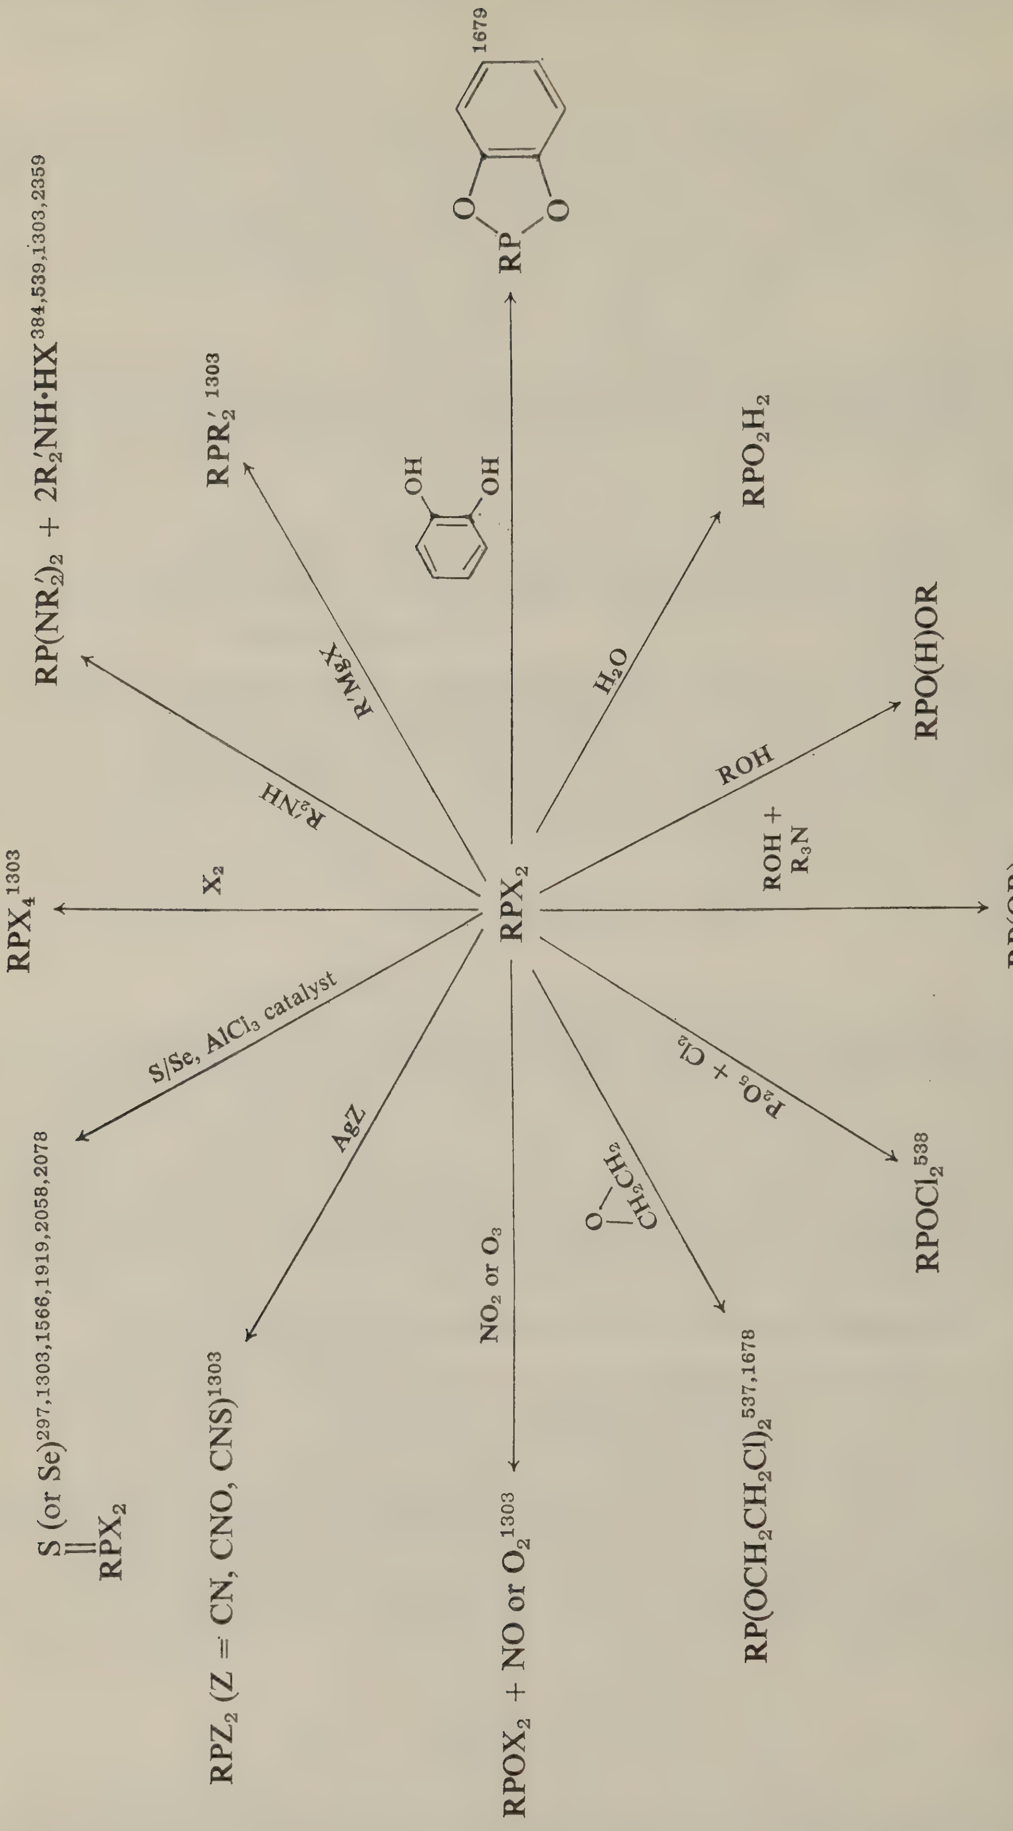


CHART VIII.—Reactions of phosphonous dihalides, $RPX_2$

**Ref. p. 1082**

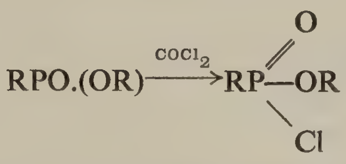
The densities, viscosities, molar polarization, dipole moments, refractive indices, vapour pressures, freezing points, and infra-red spectra of $MePOCl_2$, $Me_2POF_2$, and MePOFCl have been obtained.[1450] The nuclear magnetic resonance[384, 552] of alkylphosphonyl dichlorides, alkylarylphosphinyl chlorides and the corresponding acids and esters have been examined. Heats of formation and bond energies in $MePOCl_2$, $EtPOCl_2$, and their corresponding acids and ethyl esters have been evaluated.[1327] Phosphonic halides form complexes with metal halides such as $AlCl_3$, $BF_3$, $BCl_3$, $TiCl_4$, $SbCl_5$ and $SnCl_4$.[2367]

### PREPARATION FROM ESTERS OR ACIDS BY HALOGENATION

Phosphonic or phosphinic acids or their esters, and aromatic phosphinothioic acids[359] are readily converted to the corresponding phosphonyl and phosphinyl chlorides by treatment with reagents such as phosphorus pentachloride or thionyl chloride[358]:

$$\begin{array}{c} RPO.(OR')_2 \xrightarrow[\text{or } SOCl_2]{PCl_5} RPOCl_2 \xleftarrow{PCl_5} RPO_3H_2 \\ R_2PO.OR \longrightarrow R_2POCl \longleftarrow R_2PO_2H \end{array}$$

By judicious treatment of dialkylphosphonates with reactive chlorides such as $PCL_5$, $SOCl_2$,[353] $COCl_2$[354] or $(COCl)_2$,[353] it is possible to obtain high yields of *O*-alkyl phosphonochloridates:

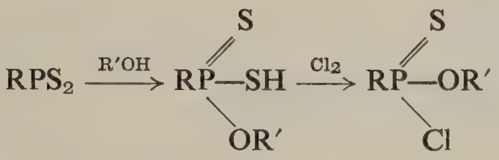


$$RPO.(OR) \xrightarrow{COCl_2} RP(=O)(-OR)(-Cl)$$

The mechanism of the reaction of pentavalent phosphorus esters with phosgene has been investigated by Green and Hudson who showed that the reaction rate decreased in the series:

$$R_2PO.OMe > ROPR'O.OMe > (RO)_2PO.OMe^{543}$$

*O*-Alkyl and *O*-aryl phosphonochloridothionates[356–7] can be obtained from thionophosphine sulphides by treatment with alcohol or phenol followed by chlorination:



$$RPS_2 \xrightarrow{R'OH} RP(=S)(-SH)(-OR') \xrightarrow{Cl_2} RP(=S)(-OR')(-Cl)$$

Aromatic phosphinodithioic acids yield diaryl phosphinochloridothionates by treatment with hydrogen chloride[328]:

$$Ar_2PS_2H + HCl \rightarrow Ar_2PSCl + H_2S$$

### FROM PHOSPHONOUS AND PHOSPHINOUS HALIDES BY ADDITION OF OXYGEN, SULPHUR OR SELENIUM

In common with other compounds containing trivalent phosphorus, phosphonous dihalides and phosphinous halides react with oxygen,[185] sulphur[357, 1303] or selenium,[169, 1303] giving the corresponding phosphonic or phosphinic, phosphonothionic or phosphinothioic, phosphonoselenoic or phosphinoselenoic[428] halides.

Phosphinous chlorides oxidize more readily than phosphonous dichlorides which usually oxidize readily only when free from impurities. A catalyst such as aluminium chloride is frequently used to effect the addition of sulphur[361] or selenium.[2058]

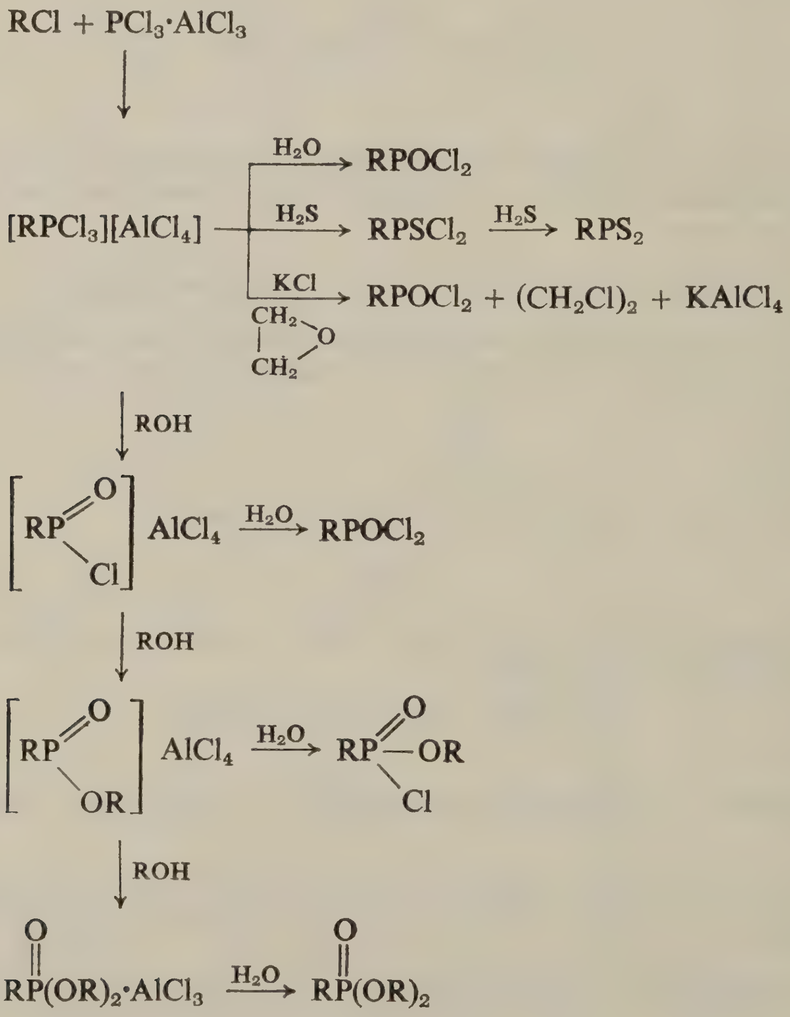
Phosphorus pentasulphide has been used to convert phosphonyl and phosphinyl chlorides into their thio analogues[362, 546, 1680]:

$$RPOCl_2 \xrightarrow{P_2S_5} RPSCl_2$$

The oxidation of $PhPCl_2$ and $Ph_2PCl$ to $PhPO.Cl_2$ and $Ph_2PO.Cl$ respectively, using sulphur dioxide and phosphorus tribromide catalyst, is reported.[1681] Benzyl- and phenylphosphonous dihalides are readily oxidized to the corresponding phosphonic dihalides with dry oxides of nitrogen.[2057] Equilibrium studies on reactions of the type $MePSCl_2 + POCl_3 \rightleftharpoons MePOCl_2 + PSCl_3$ have been carried out by Groenweghe and Payne.[545]

### PREPARATION FROM KINNEAR–PERREN[320] COMPLEXES

Phosphorus trichloride, alkyl halide and aluminium chloride react together to give a complex (an alkyltrichlorophosphonium tetrachloroaluminate) which is hydrolyzed by careful addition of water[320, 363] giving alkylphosphonyl dichloride. Treatment with hydrogen sulphide,[320] sulphur,[2364] potassium thiocyanate[2364] or alkylene sulphide[2363] gives alkylphosphonothionic dichloride. Treatment with alcohols can be adjusted to give the phosphonyl dichloride,[440] the alkyl phosphonochloridate[440] or the phosphonic diester.[440] Alkylene oxides react with the complexes at low temperature in the presence of potassium chloride to form phosphonic dichlorides and 1,2-dichloroalkene[350, 2363]:



Isomerization[541] and degradation occur with some alkyl groups. Thus, *n*-propyl and *n*-butyl chlorides give *iso*propyl and *sec*-butyl phosphonyl dichlorides[320];

*tert*-amyl chloride gives a mixture of *tert*-butyl and *tert*-amylphosphonyl dichlorides[364]; 2-chloro-2,3-dimethylbutane gives predominantly *tert*-butylphosphonyl dichloride.[542] 1-Halogeno-2-alkyl alkanes give tertiary phosphonyl dichlorides.[320, 540]

Similar complexes, $[RR'PCl_2][AlCl_4]$ are formed from phosphonous dichlorides. They are decomposed by water[356] to the phosphinyl chloride, by sulphur or a sulphide (of aluminium, phosphorus, antimony or arsenic) to phosphinothioic chlorides,[365] and by alcohol to the phosphinic acid ester.[439]

### PREPARATION BY OXIDATIVE PHOSPHONYLATION

Aliphatic hydrocarbons[366-7, 371, 2366] and substituted aliphatic hydrocarbons[368] react with phosphorus trichloride and oxygen to yield phosphonyl dichlorides. The overall reaction may be represented by the equation:

$$RH + PCl_3 + \tfrac{1}{2}O_2 \rightarrow RPOCl_2 + HCl$$

The yield of phosphonyl dichloride is generally poor and much of the phosphorus trichloride is simply oxidized to phosphorus oxychloride. Studies of the factors influencing the yield of phosphonic dichloride have been made by Isbell and Wadsworth,[370] by Pianfetti and Quin,[383] and by Mayo and co-workers.[555] The mechanism of the reaction is discussed by Flurry and Boozer.[2365] Many catalytic reagents[369, 370] have been used without success in attempts to improve the yield of phosphonyl dichloride. Single products are obtained only from hydrocarbons such as methane,[383] ethane,[367, 383] and *cyclo*hexane,[366] in which all the hydrogen atoms are equivalent; in other cases mixtures of all the possible isomers result.[371] 1-Chlorobutane gives the 1-, 2-, 3-, and 4-phosphonyl dichlorides in the following ratios: 9·5:20·5:54:16.[368]

Olefines[372-3] and acetylenes[374] yield 2-chloroalkyl- and 2-chloroalkenylphosphonyl dichlorides respectively. The products correspond to those expected for the free radical addition of phosphorus trichloride and phosphorus oxychloride to the double or triple bond. Phosphinyl chlorides have been obtained by using phosphonous dichlorides in place of phosphorus trichloride[375-6, 1302, 1325]:

$$RPCl_2 + R'H \xrightarrow{PCl_3/O_2} RR'POCl + HCl$$

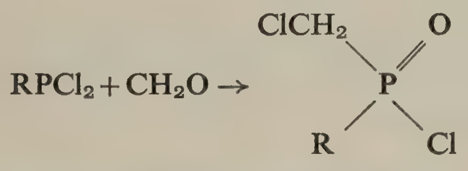
### FROM PHOSPHOROUS HALIDES AND ALDEHYDES

Formation of 1-chlorophosphonyl dichlorides by the high temperature reaction of phosphorus trichloride with aldehydes and ketones is a general reaction with few exceptions.[377] With most aromatic aldehydes[378] and formaldehyde[379] the reaction proceeds well but other aliphatic aldehydes give poor yields. Formaldehyde and phosphorus trichloride yield chloromethylphosphonyl dichloride:

$$CH_2O + PCl_3 \xrightarrow[3\text{ hr.}]{250°} ClCH_2POCl_2$$

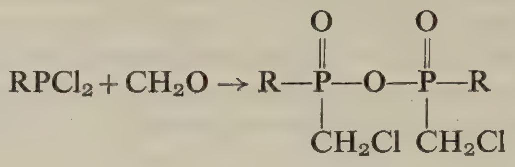
Small amounts of $ClCH_2PO.(CH_2Cl)Cl$ and $ClCH_2PO.(CH_2Cl)_2$ have been isolated as by-products.[379]

Similar reactions occur at high temperatures between aliphatic and aromatic phosphonous dichlorides and formaldehyde to give chloromethylphosphinyl chlorides[380]:



Diphenylphosphinous chloride and formaldehyde form chloromethyldiphenylphosphine oxide.[380]

Alkyl and aryl phosphonous dihalides and paraform react at moderate temperatures giving good yields of chloromethyl phosphinic acid anhydrides[562]:



$$RPCl_2 + CH_2O \rightarrow R{-}\overset{\overset{O}{\|}}{\underset{\underset{CH_2Cl}{|}}{P}}{-}O{-}\overset{\overset{O}{\|}}{\underset{\underset{CH_2Cl}{|}}{P}}{-}R$$

MISCELLANEOUS METHODS

Alkylation of thiophosphorus halides such as $PSCl_3$, $PSBr_3$, $RPSCl_2$, $(EtO)_2PSCl$, and $(Me_2N)_2PSCl$ by organoaluminium compounds has been studied by Maier.[1304]

Mixtures of phenylphosphonothioic dichloride, diphenylphosphinothioic chloride and triphenylphosphine sulphide are formed by the aluminium trichloride catalyzed reaction of thiophosphoryl chloride with benzene.[1749] The yield and product composition are determined by the molar ratio of the reactants, reaction time, and temperature. Di-(*tert*-butyl)phosphinic chloride has been obtained by the reaction[437]:

$$\text{P(white)} + Me_3CCl\ (1) \xrightarrow[\text{CS}_2\text{ solution}]{\text{AlCl}_3} (2) \xrightarrow[\text{hydrolysis}]{\text{Oxidative}} (Me_3C)_2POCl$$

Phosphonyl difluorides, phosphonothioic difluorides[381] and phosphinyl fluorides[382, 438] have been obtained from the corresponding chlorides by treating with fluorinating agents such as zinc fluoride,[381] hydrogen fluoride,[382] sodium fluoride[438] or potassium fluorosulphinate,[547] and by partial hydrolysis of tetrafluorophosphoranes.[547] Methylphosphonous dichloride reacts with potassium fluorosulphinate giving a mixture of methylphosphonic difluoride and methylphosphonothioic difluoride; similarly dimethylphosphinous chloride gives dimethylphosphinic fluoride and dimethylphosphinothioic fluoride.[547] Diphosphine disulphides and dialkylphosphinothioic chlorides react with thionyl chloride giving good yields of dialkylphosphinyl chlorides.

Phosphonothioic dihalides may be prepared by the thermal rearrangement of phosphorodihalogenidothioites:

$$RSPCl_2 \xrightarrow{\Delta} RP(S)Cl_2 \qquad (R = \text{alkyl, allyl, phenyl})$$

The rearrangement is catalyzed by iodine, methyl iodide or iodine salts and occurs at 135°–165° when R = allyl and 275°–400° when R = methyl.[2368] Methylphosphonyl dichloride can be produced by pyrolysis of dimethyl phosphite at 250°C., followed by chlorination with phosgene.[2430]

## Halogenophosphoranes

Chlorine combines with phosphonous dichlorides and phosphinous chlorides to form tetrachlorophosphoranes and trichlorophosphoranes respectively. The reactions are exothermic and are generally conducted in inert solvents. The products, yellow crystalline solids which generally resemble phosphorus pentachloride in appearance and reactivity, are isolated by filtration. A few mixed chlorobromophosphoranes have been prepared[1] by the addition of bromine to phosphonous dichlorides or phosphinous chlorides. Chlorophosphoranes are frequently prepared by chlorination of phosphonic[342] or phosphinic[341] acids and their chlorides or esters with phosphorus pentachloride:

$$RPCl_2 \xrightarrow{Cl_2} RPCl_4 \xleftarrow{PCl_5} RPO_3H_2$$
$$R_2PCl \xrightarrow{Cl_2} R_2PCl_3 \xleftarrow{PCl_5} R_2PO_2H$$

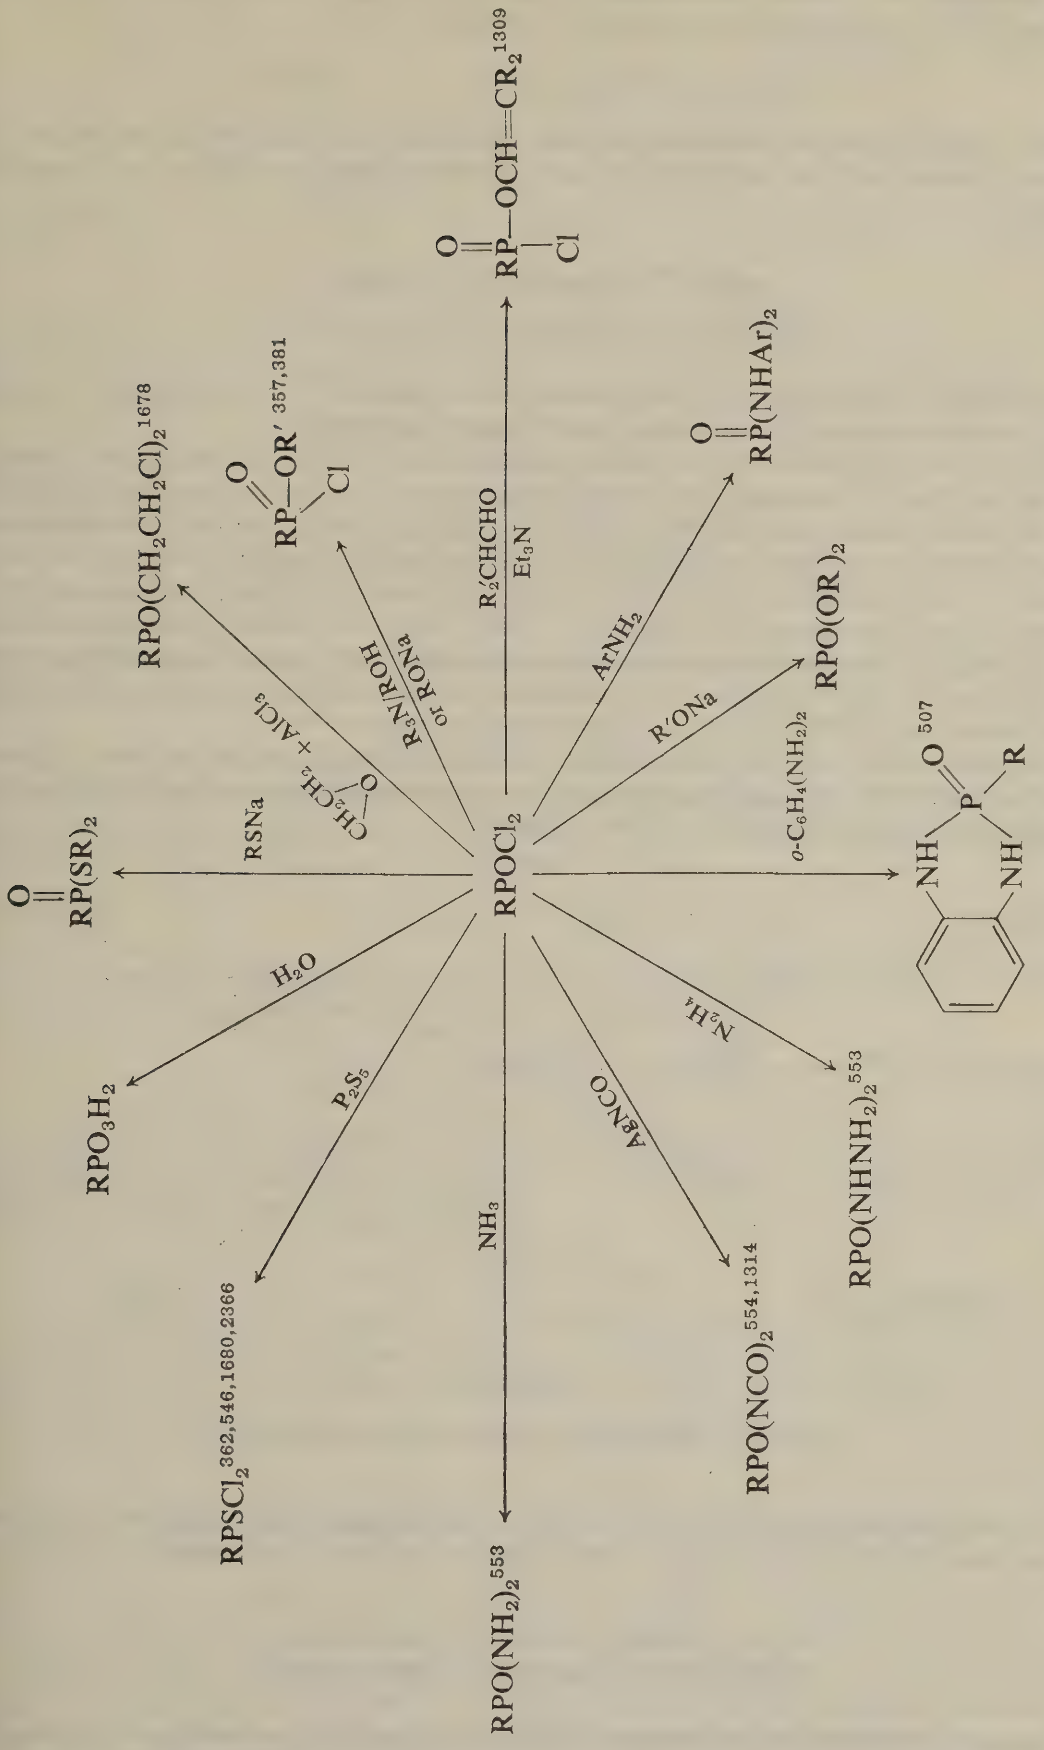


CHART IX.—Some typical reactions of phosphonodichlorides *cyclo*Hexylphosphorane tetrabromide and tetraiodide are formed in good yield by halogenation of tetra*cyclo*hexyltetraphosphine; tetra*cyclo*hexyldiphosphine similarly yields the di*cyclo*hexylphosphorane trihalides[1886]:

$$(C_6H_{11}P)_4 \xrightarrow{X_2} C_6H_{11}PX_4 \qquad (X = Br, I)$$

Mono- and di-phenylchlorophosphoranes are readily obtained by chlorination of phenylthionophosphine sulphide[338] and diphenylphosphinodithioic acid respectively:

$$PhPS_2 \xrightarrow{Cl_2} PhPS.Cl_2 \xrightarrow{Cl_2} PhPCl_4$$
$$Ph_2PS_2H \xrightarrow{Cl_2} Ph_2PS.Cl \xrightarrow{Cl_2} Ph_2PCl_3$$

Diphosphine disulphides are halogenated with chlorine[561] or bromine[561] giving trichlorophosphorane and tribromophosphorane respectively.

Crystalline compounds having the composition $R_3PX_2$ ($X = Cl, Br, I$) are formed by the addition of halogens to tertiary phosphines. The compounds are insoluble in non-polar media but soluble in solvents such as acetonitrile and nitrobenzene. Formulation as ionic solids, $[R_3PX]^+X^-$ (halogenophosphonium halides), is indicated by their solubility behaviour, by their high melting points, by electrical conductivity in nitrobenzene solution,[144] and from infra-red spectroscopy of $(CH_3)_3PX_2$.[1019] By mixing dihalogenophosphoranes with metal halides of the type $MX_n$ ($M = Sb^V, Sb^{III}, Hg^{II}$) in nitrobenzene solution, double salts, probably of ionic structure $[R_3PX]^+[MX_{n+1}]^-$, have been obtained.[144]

Pseudohalogens such as cyanogen bromide and triphenylphosphine react to form $Ph_3P,CNBr$.[16, 1987] Typical reactions of tetrachlorophosphoranes and dihalogenophosphoranes are indicated in Charts X and XI.

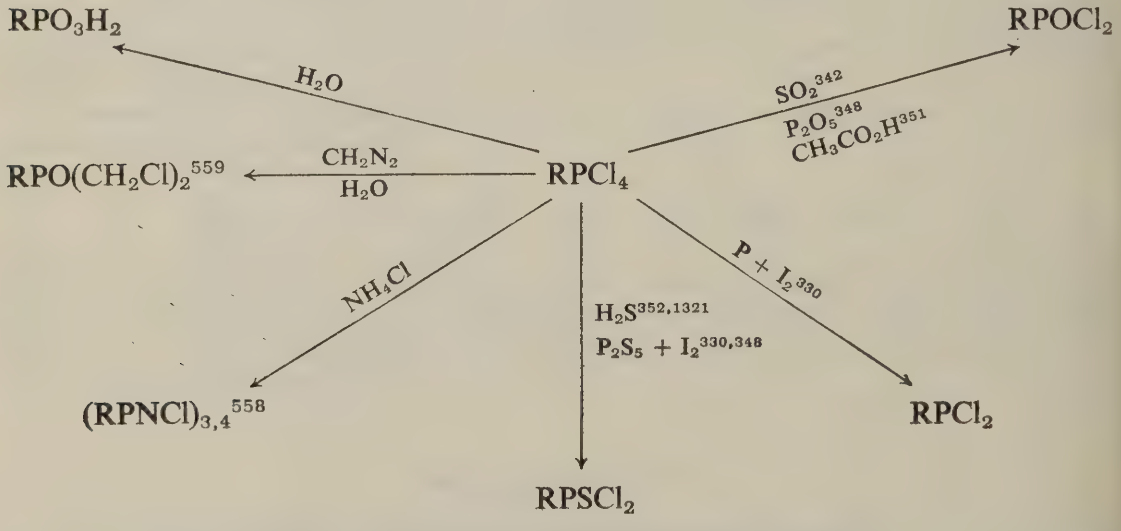

CHART X.—Reactions of tetrachlorophosphoranes

Fluorophosphoranes $R_nPF_{5-n}$ ($n = 1$ or 2) are obtained by fluorination of chlorophosphines $R_nPCl_{3-n}$ ($n = 1$ or 2) with arsenic or antimony trifluoride[302, 340, 556, 891, 991]:

$$3RPCl_2 + 4MF_3 \rightarrow 3RPF_4 + 2M + 2MCl_3$$
$$3R_2PCl + 3MF_3 \rightarrow 3R_2PF_3 + 2M + MCl_3$$

Antimony pentafluoride has been used similarly[339] and for the conversion of phenylphosphonous difluoride to phenyltetrafluorophosphorane.[339] Phenylfluorophosphoranes $Ph_nPF_{5-n}$ ($n = 1, 2, 3$) are obtained by replacing oxygen by fluorine in

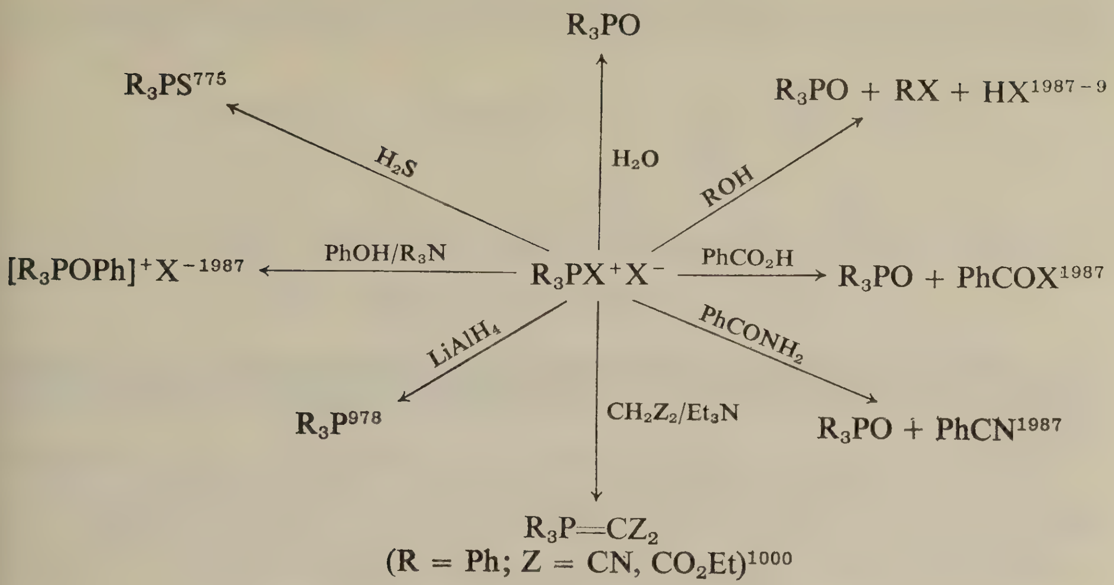

CHART XI.—Reactions of dihalogenophosphoranes

appropriate pentavalent phenylphosphorous compounds using sulphur fluoride,[775] e.g.,

$$Ph_3PO \xrightarrow{SF_4} Ph_3PF_2$$

Pentavalent phosphorus compounds containing sulphur, e.g. tributylphosphine sulphide and tetra-alkylphosphine disulphides, are readily converted to fluorophosphoranes by the use of antimony trifluoride[981, 1941]:

$$Bu_3PS \xrightarrow{SbF_3} Bu_3PF_2$$

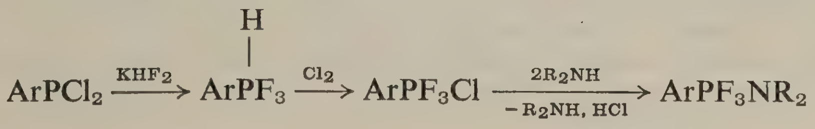
Fluorination of triphenylphosphine and diphenylphosphine with tetrafluorohydrazine affords the corresponding fluorophosphoranes[2063]:

$$2Ph_3P + N_2F_4 \rightarrow 2Ph_3PF_2 + N_2$$
$$Ph_2PH + N_2F_4 \rightarrow Ph_2PF_3 + N_2 + HF$$

Kinnear–Perren complexes $RPCl_3.AlCl_4$ and $R_2PCl_2.AlCl_4$ are converted to fluorophosphoranes by treatment with hydrogen fluoride,[892] alkali metal fluorides and antimony or arsenic trifluorides,[891] e.g.,

$$MePCl_3.AlCl_4 \xrightarrow{HF} MePF_4$$

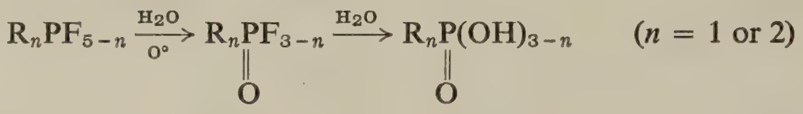
Arylphosphonous dichlorides and potassium hydrogen fluoride react to form aryltrifluorohydrogenphosphoranes which can be chlorinated to arylchlorotrifluorophosphoranes.[560] The chlorine atom in these compounds is selectively replaced on reaction with amines:



$$ArPCl_2 \xrightarrow{KHF_2} \overset{\displaystyle H \atop |}{ArPF_3} \xrightarrow{Cl_2} ArPF_3Cl \xrightarrow[-R_2NH,\ HCl]{2R_2NH} ArPF_3NR_2$$

Alkyltetrafluorophosphoranes are formed by the action of phosphorus pentafluoride on tetra-alkyltin compounds at room temperature.[2064]

Fluorophosphoranes are generally colourless liquids which are stable to distillation. Tetrafluorophosphoranes have boiling points about 80°C. below those of the corresponding dichlorophosphines; trifluorophosphoranes have boiling points about 20° below those of the monochlorophosphines[991]; methyl tetrafluorophosphorane is a gas, b.p. 10°C. They are readily hydrolyzed, the first step being production of the phosphonic or phosphinic fluoride which, under more vigorous conditions, gives the corresponding acids:



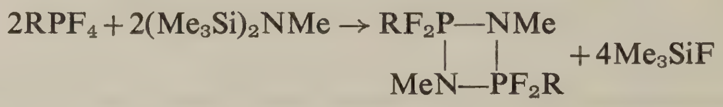
$$R_nPF_{5-n} \xrightarrow[0^\circ]{H_2O} R_nP(=O)F_{3-n} \xrightarrow{H_2O} R_nP(=O)(OH)_{3-n} \qquad (n = 1 \text{ or } 2)$$

The hydrolytic stability of di- and trifluorophosphoranes decreases in the order:

$$R_3PF_2 > R_2ArPF_2 = Ar_2PF_3 \gg R_2PF_3{}^{1941}$$

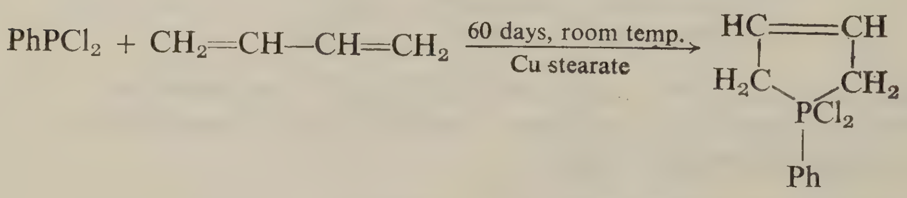
Tributyldifluorophosphorane is indefinitely stable in glass apparatus without special protection from moisture while triphenyldifluorophosphorane undergoes rapid hydrolysis.

Phosphorus fluorides such as $PF_5$, $RPF_4$, and $R_2PF_3$ react with hexamethyldisiloxane with cleavage of the Si–O bond, the products being $Me_3SiF$ and $POF_3$, $RPOF_2$, or $R_2POF$, respectively.[1564] With heptamethyldisilazane products are formed which contain a fluoro-1,3,2,4-diazadiphosphetidine ring system,[1529] e.g.,



HALOGENOPHOSPHORANES FORMED BY REACTIONS INVOLVING P–C BOND FORMATION

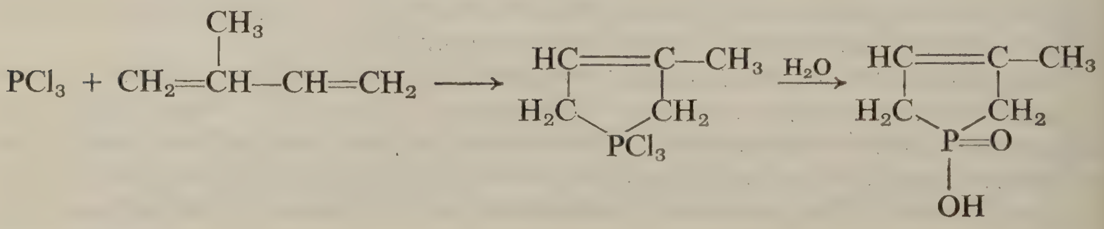
Cyclic chlorophosphoranes (P-substituted phospholine derivatives) are formed by the Diels-Alder type of reaction between phosphonous dichlorides and 1,3-dienes. The reaction is generally conducted at ambient temperatures in the presence of a polymerization inhibitor such as copper stearate or an aromatic polynitro compound.[951, 1912, 2369]



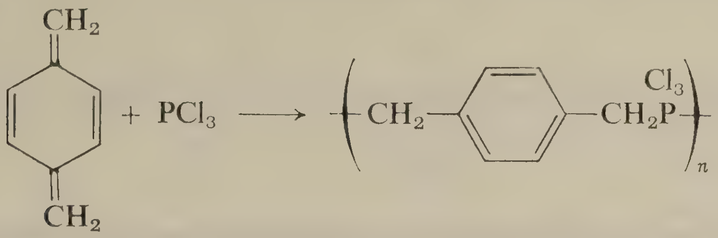
1-Phenyl-3-phospholene-1, 1-dichloride

The oxides derived from the dichlorides by hydrolysis possess high activity as catalysts for the formation of carbodi-imides from *iso*cyanates.[237, 1878, 1893, 1904, 1906]

Similar reactions are reported between dienes and phosphorus trichloride or tribromide to form 1,1,1-trihalogenophospholene derivatives[1001, 1006] and with phenylphosphorodichloridite[951] giving a *P*-phenoxydichlorophospholene:



*p*-Xylylene and trivalent phosphorous halides, e.g., the series $PCl_3$, $PhPCl_2$, and $Ph_2PCl$, react to form interesting polymeric halogenophosphoranes[343]:

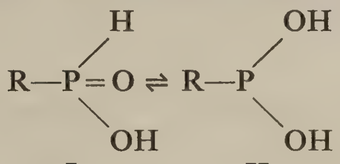


Nitriles such as acetonitrile, chloroacetonitrile and dichloroacetonitrile and phosphorus pentachloride react[557] as follows:

$$NCCHX_2 + 2PCl_5 \rightarrow NCCX_2PCl_4,PCl_5 + HCl \qquad (X = Cl \text{ or } H)$$

## Phosphonous Acids and Their Esters

The chemistry of phosphonous acids has been reviewed by Frank.[388] Phosphonous acids are monobasic acids and have been shown by nuclear magnetic resonance,[3] infra-red[3] and ultra-violet[387] spectroscopy to have the general structure **I.** As in related classes of compounds the possibility of a tautomeric equilibrium with a tricovalent form **II** has been considered, but form **I** is the overwhelmingly predominant species[3, 389]:



**I** **II**

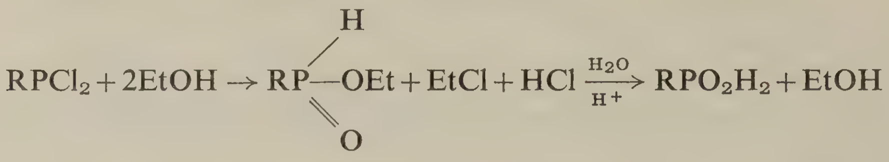
The hydrogen atom attached to phosphorus in phenylphosphonous acid, like that in $H_3PO_3$ and in diethyl hydrogen phosphate, undergoes isotopic exchange with deuterium in $D_2O/H_2O$ solution, probably *via* the formation of an intermediate of structure **II.** The relative rates of deuterium exchange of the three compounds are given by Reuben *et al.*[565] Trimeric association of phenylphosphonous acid in benzene solution has been described by Kosolapoff and Powell.[390]

Most aliphatic members are liquids which, due to disproportionation, cannot be purified by distillation; aromatic members are usually solids which are readily purified by crystallization. The $pK_a$ values of several aromatic phosphonous acids have been determined[385]; phenylphosphonous acid has $pK_a$ 1·75 at 25° in water. Methylphosphonous acid has $pK = 2{\cdot}3$, and proton magnetic resonance indicates structure **I.**[564] Trifluoromethylphosphonous acid has an acid dissociation constant, $K = 9{\cdot}8 \times 10^{-2}$; its infra-red spectrum is also in accordance with structure **I.**[563]

The acids are in general stable to atmospheric oxidation but are oxidized by a wide variety of mild oxidizing agents.[388] They form two series of derivatives; mono-derivatives RPH(O)Y, and di-derivatives $RP(Y)_2$, derived from the two isomeric forms **I** and **II.**

### PREPARATION

The most convenient and general method of obtaining phosphonous acids is hydrolysis of the corresponding phosphonous dihalide. These are rapidly hydrolyzed by ice-cold water[2356] or concentrated hydrochloric acid[330] often forming some phosphonic acid and phosphine by disproportionation. The best method is hydrolysis by addition to aqueous ethanol[390] or methyl alcohol[564]:



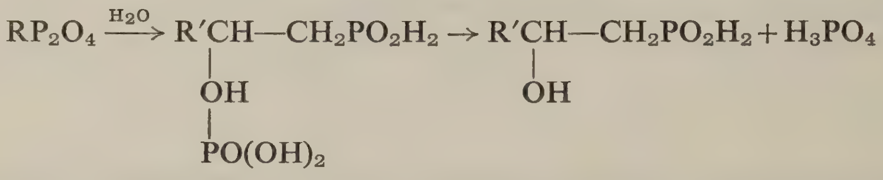
$$RPCl_2 + 2EtOH \rightarrow \underset{\diagdown O}{\overset{H \diagup}{RP}}\!\!-\!OEt + EtCl + HCl \xrightarrow[H^+]{H_2O} RPO_2H_2 + EtOH$$

Glassy polymeric phenylphosphonous anhydrides are reported to form by the action of water on phenylphosphonous dichloride or tetramethyl phenylphosphonous diamide. The analogous thio anhydride is obtained from the chloro compound and hydrogen sulphide[2373]; it reacts with bromine giving phenylphosphonothionic dibromide:

$$PhPCl_2 + H_2O \xrightarrow{-2HCl} (PhPO)_7 \xleftarrow{-2Et_2NH} PhP(NEt_2)_2 + H_2O$$
$$PhPCl_2 + H_2S \xrightarrow{-2HCl} (PhPS)_5 \xrightarrow{Br_2} PhPSBr_2$$

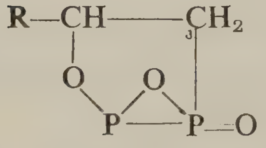
Other methods of preparation, generally of much narrower application, are outlined below.

Olefins react with white phosphorus and oxygen in inert solvents[391] giving crystalline 'phosphorates' (Willstätter) of empirical formula $RP_2O_4$ which are hydrolyzed by water to 2-hydroxyalkylphosphonous acids. More often the phosphorates have been treated with nitric acid to obtain phosphonic acids. Olefins which give soluble 'phosphorates' react further with oxygen giving compounds of empirical formula $RP_2O_5$[392]:

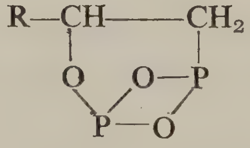


$$RP_2O_4 \xrightarrow{H_2O} \underset{\underset{PO(OH)_2}{|}}{\underset{OH}{\underset{|}{R'CH}}}\!-\!CH_2PO_2H_2 \rightarrow \underset{OH}{\underset{|}{R'CH}}\!-\!CH_2PO_2H_2 + H_3PO_4$$

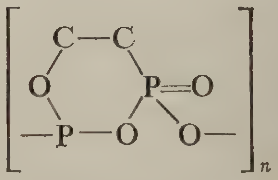
In a related reaction, olefins, phosphorus trichloride and acetic anhydride react to give crystalline 'phosphorites' $RP_2O_4$[393] (Stayner) which are hydrolyzed to $\alpha$-$\beta$ unsaturated phosphonous acids. The proposed structures of the 'phosphorates' and 'phosphorites' together with a polymeric structure suggested by Walling *et al.*[392] are given below:



Wilstätter

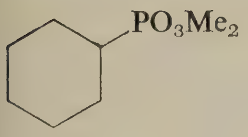


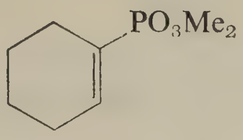
Stayner

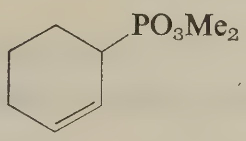


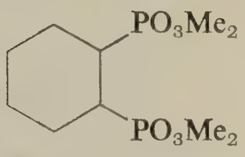
Walling

Recent work by Eckert *et al.*[2394] suggests that the structure of these compounds could be more complex than any of those indicated above with at least some components having two P–C bonds. A number of olefins were converted to the complexes [olefin, $P_2O_n$] (where $n = 4$–5) by reaction with white phosphorus and oxygen. The molecular weight of the octene complex corresponds to a pentamer with $n = 5$, i.e. $[C_8H_{15}P_2O_5]_5$. Hydrolysis of this followed by methylation with diazomethane yielded a mixture of trimethyl phosphate, dimethyl octene phosphonate and tetramethyl octane diphosphonate. The *cyclo*hexene adduct was converted with phosphorus pentachloride to a mixture of phosphonic chlorides and hence to the methyl esters indicated below:









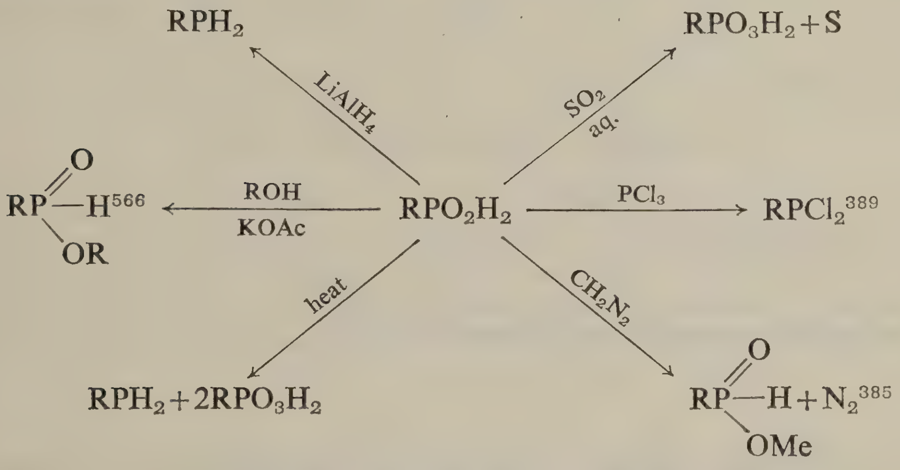
Hypophosphorous acid adds to carbonyl compounds giving $\alpha$-hydroxyalkylphosphonous acids[394] and undergoes a Mannich type of reaction with Schiff's bases forming *N*-substituted-$\alpha$-aminoalkylphosphonous acids.[395] When aldehydes or acetone are used in the reaction the initially formed phosphonous acid may undergo further condensation giving bis($\alpha$-hydroxyalkyl)phosphinic acid[396, 2376]:

$$RCHO + H_2PO_2H \rightarrow RCHOH.PH.O_2H \xrightarrow{RCHO} (RCHOH)_2PO_2H$$

Addition to dialkyl maleate gives a 1,2-dicarbalkoxyethylphosphonous acid.[1324] Sodium hypophosphite adds to olefines in the presence of free-radical initiators to give the sodium salts of a phosphonous acid which can undergo further addition to olefine giving a sodium dialkylphosphinate[397]:

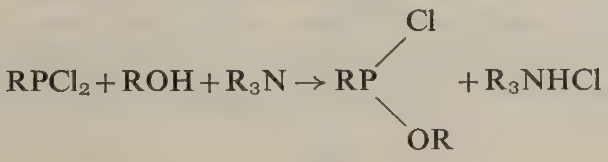
$$RCH{=}CH_2 + H_2PO_2Na \rightarrow RCH_2{-}CH_2PH.O_2Na \rightarrow (RCH_2CH_2)_2PO_2Na$$

Aryldiazonium compounds are said to react with sodium hypophosphite in the presence of copper sulphate giving arylphosphonous acids.[442] Potassium salts of acyl phosphonous acids ($\alpha$-ketoalkylphosphonous acids) are formed by the action of acyl anhydrides on $KH_2PO_2$.[1310] Some typical reactions of phosphonous acids are shown below.

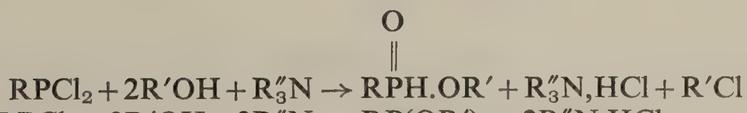


ESTERS OF PHOSPHONOUS ACIDS

The reactions of phosphonous dichlorides with alcohols in the presence of appropriate amounts of tertiary amine to give alkyl phosphonochloridites,[410] and mono[398] and dialkyl phosphonites[399, 423] are shown below:



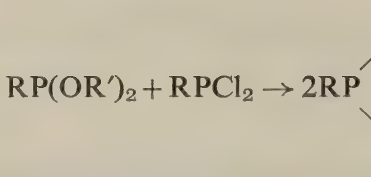
$$RPCl_2 + ROH + R_3N \rightarrow RP\begin{matrix} \diagup Cl \\ \diagdown OR \end{matrix} + R_3NHCl$$



$$RPCl_2 + 2R'OH + R''_3N \rightarrow \overset{\displaystyle O}{\overset{\|}{RPH}}.OR' + R''_3N,HCl + R'Cl$$

$$RPCl_2 + 2R'OH + 2R''_3N \rightarrow RP(OR')_2 + 2R''_3N,HCl$$

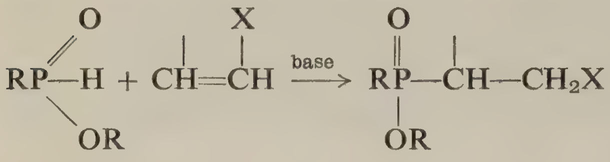
Sodium alkoxide[400] or ammonia[401] has been used in place of tertiary amine. Diesters from phenols[402] are not 'dearylated' by hydrogen chloride and can be prepared by heating the phosphonous dichloride and phenol together. The intermediate phosphonochloridous esters have been prepared indirectly by the reaction[544]:



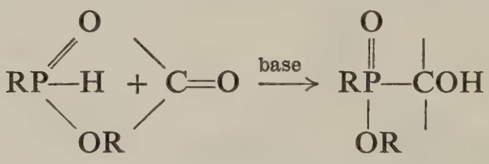
(R = alkyl, aryl)

The mono- and dialkyl esters are liquids which can generally be distilled under reduced pressure without decomposition. They undergo many reactions which are analogous to those known for dialkyl hydrogen phosphonates and trialkyl phosphites but generally exhibit a greater degree of reactivity.

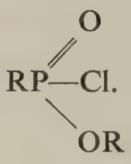
The mono-esters may also be prepared by direct esterification of phosphonous acids.[566] They form salts RPO.ORNa by treatment with sodium in anhydrous media. These add sulphur giving salts of alkylphosphonothionic acid,[404] and react with alkyl halides[405] giving alkyl phosphinates. The esters undergo many base-catalyzed addition reactions, adding in the sense RPO.OR···H, to activated olefins,[398, 406] Schiff's bases,[407] and carbonyl compounds,[407] to give alkyl phosphinates:



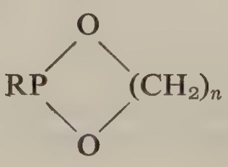
(X = —C=O, —CO$_2$R, —CN, —PO(OR)$_2$)



Chlorination gives phosphonochloridates[408]

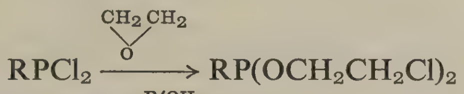


Dialkylphosphonous esters, in addition to preparation from phosphonous dichlorides, have been obtained (*a*) by the action of Grignard reagents on dialkyl and diaryl phosphorochloridites[409-10, 568] and trialkyl phosphites,[411] (*b*) by the reaction of the dichloride with alkylene oxides[412] to give 2-chloroalkyl esters, (*c*) by treatment of tetra-alkylphosphonous diamides with alcohols,[567, 1303] and (*d*) by transesterification of the lower alkyl ester with higher alcohols[399, 414]; no catalyst is required (cf. trialkyl phosphites). Higher alkyl dialkylphenyl phosphonates are conveniently obtained by transesterification of diphenylphenyl phosphonite and higher alcohols using diphenyl phosphite as catalyst.[2374] Cyclic esters:



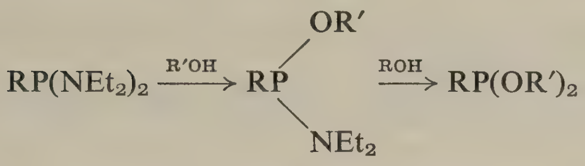
have been prepared by reaction of glycols with phosphonous dichlorides[1736] or with *N,N′*-tetra-alkylphosphonous diamides[1600]:

$$(R'O)_2PCl \xrightarrow{RMgX} (RO)_2P.R$$



$$RPCl_2 \xrightarrow{CH_2CH_2O} RP(OCH_2CH_2Cl)_2$$

$$RP(OMe)_2 \xrightarrow{R'OH} RP(OR')_2 + MeOH$$



$$RP(NEt_2)_2 \xrightarrow{R'OH} RP(OR')(NEt_2) \xrightarrow{ROH} RP(OR')_2$$

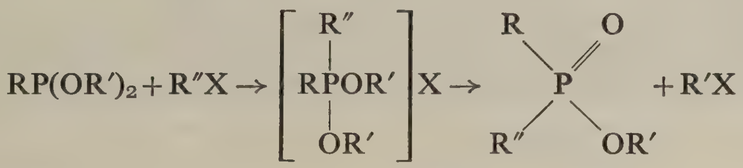
$$XMg(CH_2)_nMgX + 2(RO)_2PCl \rightarrow (RO)_2P(CH_2)_nP(OR)_2 \qquad (n = 4\text{–}6)^{568}$$

Phosphonous diesters undergo typical reactions of trivalent phosphorus compounds. They react readily with oxygen,[415] sulphur,[415–6] selenium,[416] and tellurium,[297] giving the corresponding phosphonate esters:

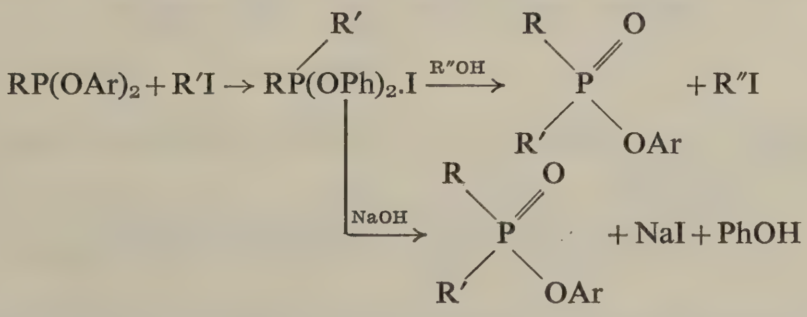
$$RP(OR')_2 \rightarrow RPX(OR')_2 \qquad (X = O, S, Se, Te)$$

Lower members such as diethyl methylphosphonite are reported to inflame on exposure to air on filter paper.[416] Many form crystalline complexes with cuprous halides ($RP(OR')_2,CuX$) which have sharp melting points and can be used for characterization.[415–6] They are hydrolyzed with one equivalent of water and a trace of acid to the mono-esters.[410]

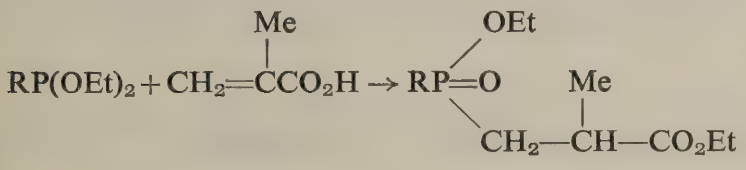
Like trialkyl phosphites the dialkyl phosphonites undergo the Arbuzov reaction with a wide variety of alkyl halides giving esters of phosphinic acids[415–8, 840]:



Reaction is usually complete in 2–3 hr. at 100°–120° compared with 5–6 hr. at 150°–160° required for trialkyl phosphites. Diaryl esters, like triaryl phosphites, do not undergo the Arbuzov rearrangement, but react with alkyl halides giving quasi-phosphonium compounds which may be decomposed by alcohols[421] (the Landauer–Rydon reaction) or by sodium hydroxide[422] giving phenyl esters of phosphinic acids:

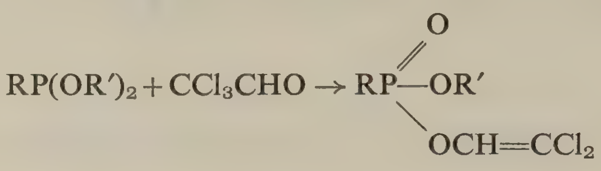


Dialkyl phosphonites react with α-β unsaturated acids such as acrylic or methacrylic acids giving phosphinic acid esters[1045, 1062]:



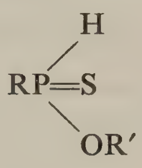
(R = Ph, Et)

α-Halogenoaldehydes react to give products which contain a new P–O bond rather than the expected P–C bond (the Perkow reaction[1010–11]—see p. 1011); thus, chloral gives a β,β-dichlorovinyl phosphonate[419]:

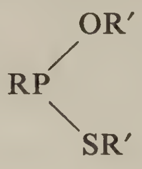


α-Halogenoketones may undergo the Arbuzov or Perkow reaction depending on the halogen and reaction conditions.[420]

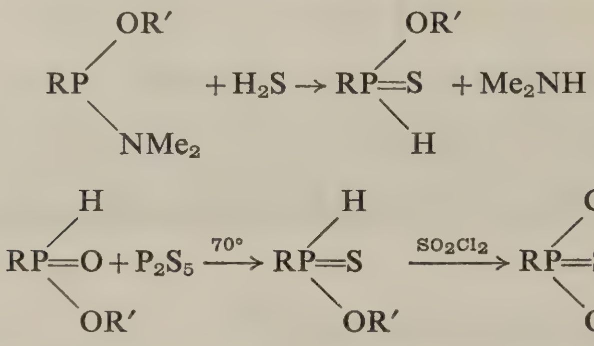
Phosphonochloridous esters react with hydrogen sulphide giving *O*-alkyl/aryl hydrogen phosphinothionates,[403]



and with mercaptans in the presence of tertiary organic bases giving *O*,*S*-dialkyl phosphonothioites[544]:



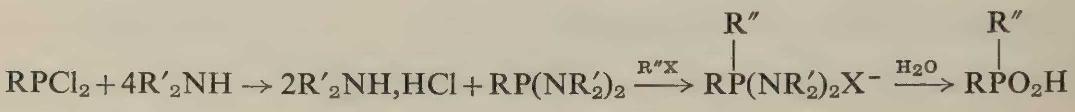
*O*-Alkyl hydrogen phosphinothionates are best prepared by the action of hydrogen sulphide on an *O*-alkyl-*N*,*N*-dimethyl phosphonamidite[569] or by the action of tetraphosphorus decasulphide on *O*-alkyl hydrogen phosphinates.[1735] They are readily chlorinated by sulphuryl chloride to *O*-alkyl phosphonochloridothionates[1735]:



The preparation and reactions of *S*,*S*-dialkyl phosphonodithioites have been described,[570, 945, 2375] e.g.,

$$RP(NMe_2)_2 + 2RSH \rightarrow RP(SR)_2 + 2Me_2NH$$
$$EtPCl_2 + 2RSH + 2Et_3N \rightarrow EtP(SR)_2 + 2Et_3NH,HCl$$

Phosphonous diamides are formed from the chlorides by reaction with secondary amines. Like the diesters they undergo reactions characteristic of tervalent phosphorus compounds and react with alkyl halides in an Arbuzov-type reaction to give quaternary salts which are readily hydrolyzed to phosphonic acids[446]:



$$RPCl_2 + 4R'_2NH \rightarrow 2R'_2NH,HCl + RP(NR'_2)_2 \xrightarrow{R''X} R\overset{R''}{\overset{|}{P}}(NR'_2)_2X^- \xrightarrow{H_2O} R\overset{R''}{\overset{|}{P}}O_2H$$

**Refs. p. 1082**

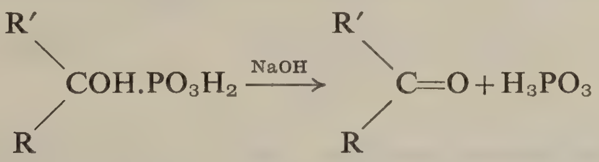
## Phosphonic Acids ($RPO_3H_2$) and their Esters

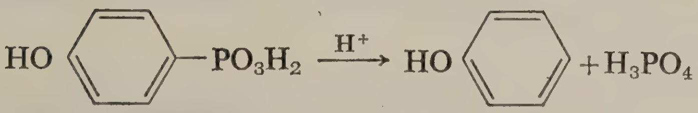
The preparation and properties of phosphonic acids have been reviewed by Kosolapoff,[1] and by Freedman and Doak.[456]

Phosphonic acids are generally crystalline compounds. They are dibasic acids. Dissociation constants of a considerable number of alkyl,[364, 458] halogenoalkyl,[364, 458] aryl,[457, 1274] vinyl,[571] triethylsilylalkyl[572] ($Et_3Si(CH_2)_nPO_3H_2$, $n = 1–4$), and alkylidine bis[742] phosphonic acids have been measured and the effects of structure and substituents discussed.[364, 456–8, 1269, 1274, 1306] Many of the dissociation constants are given by Kortüm, Vogel and Andrussow.[459] The effect of substituents on the dissociation constants is generally as would be expected; thus, electron-attracting substituents increase and electron-repelling substituents decrease the dissociation constant. The applicability of the Hammett equation to the dissociation constants of arylphosphonic acids[457] and of the Taft equation to the first and second dissociation constants of alkylphosphonic acids[1306] has been demonstrated. Molecular weight determinations on a number of phosphonic and phosphinic acids in acetic acid solution give normal molecular weights indicating absence of polymerization.[1308]

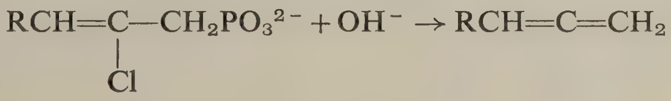
The carbon–phosphorus bond in these acids generally shows a high degree of stability and is unaffected by chemical reactions carried out on the organic residue. Thus, alkyl compounds having an $\alpha$-OH group may be dehydrated to $\alpha$-vinyl, or reduced by hydrogen iodide to $\alpha$-$CH_2$-compounds; those having $\alpha$-halogen may be dehydrohalogenated to give $\alpha$-vinyl groups, or the halogen can be replaced by reaction with amines or alkoxides; $\alpha$-vinyl groups add bromine and can be polymerized in the presence of radical initiators. Aromatic phosphonic acids undergo many reactions typical of aromatic compounds such as halogenation, nitration, reduction of nitro group to amino groups, and oxidation of alkyl groups to carboxyl.[2]

Although the P–C bond in phosphonic acids is generally very stable to hydrolytic fission (thus, phenylphosphonic acid is stable at 105° over 15 hours in 5–45% $H_2SO_4$[1305]), in a few classes of phosphonic acids, e.g., those having electron-attracting substituents attached to the $\alpha$-carbon atom, and *p*-hydroxyarylphosphonic acids,[1305] the P–C bond is readily cleaved by alkalis. Examples are trichloromethyl-, $\alpha$-hydroxyalkyl-, $\alpha$-cyanoalkyl-, and *p*-nitrobenzylphosphonic acids.[573] Aromatic phosphonic acids with hydroxyl or methoxyl groups attached to the nucleus in the *ortho*- or *para*-positions are cleaved in acid solution[471–2, 1305]:



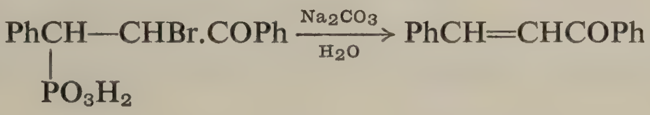


2-Chlorodecylphosphonic acid is reported to be decomposed almost instantly in water at pH 7 with the formation of dodecene. 2-Chloro-2-enylphosphonic acids are split by bases giving allenes[263]:



$$RCH{=}\underset{\displaystyle Cl}{\underset{|}{C}}{—}CH_2PO_3^{2-} + OH^- \rightarrow RCH{=}C{=}CH_2$$

$\beta$-Bromo-$\gamma$-keto acids are cleaved by alkalis giving olefins[453]:



$$\underset{\displaystyle PO_3H_2}{\underset{|}{PhCH}}{—}CHBr.COPh \xrightarrow[H_2O]{Na_2CO_3} PhCH{=}CHCOPh$$

Phosphonic acid analogues of ethylenediaminetetra-acetic acid and related compounds, e.g., ethylenediaminetetramethylenephosphonic acid $[(H_2O_3PCH_2)_2NCH_2]_2$, form relatively stable water soluble complexes with many metals.[517-8]

### PREPARATION OF PHOSPHONIC ACIDS

Phosphonic acids are obtained by hydrolysis of pentavalent compounds containing one P–C bond, such as tetrahalogenophosphoranes, phosphonyl halides, thionophosphine sulphides, and esters of phosphonic acids; and by oxidation of trivalent compounds such as $RPH_2$, $(RP)_4$, $RPO_2H_2$.

Esters are normally hydrolyzed by heating at reflux for several hours with concentrated hydrochloric acid. A mild hydrolysis route for unstable acids involves reaction with trimethylchlorosilane, the resulting trimethylsilyl ester being hydrolyzed by cold water[461]:

$$RPO(OR')_2 + Me_3SiCl \rightarrow 2R'Cl + RPO(OSiMe_3)_2 \xrightarrow{H_2O} RPO_3H_2$$

Benzyl groups may be removed from benzyl esters by hydrogenation with palladium catalyst.[460] Dialkyl alkylphosphonates eliminate olefin when heated at 250°–300°, giving the acid[462]:

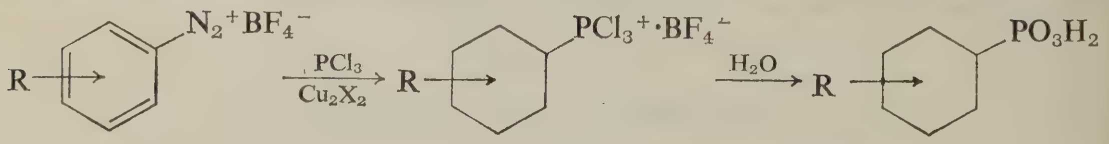
$$EtPO(OEt)_2 \xrightarrow{\Delta} EtPO_3H_2 + 2C_2H_4$$

The kinetics of hydrolysis of phosphonochloridates and phosphonate esters have been extensively studied by Hudson and co-workers.[474, 497-8, 1035] Silver ion exerts a considerable catalytic effect on the hydrolysis of dialkylphosphonothiolate esters.[484]

The more important methods for synthesis of phosphonic acids which involve P–C bond formation are outlined below.

#### *The Diazonium Fluoroborate Method*[463]

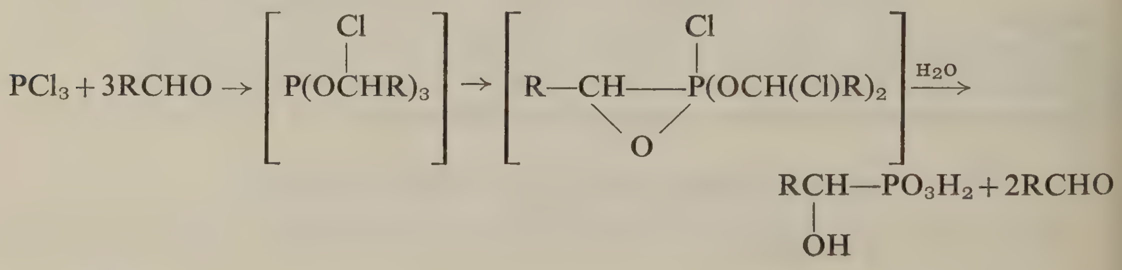
This is one of the most widely used methods for preparing aromatic phosphonic acids of known orientation. An aryldiazonium fluoroborate is caused to react with phosphorus trichloride in an inert solvent (ethyl acetate or dioxan) with cuprous bromide or chloride catalyst to give an aryltrichlorophosphonium fluoroborate which is hydrolyzed to phosphonic acid:



Aryldiazonium fluorosilicates have been used in place of the fluoroborate in a few cases.[464] Use of alkyl- or arylphosphonous dichloride in place of phosphorus trichloride gives a phosphinic acid.[475]

#### *The Reaction of Phosphorus Trihalides with Carbonyl Compounds*

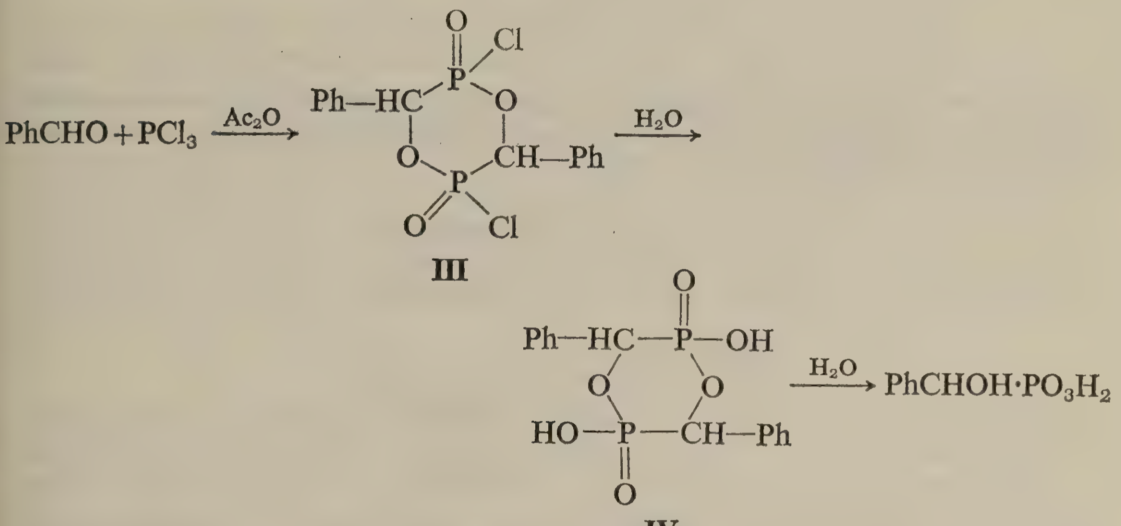
In addition to the high temperature reactions mentioned earlier phosphorus trichloride combines, at or near room temperature, with three moles of aldehyde[447] to form α-chloroesters of trivalent phosphorus which undergo the Arbuzov reaction.[378, 380] Hydrolysis yields 2 moles of aldehyde and one mole of α-hydroxyalkylphosphonic acid:



$$PCl_3 + 3RCHO \rightarrow \left[ P(O\overset{Cl}{\overset{|}{C}}HR)_3 \right] \rightarrow \left[ R{-}\underset{O}{\underbrace{CH{-}\overset{Cl}{\overset{|}{P}}}}(OCH(Cl)R)_2 \right] \xrightarrow{H_2O} \underset{\underset{OH}{|}}{RCH}{-}PO_3H_2 + 2RCHO$$

Physicochemical analysis of the system benzaldehyde–phosphorus trichloride proves the formation of a compound $PCl_3,3PhCHO$.[1326]

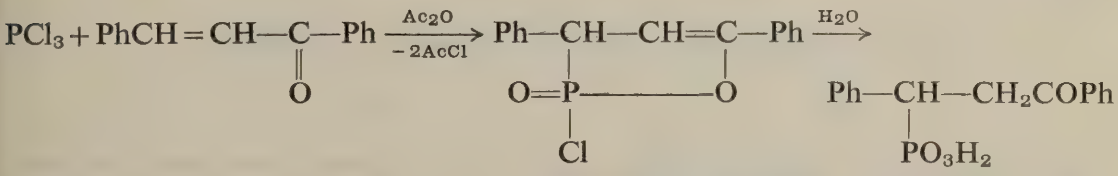
Addition of an aldehyde to an equivalent amount of phosphorus trichloride followed by hydrolysis with acetic acid[448] or acetic anhydride[449] gives acetyl chloride and a phosphonyl chloride which can be further hydrolyzed with water to α-hydroxyalkylphosphonic acid. Benzaldehyde and phosphorus trichloride[450] gave the cyclic phosphonyl chloride **III**, which by careful hydrolysis afforded the acid **IV**:



**III**

**IV**

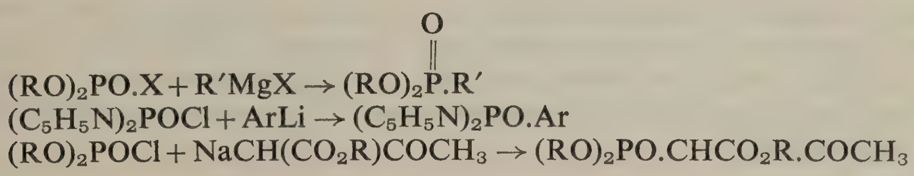
Other trivalent phosphorus halides, $PBr_3$, $ROPCl_2$, $(RO)_2PCl$, $RPCl_2$, $R_2PCl$ (but not $PI_3$) react like phosphorus trichloride with aldehydes[451, 453] giving respectively phosphonic acid, monoester of phosphonic acid, diester, phosphinic acid or *tert*-phosphine oxide. Unsaturated ketones, e.g., benzylidineacetophenone, react with phosphorus trichloride and acetic anhydride[451, 453-4] giving cyclic phosphonyl chlorides[449] which are hydrolyzed to γ-ketophosphonic acids:



Compounds of the type $APCl_2$ ($A = Ph$ or $OPh$)[451-3, 2370] react similarly to phosphorus trichloride.

### *Use of Organometallic Compounds*

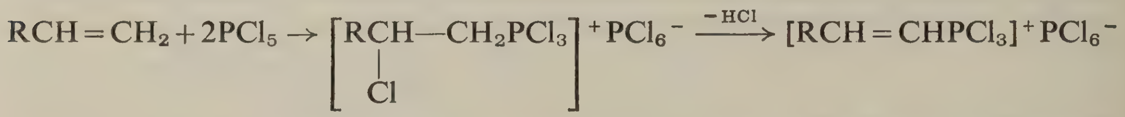
Grignard reagents react with dialkyl phosphorochloridates[465] or fluoridates,[521] and organolithium compounds with phosphoramidic chlorides[466] replacing the halogen atom and giving a carbon–phosphorus bond. Similarly, the sodium salts of aliphatic compounds containing active hydrogen such as ethyl acetoactate[467] react with phosphorochloridate. The products may be isolated as such or converted by hydrolysis to the acids:



$$(RO)_2PO.X + R'MgX \rightarrow (RO)_2\overset{\overset{\displaystyle O}{\|}}{P}.R'$$
$$(C_5H_5N)_2POCl + ArLi \rightarrow (C_5H_5N)_2PO.Ar$$
$$(RO)_2POCl + NaCH(CO_2R)COCH_3 \rightarrow (RO)_2PO.CHCO_2R.COCH_3$$

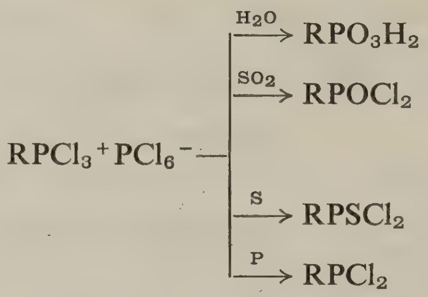
### *From Unsaturated Hydrocarbons and Phosphorus Pentachloride*

Phosphorus pentachloride adds readily to a wide variety of olefins having a terminal double bond to form crystalline complexes which are generally represented as 2-chloroalkyltrichlorophosphonium hexachlorophosphates. Many of these complexes readily lose hydrogen chloride giving the corresponding 1-alkenyl complexes[344-7, 1320]:



$$RCH{=}CH_2 + 2PCl_5 \rightarrow \left[\underset{\underset{Cl}{|}}{RCH}{-}CH_2PCl_3\right]^{+}PCl_6^{-} \xrightarrow{-HCl} [RCH{=}CHPCl_3]^{+}PCl_6^{-}$$

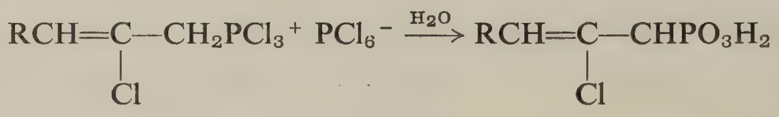
One report[348] claims that phosphorus pentachloride adds in the opposite sense to the olefin to form $RCH(PCl_3^{+})CH_2Cl.PCl_6^{-}$ as the initial product. Reactions of these complexes are indicated below:



Numerous workers (e.g., ref. 344) have claimed that 1-alkynes and phosphorus pentachloride interact to form β-chlorovinyl complexes of the type:

$$RCCl{=}CHPCl_3^{+}PCl_6^{-}$$

A recent investigation of the process shows that reaction of 1-alkynes with phosphorus pentachloride is accompanied by a hydride shift to form 2-chloroalkyl-2-enylphosphonium complexes which, by hydrolysis, yield 2-chloro-2-enylphosphonic acids[263]:



$$RCH{=}\underset{\underset{Cl}{|}}{C}{-}CH_2PCl_3^{+}\ PCl_6^{-} \xrightarrow{H_2O} RCH{=}\underset{\underset{Cl}{|}}{C}{-}CHPO_3H_2$$

Reactions of phosphorus pentachloride with conjugated dienes such as butadiene[349, 1350] and vinylacetylene[1317] are reported. The precise structures of the complexes so formed and of the phosphonic acids derived from them have yet to be established with certainty. However, 1-phenylbutadiene with phosphorus pentachloride or phenyl tetrachlorophosphorane is reported to form compounds **I** and **II** respectively as indicated below.[2371] The adduct from piperylene and phosphorus pentachloride yields penta-1:3-dienyl phosphonyl dichloride after treatment with sulphur dioxide.[2372]

$$\underset{\textbf{I}}{(PhCH{=}CH{-}CH{=}CH)_2PCl_3} \qquad \underset{\textbf{II}}{PhCH{=}CH{-}CH{=}CH{-}P(Ph)Cl_3}$$

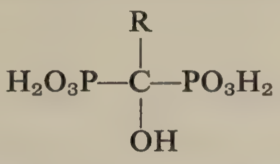
### *Miscellaneous Methods*

The direct phosphonylation of benzene with phosphoric acid has not been reported. Hexagonal phosphorus pentoxide reacts with benzene at 250°–325°C. to give a product $ArHP_4O_{10}$ which by hydrolysis yields phenylphosphonic acid. Yields are poor except when a large excess of benzene is used.[468] A few other aromatic hydrocarbons react similarly.

Phosphorous acid adds to olefins in the presence of free-radical catalysis[469, 470]:

$$\mathrm{RCH{=}CH_2 + H_3PO_3 \rightarrow RCH_2CH_2PO_3H_2}$$

Compounds claimed to be alkylhydroxymethylene bisphosphonates,



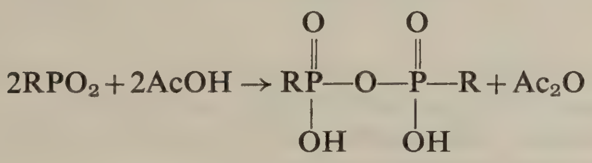
$$\mathrm{H_2O_3P{-}\underset{\displaystyle OH}{\overset{\displaystyle R}{C}}{-}PO_3H_2}$$

are obtained from phosphorous acid and carboxylic acid anhydrides[481] or from organic acids, water and phosphorus trichloride.[482] 'Acetyl phosphite', formed by interaction of phosphorous acid and acetic anhydride, has been shown to consist largely of monoacetyl phosphonate, $\mathrm{CH_3COPO_3H_2}$.[584] Nitrilotrismethylenephosphonic acid, $\mathrm{N(CH_2PO_3H_2)_3}$, is formed in high yield by the interaction of ammonium chloride, formaldehyde, and phosphorous acid.[1311] Addition of phosphorous acid to dialkyl maleates gives esters of phosphonosuccinic acid.[1324]

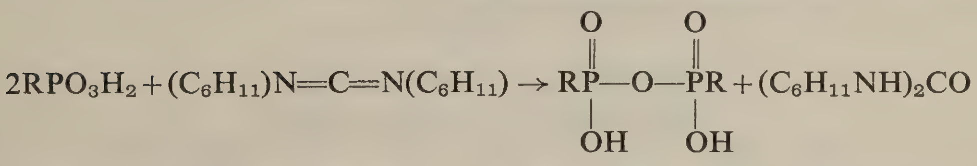
Tetraphenyl silicate and phosphorus pentasulphide interact at 195° to give, after hydrolysis of the intermediate product, a 41% yield of *p*-hydroxyphenylphosphonic acid.[523]

### Anhydrides of Phosphonic Acids

Polymeric anhydrides of the type $\mathrm{(RPO_2)}_n$ are formed by the interaction of phosphonyl dihalides and phosphonic diesters[1, 1318–9, 2379] and by treating a phosphonic dichloride with formic acid[1677, 2377] or with one mole of water at 120°–130° under vacuum.[2056, 2378] Van Wazer and co-workers have examined the NMR spectra of the polymeric methyl and phenyl phosphonic anhydrides formed by several of the above methods. They consider the compounds as condensation polymers which, depending on the proportions of reagents used and polymerization conditions, consist of mixtures of chain molecules of the type $\mathrm{X{-}PO.R[OPO.R]}_n\mathrm{X}$ (where $\mathrm{R=CH_3}$, $\mathrm{X=OCH_3}$, Cl, OH; where R = Ph, X = Cl, OH).[2379] Pyrophosphonic acids have been obtained[476] by the action of di*cyclo*hexyl carbodi-imide (DCC) on the acids, and by the action of acetic acid on phosphonic anhydrides[2380]:

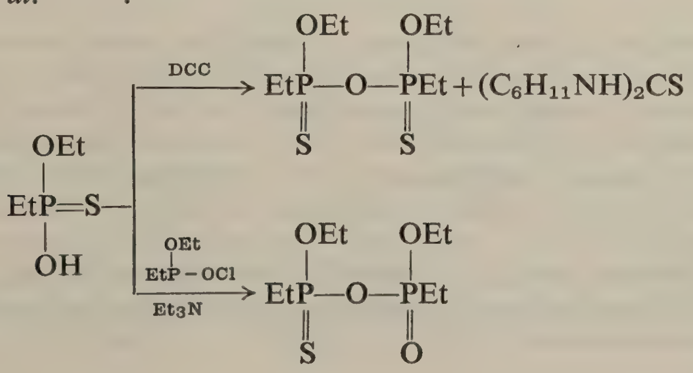


$$\mathrm{2RPO_2 + 2AcOH \rightarrow R\underset{\displaystyle OH}{\overset{\displaystyle O}{\overset{\|}{\underset{|}{P}}}}{-}O{-}\underset{\displaystyle OH}{\overset{\displaystyle O}{\overset{\|}{\underset{|}{P}}}}{-}R + Ac_2O}$$



$$\mathrm{2RPO_3H_2 + (C_6H_{11})N{=}C{=}N(C_6H_{11}) \rightarrow R\underset{\displaystyle OH}{\overset{\displaystyle O}{\overset{\|}{\underset{|}{P}}}}{-}O{-}\underset{\displaystyle OH}{\overset{\displaystyle O}{\overset{\|}{\underset{|}{P}}}}R + (C_6H_{11}NH)_2CO}$$

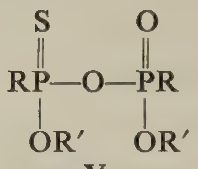
Dialkyl pyrophosphonates are readily obtained from monoalkyl phosphonates[476] using DCC. The stereochemistry of the reactions of ethyl ethylphosphonothioic acid to diethyl *PP′*-diethyl dithiopyrophosphonate with DCC and to diethyl *PP′*-diethyl thiopyrophosphate with ethyl ethylphosphonochloridothionate has been examined by Michalski *et al.*[2381–2]:



$$\mathrm{Et\underset{\displaystyle OH}{\overset{\displaystyle OEt}{P}}{=}S \xrightarrow{DCC} Et\underset{\displaystyle S}{\overset{\displaystyle OEt}{P}}{-}O{-}\underset{\displaystyle S}{\overset{\displaystyle OEt}{P}}Et + (C_6H_{11}NH)_2CS}$$

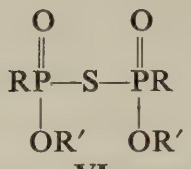
$$\mathrm{Et\underset{\displaystyle OH}{\overset{\displaystyle OEt}{P}}{=}S \xrightarrow[Et_3N]{Et\overset{OEt}{P}-OCl} Et\underset{\displaystyle S}{\overset{\displaystyle OEt}{P}}{-}O{-}\underset{\displaystyle O}{\overset{\displaystyle OEt}{P}}Et}$$

The infra-red spectrum of dialkyl monothiopyrophosphonates indicates the thiono structure V, as for analogous tetra-alkyl thiopyrophosphates, rather than the thiolo structure VI[354]:



$$\underset{OR'}{\overset{S}{\overset{\|}{RP}}}-O-\underset{OR'}{\overset{O}{\overset{\|}{PR}}}$$

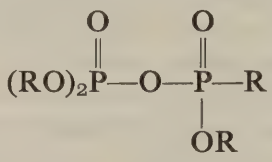
V



$$\underset{OR'}{\overset{O}{\overset{\|}{RP}}}-S-\underset{OR'}{\overset{O}{\overset{\|}{PR}}}$$

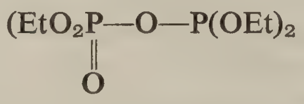
VI

Esters of isohypophosphonic acid:



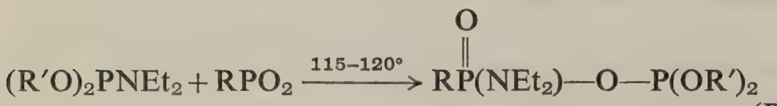
$$(RO)_2\overset{O}{\overset{\|}{P}}-O-\underset{OR}{\overset{O}{\overset{\|}{P}}}-R$$

are formed by heating $(RO)_2POCl$ with $(RO)_3P$ or $RPO(OR)_2$ ($R = Me, Et$),[1451] or by an Arbuzov reaction between tetraethyl *iso*hypophosphate:



$$(EtO_2\underset{O}{\underset{\|}{P}}-O-P(OEt)_2$$

and ethyl iodide.[1584] Amide anhydrides of mixed $P^{III}P^{V}$ acids are formed by the interaction of phosphorous amides and phosphonic anhydrides[2419]:



$$(R'O)_2PNEt_2 + RPO_2 \xrightarrow{115\text{–}120°} R\overset{O}{\overset{\|}{P}}(NEt_2)-O-P(OR')_2$$

($R = Me, Ph; R' = Pr, Bu$)

Dimeric arylthionophosphine sulphides result from the reaction of benzene or aromatic hydrocarbons with tetraphosphorus decasulphide at elevated temperature.[338,480] If the reaction is conducted in the presence of aluminium trichloride, benzene gives diphenylphosphinodithioic acid[328]:

$$ArH + P_4S_{10} \rightarrow (ArPS_2)_2 + P_4S_7$$

$$C_6H_6 + P_4S_{10} \xrightarrow{AlCl_3} (C_6H_5)_2PS_2H$$

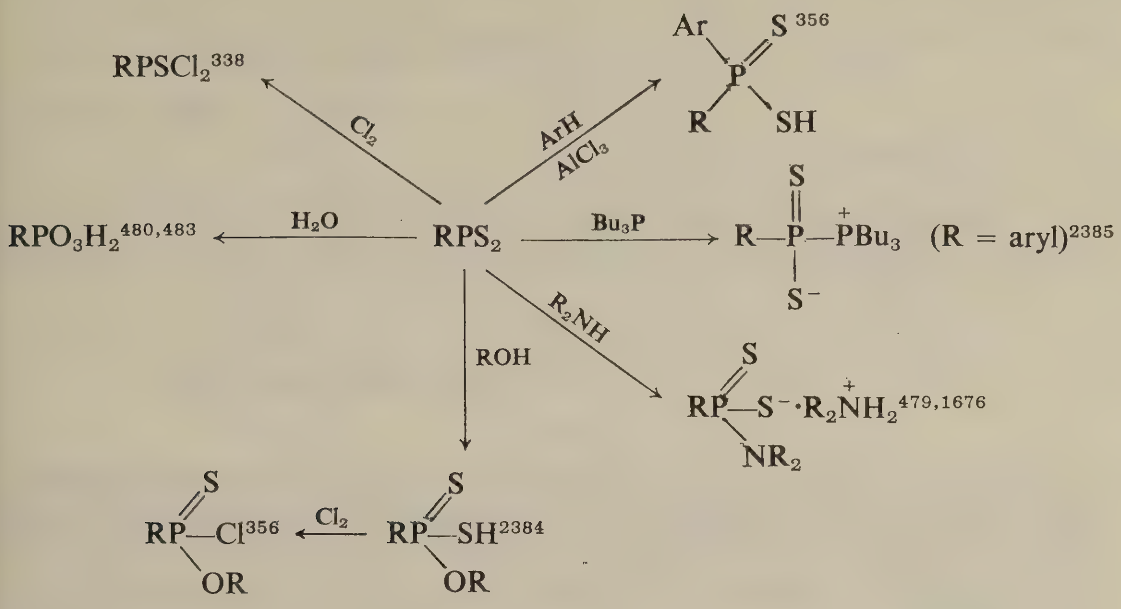
Alkyl and aryl thionophosphine sulphides result from the action of hydrogen sulphide on phosphonothionic dichlorides[356,2366]:

$$RPSCl_2 + H_2S \rightarrow (RPS_2)_2 + 2HCl$$

Many olefins react with tetraphosphorus decasulphide giving products of unknown structure which have found wide commercial use as oil additives.[3] *cyclo*Hexene gives dimeric *cyclo*hexenyl thionophosphine sulphide,[483] which is converted by hydrolysis to $\Delta^2$-*cyclo*hexenephosphonic acid. With a 25% excess of tetraphosphorus decasulphide, hexene-2, octene-2 and decene-2 form dithiophosphinic acids $R_2PS_2H$ in which the carbon–carbon double bonds are preserved; an allylic type addition has been postulated.[2383]

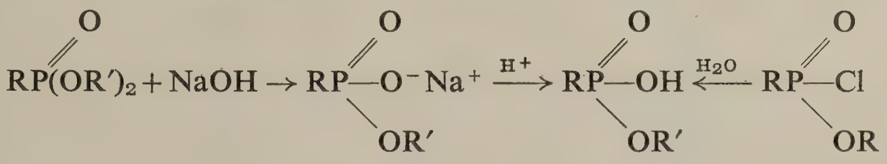
An *X*-ray diffraction analysis of methylthionophosphine sulphide shows it to be dimeric.[478,1675] Cryoscopic measurements on the phenyl compound (from $PhPH_2$ and $S_2Cl_2$) indicate a trimer.[479]

The thionophosphine sulphides are interesting intermediates. Some of their reactions are indicated below:

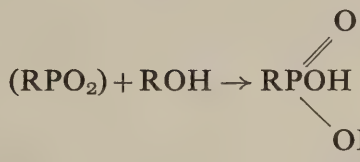


## Monoesters of Phosphonic Acids

Monoalkyl esters of alkyl- and arylphosphonic acids are readily obtained from the diesters by refluxing with aqueous or alcoholic sodium hydroxide,[473] by the action of alcohols on phosphonic acid anhydrides[1318-9, 1677, 2056, 2377] or by single dealkylation of the diesters by heating with alkali metal halides[1322]:



$$RP(OR')_2 + NaOH \rightarrow R\overset{O}{\underset{OR'}{P}}—O^-Na^+ \xrightarrow{H^+} R\overset{O}{\underset{OR'}{P}}—OH \xleftarrow{H_2O} R\overset{O}{\underset{OR}{P}}—Cl$$

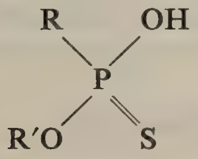


$$(RPO_2) + ROH \rightarrow R\overset{O}{\underset{OR}{P}}OH$$

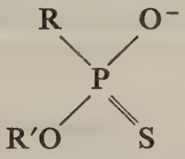
$$RPO(OR)_2 + MX \rightarrow RPO.OMOR + RX \qquad (X = Br, I)$$

Dissociation constants of several monoalkyl phosphonates are reported.[485, 571]

Kabachnik *et al.* concluded from physical evidence that *O*-alkylphosphonothioic acids[486] and their salts[487] exist largely in the forms **VII** and **VIII** indicated below:

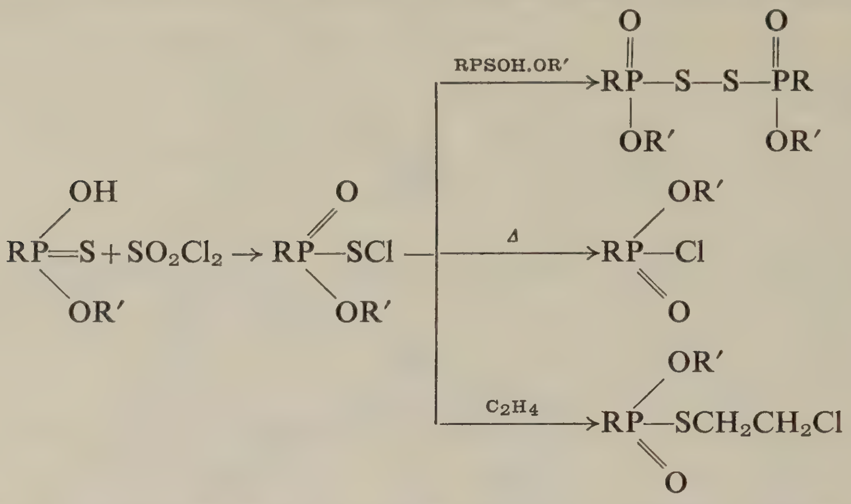


**VII**

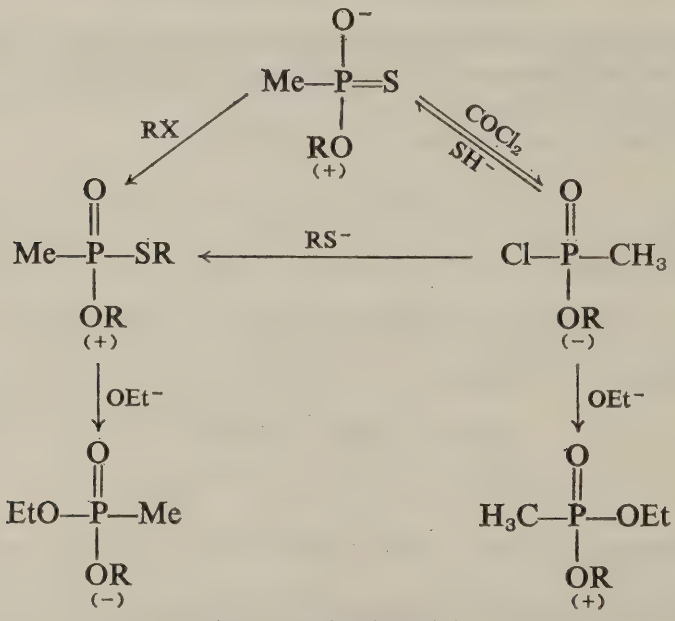


**VIII**

The salts react with alkyl halides giving *S*-alkyl esters, but with acyl halides giving *O*-acyl anhydrides.[487] Chlorination of *O*-alkylalkylphosphonothioic acids with sulphuryl chloride gives either *P*-alkoxy-*P*-alkyloxophosphoranesulphenyl chlorides or bis(*P*-alkoxy-alkylphosphinyl) disulphides depending on the amount of reagent used.[404, 489] The sulphenyl chlorides are thermally unstable and decompose to alkylalkylphosphonochloridates. They add to olefins giving $\beta$-chloroethyl esters:



Asymmetric phosphonic acid derivatives such as *O*-phenyl-*N*-($\beta$-dimethylaminoethyl)-*P*-phenylphosphonamidate[490] and a number of *O*-alkylphosphonothioic acids[491-2] have been resolved into optical isomers. The optically active acids have proved a particularly valuable starting point for the study of the stereochemistry of displacement reactions at the phosphorus atom. A sequence of reactions established by Aaron and his co-workers is shown below[493]:



$(R = -CH(CH_3)_2)$

Optically active dialkyl monothioalkylpyrophosphonates, prepared from optically active *O*-alkyl alkylphosphonothionic acid and the *O*-alkyl alkylphosphonochloridate, have been used to follow the stereochemical course of pyrophosphate hydrolysis.[495-6]

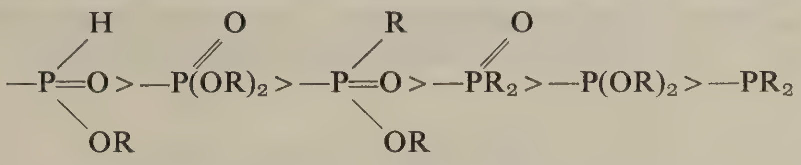
### Diesters of Phosphonic Acids

Vapour pressures,[1396, 1430] densities,[1430] dipole moments[1414] and viscosities[948] of a number of alkyl phosphonates are recorded.

These esters (e.g., dioctyl phenylphosphonate) are thermally more stable than the corresponding trialkyl phosphates (e.g., trioctyl phosphate).[499] As in phosphonic acids the C–P bond generally exhibits a high degree of stability. The diesters undergo numerous reactions[2] in which the P–C and P–OC bonds remain intact. For example, hydroxyl groups in alkyl phosphonates may be replaced by amino groups by ammonolysis, and aminoalkyl compounds react with phosgene to give isocyanates which undergo the typical reactions of organic isocyanates.[501] In vinyl phosphonates the phosphoryl group activates the double bond for addition of nucleophilic reagents and for the Diels–Alder reaction with conjugated dienes[519, 520, 580]:

$$XH + H_2C{=}CH{-}PO(OR)_2 \xrightarrow{\text{base}} XCH_2CH_2PO(OR)_2$$
$$(X = CH(CO_2R)_2,\ RS,\ R_2N,\ (RO)_2PO,\ RO)$$

Kabachnik *et al.* showed that secondary amines add to the $\beta$-position of the vinyl group of vinyl phosphorus compounds regardless of the valency of the phosphorus atom or the groups attached to it. The reactivity decreased in the following order[578]:



$$-P(H)(OR){=}O > -P(O)(OR)_2 > -P(R)(OR){=}O > -P(O)R_2 > -P(OR)_2 > -PR_2$$

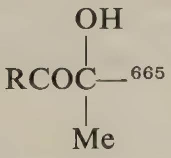
1-Alkynyl phosphonates can undergo additions of nucleophiles to the acetylenic bond.[521] In electrophilic substitutions of aryl phosphonates the phosphonyl group is largely *meta*-directing.[522] Polar substituent constants for the groupings

$$-CH_2PO(OR)_2, \qquad -CH_2POR_2, \qquad -CH_2PSR_2 \qquad -CH_2\overset{+}{P}R_3$$

have been determined.[2386]

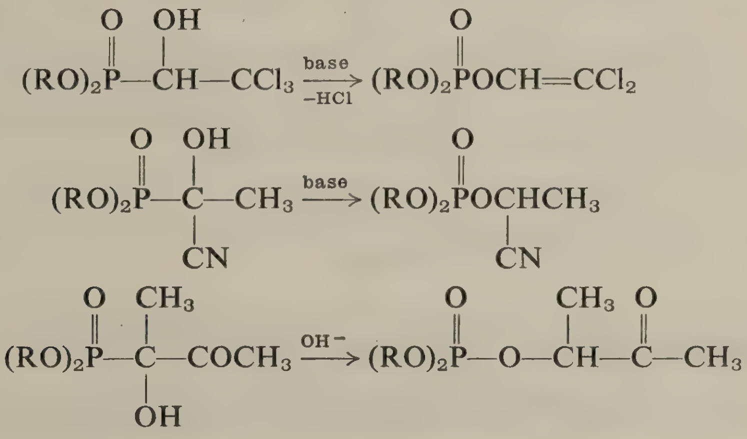
Ester groups of phosphonic esters undergo transesterification; allyl esters polymerize in the presence of radical initiators[499, 502] and can be co-polymerized with compounds such as styrene, methyl methacrylate, vinyl acetate and allylcarboxylic acid esters. Glassy solids having considerable flame-resistance are obtained when the substituent attached to phosphorus is more electronegative than methyl (e.g., diallyl phenylphosphonate) whereas when the substituent is methyl or a group with electronegativity similar to, or more positive than, methyl the polymers range from soft solids to rubbery gels.[502]

Some exceptions to the general stability are compounds which have electronegative substituents attached to the $\alpha$-carbon atom. In compounds with $CF_3$—, $CCl_3$—,[504] or RCHOH–[503] groups attached to phosphorus the P–C bond is readily cleaved by alkalis. $\alpha$-Keto esters are cleaved by acid[505]; aroylphosphonic esters are cleaved by dilute acid or base.[500] Compounds with $CH_3C(CN)OH$–,[508-9] $CCl_3CHOH$–[506, 908, 1007, 1014, 1036, 1192] or



$$RCOC(OH)(Me){-}^{665}$$

groups undergo rearrangement on treatment with alkali giving phosphoric acid derivatives:

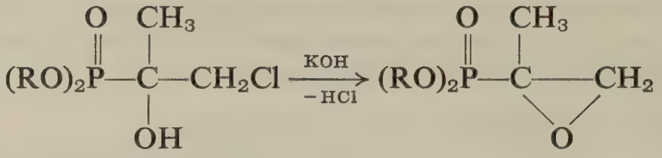


$$(RO)_2P(O){-}CH(OH){-}CCl_3 \xrightarrow[-HCl]{\text{base}} (RO)_2P(O)OCH{=}CCl_2$$

$$(RO)_2P(O){-}C(OH)(CN){-}CH_3 \xrightarrow{\text{base}} (RO)_2P(O)OCH(CN)CH_3$$

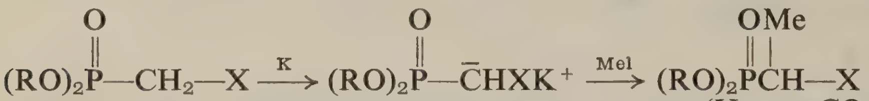
$$(RO)_2P(O){-}C(CH_3)(OH){-}COCH_3 \xrightarrow{OH^-} (RO)_2P(O){-}O{-}CH(CH_3){-}C(O){-}CH_3$$

A number of dialkyl 2-chloro-1-hydroxy-1-methylethylphosphonates eliminate hydrogen chloride on treatment with alkali giving 1,2-epoxyalkylphosphonates[1037-8]:



Diethyl 2-pyrrylphosphonate undergoes facile P–C bond cleavage on treatment with aqueous sodium hydroxide to give a mixture of pyrrole and 2-ethylpyrrole.[1986]

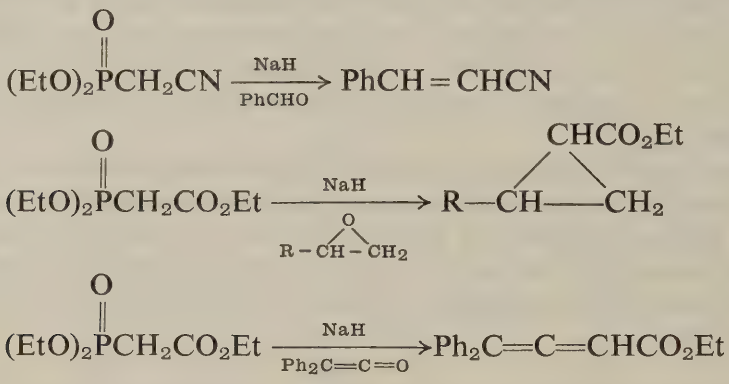
The α-hydrogen atom of phosphonates, particularly those with electronegative substituents attached to the α-carbon atom, is replaceable by metals giving phosphonate anion salts which can be alkylated with alkyl halides. Tetra-alkyl methylenediphosphonate[511] and trialkylphosphonacetic acid[510] react in this way:



$$(RO)_2\overset{O}{\overset{\|}{P}}-CH_2-X \xrightarrow{K} (RO)_2\overset{O}{\overset{\|}{P}}-\bar{C}HXK^+ \xrightarrow{MeI} (RO)_2\overset{O\ Me}{\overset{\|\ \ |}{PCH}}-X$$

$(X = -CO_2Et \text{ or } -PO.(OR)_2)$

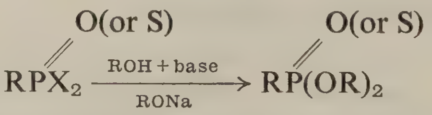
The preparation and characterization of a number of salts NaL, $ZnL_2$, $CrL_3$ (where L = the phosphonate anion $(EtO)_2PO.CH\text{–}COCH_3{}^-$) are reported.[1489] Wadsworth and Emmons[512] have extended the use of phosphonate anions to olefin synthesis using sodium hydride for their generation. Reaction of the anion with aldehydes or ketones, epoxides and ketenes yields olefins, *cyclo*propanes and allenes respectively. Olefins formed by this method generally have a *trans*-configuration about the C=C double bond.[441] The reaction between optically active styrene oxide and phosphonate carbanions proceeds with inversion of configuration at the asymmetric centre[1306, 1312]:



Further work on olefin preparations by this method is described.[1513-6]

### PREPARATION

The direct esterification of phosphonic acids with alcohols has not been reported. Alkyl esters may be obtained from the phosphonyl dihalide by treatment with an excess of the alcohol in the cold under reduced pressure to remove hydrogen chloride,[309] or more generally by use of alcohol and tertiary base or sodium alkoxide. Boron trifluoride catalyzes the reaction of phosphonodichloridothionates with alcohols.[524] Aryl esters are not dealkylated by hydrogen chloride and can be prepared by heating the phosphonyl dihalide and phenol:



Transesterification, although slow, may be used to prepare mixed and higher esters of alkane phosphonic acid[414, 715] (see also p. 1033).

$$MePO.(OEt)_2 + ROH \xrightarrow{\text{base}} MePO.OEtOR + EtOH \xrightarrow{ROH} MePO(OR)_2 + EtOH$$

Asymmetric esters of alkyl and aryl phosphonic acids may be obtained by treating a tetramethylammonium methylphosphonate with alkyl halides[2378]:

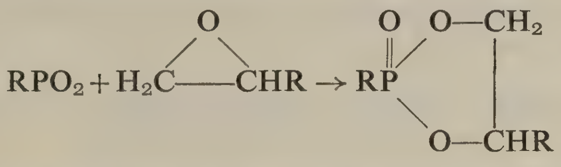
$$\mathrm{RPO(OMe)_2 + Me_3N \rightarrow RP(O)(OMe)O^- Me_4N^+ \xrightarrow{RX} RP(O)(OMe)OR + Me_4NX}$$

Numerous alkyl- and substituted alkylphosphonic acids have been prepared by reactions which start with dialkyl hydrogen phosphonates or trialkyl phosphites (pages 988, 989, 991, 994, 1006).

Vinyl esters, $\mathrm{RPO(OCH{=}CH_2)_2}$, are formed in the reaction of the corresponding chlorides with acetaldehyde and tertiary amine[1506]:

$$\mathrm{RPOCl_2 + CH_3CHO \xrightarrow{Et_3N} RPO(OCH{=}CH_2)_2} \qquad (\mathrm{R} = \text{alkyl, vinyl, aryl})$$

Cyclic esters of alkylphosphonic acids have been obtained by the action of oxiranes on phosphonic acid anhydrides[2056]:



Dialkylselenophosphonic acid can be readily obtained by refluxing an equimolar mixture of alkylphosphonous dichloride, alcohol and selenium in benzene solution. Similar preparation of the tellurium analogues failed, owing to their instability.[2058]

Photolysis of iodobenzene in the presence of trialkyl phosphite affords a mixture of dialkyl phenylphosphonate and alkyl iodide. The only competing reaction is the Arbuzov reaction between the phosphite and by-product alkyl iodide. An excess of phosphite and low temperature favour high yields. In a similar reaction triphenylphosphine and triphenyl phosphite give phosphonium salts[2006, 2415]:

$$\mathrm{PhI + (RO)_3P \xrightarrow{u.v.} PhPO(OR)_2 + RI}$$
$$\mathrm{PhI + (PhO)_3P \xrightarrow{u.v.} PhP(OPh)_3{}^+I^-}$$
$$\mathrm{PhI + Ph_3P \xrightarrow{u.v.} Ph_4\overset{+}{P}I^-}$$

Photolysis of 5-valent phosphorus compounds having a P–H bond and chlorine in an excess of *cyclo*hexane gives 75–85% yields of compounds with a *P–cyclo*hexyl bond. Dialkyl *cyclo*hexyl phosphonates are formed from dialkyl phosphites, alkyl phosphonite affords a phosphinic ester and secondary phosphine oxide a tertiary phosphine oxide. Similar radical reactions take place using compounds having a P–Cl bond and are catalyzed by radiation below 220 mμ[2416]:

$$\mathrm{(RO)_2P(O)H + C_6H_{12} + Cl_2 \xrightarrow{u.v.} C_6H_{11}PO(OR)_2}$$
$$\mathrm{RO(R)P(O)H + C_6H_{12} + Cl_2 \xrightarrow{u.v.} C_6H_{11}(R)P(O)OR}$$
$$\mathrm{Et_2P(O)Cl + C_6H_{12} \xrightarrow{u.v.} Et_2P(O)C_6H_{11}}$$

### **Phosphinous Acids** (see Secondary Phosphine Oxides)

#### ESTERS OF PHOSPHINOUS ACIDS, $\mathrm{R_2P{-}OR}$

Phosphinite and phosphinothioite esters have been prepared by the action of alcohols or mercaptans on phosphinyl halides in the presence of tertiary organic bases[329, 526, 1919, 2387] and by the action of alcohols on *N,N*-dimethyl phosphinous amides[413, 576]:

$$\mathrm{R_2PCl + R'OH \xrightarrow{R_3N} R_2POR' + R_3N,HCl}$$
$$\mathrm{R_2PCl + R'SH \xrightarrow{R_3N} R_2PSR' + R_3N,HCl}$$
$$\mathrm{R_2P{-}NMe_2 + R'OH \rightarrow R_2P{-}OR' + Me_2NH}$$

Grignard reagents react with phosphorodichloridites[411, 494] or with *O*-alkyl phosphonochloridites[544] giving the phosphinite ester. The use of powdered Grignard reagent in non-ethereal solvents gives good yields[525]:

$$RO{-}PCl_2 + 2R'MgX \rightarrow R'_2P{-}OR$$

*N,N*-Dimethyl phosphinous amides may be synthesized from aryl-lithium compounds and *N,N*-dimethyl-*O*-alkylphosphorochloridite[576] from the phosphinous halides and dimethylamine or by alkylation of *N,N*-dimethyl phosphoroamidodichloridite with organo-aluminium[477] compounds. They exchange with phosphorus trichloride to form phosphinous chloride[477]:

$$3Me_2NPCl_2 + 2AlR_3 \rightarrow 3Me_2NPR_2 + 2AlCl_3$$
$$Et_2NPEt_2 + PCl_3 \rightarrow Et_2NPCl_2 + Et_2PCl$$

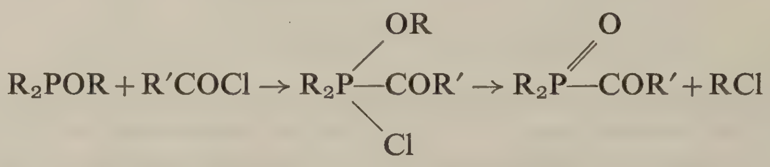
Acyl bis(trifluoromethyl)phosphinates have been recently described; they are prepared by the reactions[1597]:

$$(CF_3)_2PX + AgOAc \rightarrow (CF_3)_2POCOCH_3 \qquad (X = Cl, Br)$$
$$[(CF_3)_2P]_2O + (CH_3CO)_2O \rightarrow (CF_3)_2POCOCH_3$$

The phosphinite esters readily undergo typical reactions of trivalent phosphorus compounds, forming complexes with heavy metal halides such as cuprous halides[1919] and adding sulphur to give phosphinothioic esters.[526] They readily isomerize on heating giving tertiary phosphine oxides. The order of reactivity of trivalent phosphorus compounds with alkyl halides increases in the series[527]:

$$(RO)_3P < RP(OR')_2 < R_2POR' < R_3P$$

Reaction of phosphinites with alkyl halides such as methyl iodide, or acyl halides, in the Arbuzov reaction is spontaneous and exothermic.[526, 1919] Several examples of isolable onium intermediates are reported[2387, 2388]:



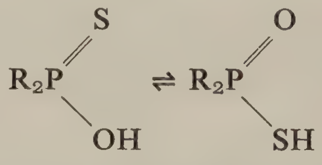
$$R_2POR + R'COCl \rightarrow R_2\overset{OR}{\underset{Cl}{P}}{-}COR' \rightarrow R_2\overset{O}{\overset{\|}{P}}{-}COR' + RCl$$

Alkyl diphenylphosphonites undergo the expected Perkow reaction with chloral to form *β,β*-dichlorovinyl diphenylphosphinate.[494] In common with esters of phosphorous and phosphonous acids, the phosphinous lower esters readily undergo transesterification[577]:

$$R_2POEt + R'OH \rightarrow R_2POR' + EtOH$$

## Phosphinic Acids, $R_2PO_2H$

These are monobasic acids which are generally crystalline. Dissociation constants of several symmetrical dialkylphosphinic acids are given by Crofts and Kosolapoff[364] and by Kabachnik *et al.*[1269, 1274] The position of the equilibrium,



$$R_2\overset{S}{\overset{\|}{P}}{-}OH \rightleftharpoons R_2\overset{O}{\overset{\|}{P}}{-}SH$$

in monothiophosphinic acids has been determined from p$K$ measurements on the acids[1269] (see Table VII, p. 1036). Acid strengths of diethylphosphinic acids increase on replacing the oxygen atoms successively by sulphur and selenium (cf. ref. 2389).

The diseleno acid is stable for only a short time in aqueous solution; salts such as $Et_2P(Se)SeNa,2H_2O$ can be isolated.

p*K* in 80% aqueous *iso*propyl alcohol

| $Et_2PO_2H$ | $Et_2P(S)OH$ | $Et_2P(S)SH$ | $Et_2P(S)SeH$ | $Et_2P(Se)SeH$ |
|---|---|---|---|---|
| | 4·98 | 2·6 | 2·29 | 2·18 |

The vapour pressures of liquid $Me_2PO_2H$, b.p. 377° at 760 mm. Hg, are recorded.[1388] The C–P bond in these compounds, like that in phosphonic acids, is very stable; exceptions are compounds having α-hydroxy, α-keto, trichloromethyl or trifluoromethyl groups attached to the phosphorus atom.

PREPARATION

Common methods of preparation are by hydrolysis of phosphinyl halides and hydrolysis of phosphinic esters:

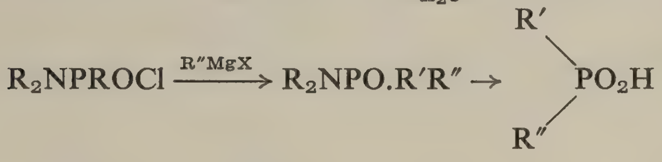
$$R_2POCl \xrightarrow{H_2O} R_2PO_2H$$
$$R_2PSCl \xrightarrow{H_2O} R_2PS.OH^{430}$$
$$R_2PSCl \xrightarrow{NaSH} R_2PS_2H^{429}$$
$$R_2POOR \xrightarrow{HCl} R_2PO_2H$$

A number of the more important methods of synthesizing phosphinic acids have been mentioned earlier. These are, hydrolysis of Kinnear–Perren complexes and diaryldichlorophosphonium tetrafluoroborates, the fission of tertiary phosphine oxides with sodium hydroxide, and the reaction of phosphorus pentasulphide, aluminium trichloride aromatic and hydrocarbons, giving dithio acids. Other methods are:

*From Grignard Reactions*

Grignard reagents react with phosphorus oxychloride replacing the chlorine atoms in a stepwise manner giving tertiary phosphine oxides as final products. By reverse addition two chlorine atoms may be replaced giving, after hydrolysis, the phosphinic acid.[431–2] A better method involves replacement of one chlorine atom in phosphoryl chloride[433] or a phosphonyl dichloride[382, 435] with a dialkylamine giving *N,N*-dialkyl phosphoramidic dichloride and *N,N*-dialkyl phosphonamidic chloride respectively, followed by reaction with Grignard reagent:

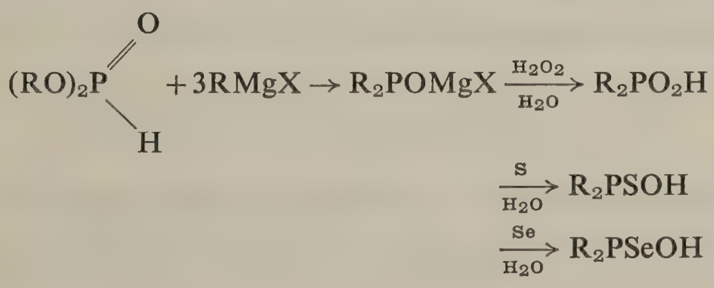
$$POCl_3 + 2RMgX \rightarrow R_2POCl.2MgXCl \xrightarrow{H_2O} R_2PO_2H$$
$$R_2NPOCl_2 \xrightarrow{2R'MgX} R_2NPOR'_2 \xrightarrow[H_2O]{H^+} R'_2PO_2H$$



$$R_2NPROCl \xrightarrow{R''MgX} R_2NPO.R'R'' \rightarrow R'R''PO_2H$$

*Miscellaneous Methods*

Grignard reagents react with dialkyl hydrogen phosphonates giving secondary phosphine oxides which may be oxidized with hydrogen peroxide to the phosphinic acid.[364] Phosphinothioic and phosphinoselenoic acids have been obtained by adding sulphur[430] or selenium[428] to the intermediate magnesium halide salt of the phosphine oxide:



$$(RO)_2P(O)H + 3RMgX \rightarrow R_2POMgX \xrightarrow[H_2O]{H_2O_2} R_2PO_2H$$
$$\xrightarrow[H_2O]{S} R_2PSOH$$
$$\xrightarrow[H_2O]{Se} R_2PSeOH$$

Tetrasubstituted diphosphine disulphides are an important starting point for the synthesis of symmetrical and unsymmetrical phosphinic acids. They are readily oxidized to phosphinic acids,[426, 1903] and by treatment with elemental sulphur and ammonium hydroxide[585] or with sulphur and sodium sulphide[586] yield ammonium or sodium salts of the corresponding phosphinodithioic acids. Phosphorus pentasulphide and methyl magnesium bromide give a small yield of dimethyl phosphinodithionate (isolated as the nickel salt).[134] The dithio acids are readily oxidized by iodine to bis(thiophosphinyl) disulphides.[586] Heavy metal salts of phosphinodithioic acids have been described.[2390]

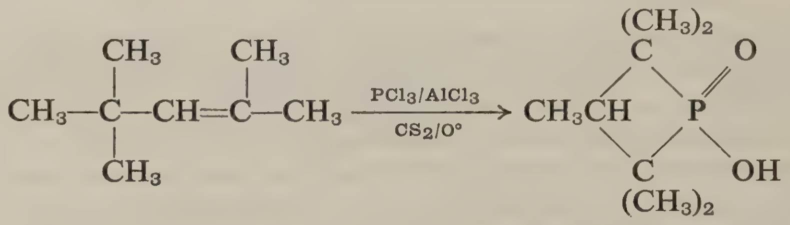
Tertiary aromatic amines such as *N,N*-dimethylaniline react with phosphoryl chloride replacing the chlorine atoms successively with *p*-dialkylaminophenyl groups. Use of two equivalents of dimethylaniline gives, after hydrolysis, bis(*p*-dimethylaminophenyl)phosphinic acid together with some tris(*p*-dimethylaminophenyl)-phosphine oxide and bis(*p*-dimethylaminophenyl)methane.[424–5] Hypophosphorous acid adds to olefins with free-radical catalysts giving phosphinic acids[443–4]:

$$H_2PO_2H + 2RCH{=}CH_2 \rightarrow (RCH_2CH_2)_2PO_2H$$

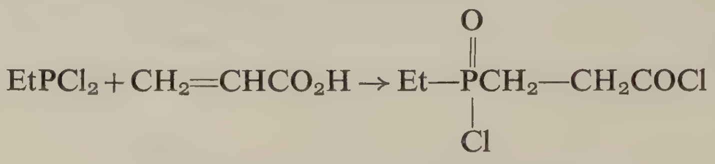
and to aldehydes giving bis(α-hydroxyalkyl)phosphinic acids. Sodium hypophosphite and formaldehyde react at 130°–135° giving sodium bishydroxymethylphosphinate[1734]:

$$NaH_2PO_2 + HCHO \xrightarrow{135^\circ} (HOCH_2)PO_2Na \xrightarrow{HCl} (HOCH_2)_2PO_2H \qquad (93\%\ \text{yield})$$

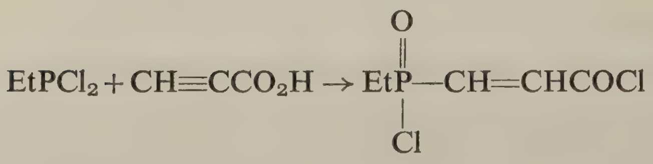
A comparatively new method of forming carbon–phosphorus bonds is the interaction of phosphorus trichloride, aluminium trichloride and olefins.[1461] By this method 1,1,2,3,3-pentamethyltrimethylenephosphinic acid chloride may be obtained from 2,4,4-trimethyl-2-pentene followed by partial hydrolysis of the intermediate complex; complete hydrolysis yields the corresponding acid:



Ethyl dichlorophosphine adds to the double bond of unsaturated acids such as acrylic acid and propiolic acid to form phosphinyl chloride derivatives which can be hydrolyzed to the acids or esterified[2391–2]:



$$EtPCl_2 + CH_2{=}CHCO_2H \rightarrow Et{-}\underset{\displaystyle Cl}{\overset{\displaystyle O}{\overset{\|}{\underset{|}{P}}}}CH_2{-}CH_2COCl$$

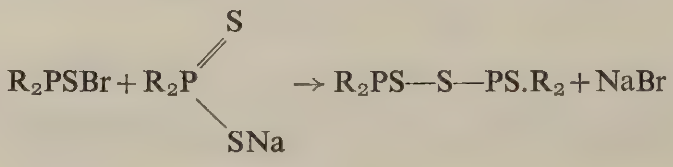


$$EtPCl_2 + CH{\equiv}CCO_2H \rightarrow Et\underset{\displaystyle Cl}{\overset{\displaystyle O}{\overset{\|}{\underset{|}{P}}}}{-}CH{=}CHCOCl$$

PHOSPHINIC ACID ANHYDRIDES

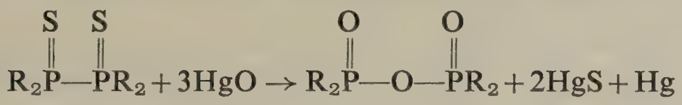
These have been prepared by the reactions[426, 1487, 1566]:

$$R_2POCl + R_2PO.OEt \xrightarrow{\text{heat}} R_2PO{-}OPO.R_2 + EtCl$$



$$R_2PSBr + R_2P\begin{matrix}{/\!\!/}S\\ \diagdown SNa\end{matrix} \rightarrow R_2PS{-}S{-}PS.R_2 + NaBr$$

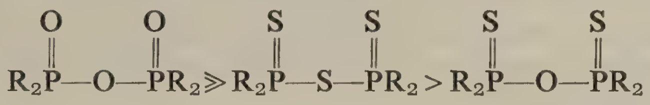
and from tetra-alkylphosphine disulphides by treatment with mercuric oxide[587, 1903]:



$$R_2\overset{\overset{S}{\|}}{P}-\overset{\overset{S}{\|}}{P}R_2 + 3HgO \rightarrow R_2\overset{\overset{O}{\|}}{P}-O-\overset{\overset{O}{\|}}{P}R_2 + 2HgS + Hg$$

Diphenylphosphinodithioic acid loses hydrogen sulphide on heating to give the trithioanhydride.[427]

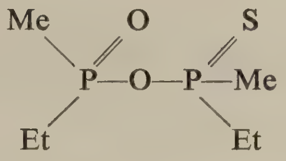
The oxygen compounds are much more readily hydrolyzed than tetra-alkyl pyrophosphates,[426] and react with alcohols giving equimolar amounts of acid and alkyl ester. In alkylpyrophosphinates the rates of hydrolysis of oxygen- and sulphur-containing compounds decreases in the order:

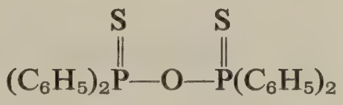


$$R_2\overset{\overset{O}{\|}}{P}-O-\overset{\overset{O}{\|}}{P}R_2 \gg R_2\overset{\overset{S}{\|}}{P}-S-\overset{\overset{S}{\|}}{P}R_2 > R_2\overset{\overset{S}{\|}}{P}-O-\overset{\overset{S}{\|}}{P}R_2$$

With respect to the R group the rate sequence is $C_3H_7 > C_2H_5$.[587]

The nuclear magnetic resonance spectra of dimethyl diethyl monothiopyrophosphinate and tetraphenyl dithiopyrophosphinate indicate the compounds to have the thiono structure[1566]:





$$(C_6H_5)_2\overset{\overset{S}{\|}}{P}-O-\overset{\overset{S}{\|}}{P}(C_6H_5)_2$$

Bis(thiophosphinyl) disulphides and trisulphides result from the action of iodine or sulphur dichloride respectively on the phosphinyldithioic acid.[586]

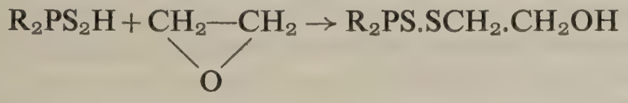
PHOSPHINIC ESTERS

These may be prepared by conventional methods from the phosphinyl halide

$$R_2POX \xrightarrow{NaOR'} R_2POOR'$$

and $$R_2PSX \xrightarrow{NaOR'} R_2PS.OR'$$

Esters of unsymmetrical acids have been obtained from esters of phosphonous acids by the Arbuzov reaction. Dithio esters are formed by the addition of the thio acids to ethylene oxide[429] or to electronegatively substituted olefins,[445] or by the reaction of the salts of the acid with alkyl halide[586, 2393]:



$$R_2PS_2H + CH_2{=}CHX \rightarrow R_2PS.SCH_2CH_2X \qquad (X = CN, CNO, CO_2R)$$

A number of esters of the type RR′PO.OR″ having an asymmetric phosphorus atom have been resolved.[417, 574, 589] Use of optically active *O*-methyl phenyl ethyl phosphinate has shown that, in methoxyl exchange with methoxide ion in methyl alcohol, each exchange involves inversion of configuration at the phosphorus atom.[591] Similarly, compounds $Me(\alpha\text{-}C_{10}H_8)POX$ (where $X = -SCH_2Ph$, Cl, F) react with methoxide ion giving the methyl ester with predominant inversion of configuration.[496, 590]

## DERIVATIVES OF PHOSPHOROUS ACID

### The Reaction of Phosphorus Trihalides with Hydroxy Compounds

Phosphorus trihalides are used both for the replacement of hydroxyl groups in alcohols with halogen groups and for the preparation of esters of phosphorous acid;

these two functions have been correlated, and the sequence of reactions which occurs has been studied by Gerrard and co-workers.[592–4, 596–601, 939]

Addition of an alcohol to phosphorus trihalide at 0° in the absence of a base results in rapid stepwise alkoxylation giving successively alkyl phosphorodichloridite, dialkyl phosphorochloridite, and trialkyl phosphite[592]:

$$\text{(1)} \qquad ROH + PCl_3 \rightarrow ROPCl_2 + HCl \qquad \text{(fast)}$$
$$\text{(2)} \qquad ROH + ROPCl_2 \rightarrow (RO)_2PCl + HCl$$
$$\text{(3)} \qquad ROH + (RO)_2PCl \rightarrow (RO)_3P + HCl$$

These reactions compete with dealkylation of the esters by hydrogen halide giving alkyl halide; the relative rates of dealkylation of the chloro esters by hydrogen chloride are $ROPCl_2 < (RO)_2PCl < (RO)_3P$[592]; and *n*-alkyl < *sec*-alkyl < *tert*-alkyl. For the corresponding bromo- and iodo-compounds with corresponding hydrogen halide the relative rates are[599]

$$HCl < HBr < HI.$$

With tributyl phosphite and hydrogen chloride at 0°C. the dealkylation is fairly fast[593]:

$$\text{(4)} \qquad (RO)_3P + HCl \rightarrow RCl + (RO)_2POH$$

the overall reaction becoming:

$$\text{(5)} \qquad 3ROH + PCl_3 \rightarrow (RO)_2POH + 2HCl + RCl$$

Gerrard[799] mentions only two exceptions to dealkylation of trialkyl phosphites according to Equation (4). These are $(Cl_3CCH_2O)_3P$[799] and $[(Cl_3C)_2CHO]_3P$,[798] which react with hydrogen chloride or bromide giving phosphorohalidite and alcohol. Further dealkylation of the dialkyl phosphite to monoalkyl phosphite and thence to phosphorous acid occurs. The rates of dealkylation are, for a given ester with respect to hydrogen halide, $HI > HBr \gg HCl$[593–4] and for a given halide with respect to the phosphite, $P(OR)_3 \gg (RO)_2POH > ROPO_2H_2$.

In reaction (4) phosphites derived from optically active alcohols such as 2-octanol give the alkyl halide (Cl, Br, I) with predominant inversion of configuration.[594, 596–8]

Dealkylation of di-*iso*propyl phosphite by HCl was studied by Campbell and Chadwick.[595] It was found that the phosphite forms with hydrogen chloride a complex having $\Delta H = 10{\cdot}7$ kcal./mole. Dealkylation proceeds by attack of free hydrogen chloride on this complex.

Phosphorus trifluoride is reported to react with alcohols giving organic phosphites,[842] the exact nature of which is unspecified.

### Phosphorohalidites, $(RO)_nPX_{3-n}$, $n = 1$ or 2, X = halogen

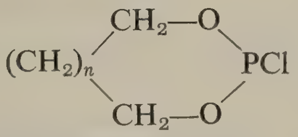
Alkyl phosphorodichloridites are generally prepared by the addition of an alcohol to a slight excess of phosphorus trichloride at room temperature.[824–5, 837, 1070] Generally a stream of inert gas is passed through the solution during and after the reaction to assist removal of hydrogen chloride before distillation. Alkyl phosphorobromidites have been obtained similarly by carrying out the reaction at −15°C.[601] Alkyl phosphorodiiodites have not been reported. Aromatic and sulphur-containing derivatives, $ArOPCl_2$, $ArSPCl_2$, $AlkSPCl_2$, have been obtained by similar methods at somewhat higher reaction temperatures[1] using phenol, thiophenol and alkyl mercaptan, respectively. Good yields of aryl phosphorodichloridites are obtained by treating phenols with an excess of phosphorus trichloride under reflux in the presence of anhydrous magnesium chloride catalyst.[1682] Trichloromethylsulphenyl chloride reacts with tetraphosphorus heptasulphide giving $Cl_3CSPCl_2$, together with

$Cl_3CSPSCl_2$ and $(Cl_3CS)_2PSCl$.[826] Elemental phosphorus and sulphenyl chlorides react to form a mixture of $RSPCl_2$, $(RS)_2PCl$, and $(RS)_3P$.[827]

Dialkyl phosphorochloridites[600] and dialkyl phosphorobromidites,[601] and the corresponding aryl and thiol derivatives, are obtained in poor yield by the addition of two equivalents of an alcohol, phenol or mercaptan, to phosphorus trihalide. Better yields are obtained by conducting the reaction in an inert solvent at low temperature in the presence of two equivalents of a tertiary organic base,[829, 1070] or by further alkylation of a phosphorochloridite with an alcohol in the presence of a tertiary base[532, 1070] or a sodium alkoxide[837] or by the equilibration of phosphorus trichloride and a trialkyl phosphite at room temperature[600, 1070]:

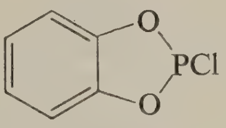
$$PCl_3 + 2ROH + 2B \rightarrow (RO)_2PCl + 2BHCl \qquad (B = \text{base})$$
$$ROPCl_2 + RONa \rightarrow (RO)_2PCl + NaCl$$
$$PCl_3 + 2P(OR)_3 \rightarrow 3(RO)_2PCl$$

1,2- 1,3- and 1,4-Glycols,[781, 796-7, 828] catechol[831, 877] and salicylic acid,[830] react with phosphorus trichloride giving fair yields of phosphorochloridites in which the phosphorus atom forms part of a 1,3,2-dioxaphospholane ring, compounds **I**, **II** and **III** respectively.

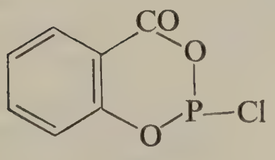


$n = 0, 1, 2$

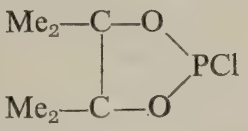
**I**



**II**



**III**

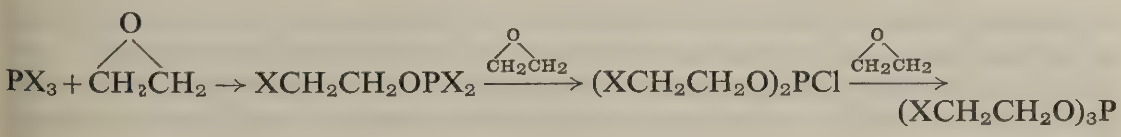


**IV**

$^1$H-Nuclear magnetic resonance of 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane, **IV**, indicates a relatively stable pyramidal stereochemical configuration about the phosphorus atom.[1082]

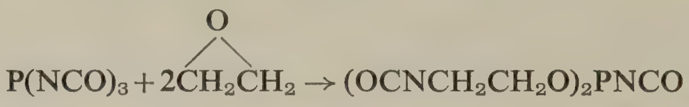
Equilibration in the systems $(PhO)_3P$–$PCl_3$,[833] $(EtO)_3$–$PCl_3$[1683] and $(EtS)_3P$–$PCl_3$[1713] has been studied by Van Wazer. In the triphenyl phosphite system no reaction takes place during 15 hr. at room temperature; at equilibrium, after 66 hr. at 180°, nuclear magnetic resonance showed a mixture of products whose molar percentages were greater than expected for a purely random distribution of chloro- and phenoxy-groups. Thus, starting with a mixture having a 1 : 1 molar ratio of –Cl to –OPh groups the relative amounts of $PCl_3$, $PhOPCl_2$, $(PhO)_2PCl$ and $(PhO)_3P$ at equilibrium were 1 : 7 : 7 : 1. In the $PCl_3$–$P(OEt)_3$ system exchange occurs readily; equilibrium product determination shows that the intermediates are more stable than would be expected from a statistical distribution, the ratios $(EtO)_3P : (EtO)_2PCl : EtOPCl_2 : PCl_3$ being 1 : 7 : 7 : 1. In the $P(SBu)_3$–$PCl_3$ system the equilibrium ratios, after 48 hr. at 120°, of $(BuS)_3P : (BuS)_2PCl : BuSPCl_2 : PCl_3$ are 0·7 : 7 : 8·5 : 3.

2-Halogenoethyl phosphorodihalidites and phosphorohalidites have been obtained by the reaction of ethylene oxide with phosphorus trichloride[834, 1283] and tribromide[835]:



$$PX_3 + \overset{O}{CH_2CH_2} \rightarrow XCH_2CH_2OPX_2 \xrightarrow{\overset{O}{CH_2CH_2}} (XCH_2CH_2O)_2PCl \xrightarrow{\overset{O}{CH_2CH_2}} (XCH_2CH_2O)_3P$$

The pseudohalogen compound, phosphorus triisocyanate, reacts similarly with ethylene oxide giving bis- (2-cyanoethyl)phosphorus(III) *iso*cyanate[836]:



$$P(NCO)_3 + 2\overset{O}{CH_2CH_2} \rightarrow (OCNCH_2CH_2O)_2PNCO$$

Phosphorofluoridites $(RO)_nPF_{n-3}$ have been prepared by metathetical reactions from the corresponding chloridites using reagents such as sodium fluoride, potassium fluosulphinate, antimony(III) fluoride or arsenic(III) fluoride.[838, 841, 906, 935, 1072] Diethyl phosphorofluoridite can be obtained by reaction of ethyl alcohol with phosphorus dichlorofluoride.[1070] The fluoridites form Ni(0) and Mo(0) complexes such as $Ni(n\text{-}C_3H_7OPF_2)_4$ and $Mo(CO)_3.(n\text{-}C_3H_7OPF_2)_3$ by displacement of carbon monoxide from nickel or molybdenum carbonyl.[838]

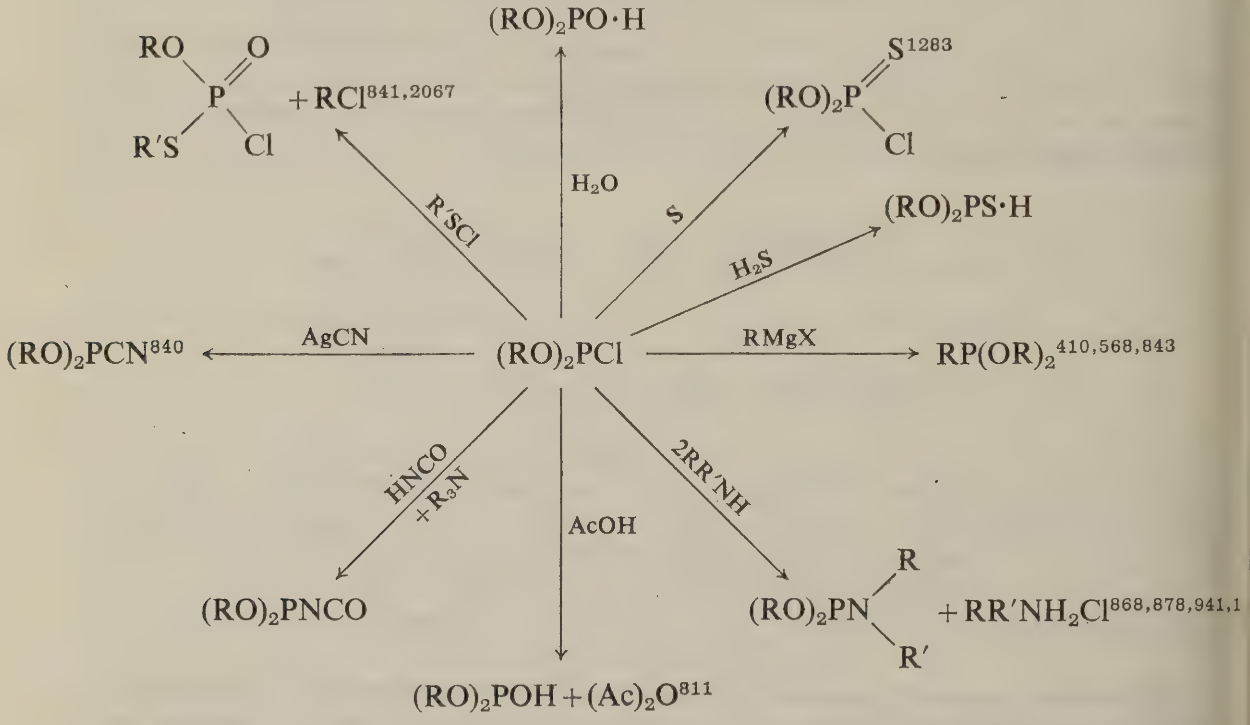


CHART XII.—Some typical reactions of phosphorochloridites

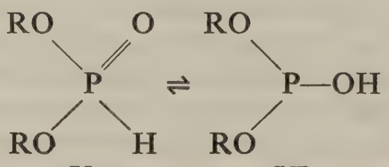
### Dialkyl Hydrogen Phosphonates and Dialkyl Hydrogen Phosphonothionates

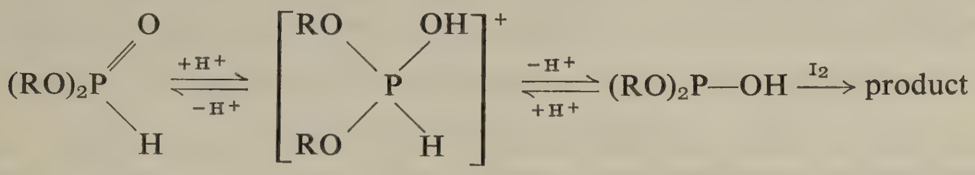
The structure of dialkyl phosphites was a subject of considerable controversy in the early days of organophosphorus chemistry. It is now generally agreed, on the basis of infra-red,[613] Raman,[611] ultra-violet,[612] P-nuclear magnetic resonance[602] and H-nuclear magnetic resonance[603] spectroscopy, that the compounds exist predominantly in the phosphonate structure **V** with no detectable amount of the phosphite form **VI**:



**V** **VI**

However, many reactions of the compounds which appear to proceed through the phosphite form, such as the slow reaction with sulphur and phenyl azide,[615] are difficult to explain without assuming the existence of a tautomeric equilibrium between the two forms. In a valuable review of the chemical and kinetic evidence, Doak and Freedman[604] conclude that the dialkyl phosphites do exist as equilibrium mixtures of the two tautomeric forms with an overwhelming preponderance of V.

Nylén[607] showed the rate of oxidation of diethyl phosphite by iodine or bromine to be proportional to the concentration of (RO)$_2$POH but of zero order with respect to halogen at high halogen concentration. He further found the reaction to be subject to general acid-base catalysis and proposed a prototropic shift as the rate-determining step in the oxidation:



In agreement with this Luz and Silver showed the rate of oxidation and rate of exchange of the P–H hydrogen in diethyl phosphite in acid solution to be the same.[605–6] Using (EtO)$_2$PO.H and (EtO)$_2$PO.D they demonstrated a kinetic isotope effect, $k^{\mathrm{H}}/k^{\mathrm{D}} = 4$, indicating the reaction to proceed by a fast pre-equilibrium protonation of the P=O group followed by slow rate-determining fission of the P–H bond. Deuterium exchange between (BuO)$_2$PO.H and *n*-butyl alcohol-*D* is subject to acid-base catalysis; in neutral solution the exchange rate is several orders lower than for the catalyzed reactions, and Bailey and Fox[614] conclude that if a tautomeric equilibrium exists in the neutral solution the concentration of enol form is of the order of $10^{-4}$ per cent. In the base-catalyzed exchange reaction removal of the P–H proton has been suggested to be the rate-controlling step.[614]

Dialkyl phosphites have much higher boiling points than the corresponding trialkyl phosphites. Many workers have cited this fact, together with results of Raman and infra-red spectroscopy, viscosity and parachor measurements, and M.W. determination to show that the compounds are associated in solution, with hydrogen-bonding usually suggested as the linkage. After carefully reviewing the work, Doak and Freedman[604] concluded that there is no convincing evidence for hydrogen-bonding but that in the liquid state, in the absence of solvent, association occurs through dipole–dipole interaction of the phosphoryl groups.

The proton nuclear magnetic resonance,[608] infra-red spectrum,[609] and molecular refraction of dialkyl hydrogen phosphorothionates confirm the phosphorothionate structure. The possibility of the existence of a tautomeric equilibrium as in dialkyl phosphites was suggested by Kabachnik *et al.*,[610] who concluded that the tautomeric shift to (RO)$_2$P–SH is relatively small.

Chemical evidence alone suggests that the equilibrium enol concentration decreases in the series (PhO)$_2$PO.H > (AlkO)$_2$PO.H > (AlkO)$_2$PS.H. Thus, in the absence of solvent, diphenyl phosphite reacts with sulphur giving diphenyl phosphonothioate[615]; with diethyl phosphite the reaction proceeds to 7% of completion in 8–9 hr. at 100°–105°[636] and with diethyl hydrogen phosphonothionate no reaction takes place in 5 hr. at 100°.[610] Relatively basic solvents have been suggested to favour formation of the enol form of the phosphite; the evidence advanced to support this idea is the increasing degree of sulphuration of diethyl phosphite in a series of solvents of increasing basicity; the solvent and percentage yields of (EtO)$_2$PSOH are: none, 7%; EtOH, 8·8%; PhMe, 10·6%; C$_6$H$_6$, 12·6%; Et$_2$O, 13·5%; dioxan, 68–73%.[616]

### PREPARATION OF DIALKYL AND DIARYL HYDROGEN PHOSPHONATES

The most generally used method of preparing dialkyl compounds is by the interaction of three or more moles of an alcohol with phosphorus trichloride (Equation (4), p. 982). Various solvents, such as benzene, carbon tetrachloride, methyl chloride[617] or butane,[618] have been suggested, particularly for the preparation of lower alkyl and the *iso*propyl compounds where effective cooling is more difficult and high reaction temperatures must be avoided to prevent dealkylation of the phosphite by hydrogen chloride. The heat of reaction of phosphorus trichloride with methanol is 42 kcal./mole in the reaction zone and 32 kcal./mole when all the hydrogen chloride has been removed.[617] With *iso*propanol the heat of reaction is 42 kcal./mole; the heat of solution of hydrogen chloride in the phosphite to give (*iso*-$C_3H_7O)_2PO.H.HCl$ is 10·7 kcal./mole.[595, 619] Continuously operating processes for the preparation of dialkyl phosphites have been described.[617, 619]

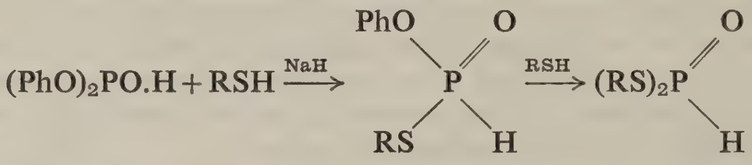
Tertiary organic bases (2 moles) have been used to prepare compounds such as dibenzyl phosphite which are very readily dealkylated by hydrogen chloride[620]:

$$3PhCH_2OH + PCl_3 + 2R_3N \rightarrow (PhCH_2O)_2PO.H + PhCH_2Cl + 2R_3N,HCl$$

A modification of the standard procedure which avoids the loss of one mole of alcohol as alkyl chloride is the reaction[621–2, 1088]:

$$2ROH + H_2O + PCl_3 \rightarrow (RO)_2PO.H + 3HCl$$

Dialkyl phosphites derived from higher molecular-weight alcohols[625–7] and mixed alkyl phosphites[624] have been prepared by transesterification of the lower dialkyl phosphites with higher alcohols (review, ref. 2398). The reaction proceeds smoothly in the presence of a catalyst such as a metal alkoxide or amide or phosphoric acid. Van Wazer finds that equilibration occurs between dimethyl or diethyl phosphite with acid but not basic catalysts. The equilibrium constant is close to the random value.[1713] Diphenyl phosphite undergoes transesterification with alcohols at about 100°,[628] compared with temperatures of up to 160° required for dialkyl phosphites. Transesterification of diphenyl phosphite with mercaptans in the presence of sodium hydride catalyst has been used to prepare *O*-phenyl, *S*-alkyl hydrogen phosphonothiolates and *S,S*-dialkyl hydrogen phosphonodithiolates[846]:



$$(PhO)_2PO.H + RSH \xrightarrow{NaH} (PhO)(RS)P(=O)H \xrightarrow{RSH} (RS)_2P(=O)H$$

Dialkyl phosphites of higher molecular weight are also obtained in good yield by the direct esterification of phosphorous acid with alcohol using catalysts such as zinc chloride, sulphuric acid or potassium acetate.[566, 623]

Diphenyl phosphite and bis-2-chloroalkyl phosphites are best prepared by the proportionation of the corresponding tertiary phosphite with phosphorous acid[632, 1073]:

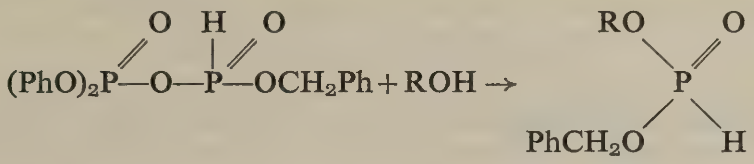
$$2(PhO)_3P + H_3PO_3 \rightarrow 3(PhO)_2PO.H$$

### MISCELLANEOUS METHODS

Dialkyl phosphites have been prepared by introducing oxygen into a suspension of white phosphorus in an alcohol,[629] by the reaction of diazoalkanes such as diazomethane[630] or phenyldiazomethane[620] with phosphorous acid and by the alkylation of salts of phosphorous acid, e.g., $Na_2HPO_3$, with dimethyl sulphate.[631] Bis-trialkylsilyl phosphites can be prepared by the slow distillation of a mixture of a trialkylmethoxysilane with $H_3PO_3$,[1074] or by esterification of phosphorous acid with hexa-alkyl disiloxane[2399]:

$$CH_3OSiR'_3 + H_3PO_3 \rightarrow (R'_3SiO)_2PO.H + CH_3OH\uparrow$$
$$H_3PO_3 + (Me_3Si)_2O \xrightarrow{ZnCl_2} (Me_3SiO)_2PO.H + H_2O\uparrow$$

Todd and co-workers[1598] showed that solutions of *O'*-benzyl-*O,O*-diphenyl phosphoric anhydride, formed by the reaction of monobenzyl phosphite with diphenyl phosphorochloridate or tetraphenyl pyrophosphate, react with alcohols giving alkyl benzyl phosphites:



$$(PhO)_2P(O){-}O{-}P(O)(H){-}OCH_2Ph + ROH \rightarrow (RO)(PhCH_2O)P(O)H$$

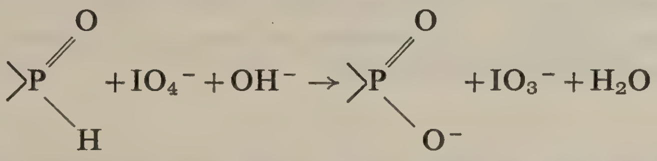
Benzyl nucleoside-5′-phosphites were used as intermediates for the synthesis of nucleosides-5′-pyro- and tri-phosphates.[1589, 1599]

## Reactions of Dialkyl Phosphites

Dialkyl phosphites are extremely versatile reagents which undergo reactions in which the phosphorus atom can act as a nucleophilic, electrophilic or free-radical centre. Many of the reactions involve the P–H hydrogen atom and are in general base-catalyzed. In this respect the hydrogen atom may be considered roughly comparable in its chemical reactions with the hydrogen atoms of the active methylene groups of malonic ester or ethyl acetoacetate.

### OXIDATION

Dialkyl phosphites are stable to atmospheric oxidation; amongst the reagents suggested for their oxidation to dialkyl phosphates are aqueous potassium permanganate,[708] aqueous chloramine-*T*,[637] nitrogen tetroxide,[707, 1117–8] lead tetra-acetate[889] and peracids.[1116] Brown and Hammond[1114] investigated the oxidation of dibenzyl phosphite by permanganate, periodate, iodate and hypochlorite: of these the preferred reagent was periodate in mildly alkaline solution which reacts according to the equation:

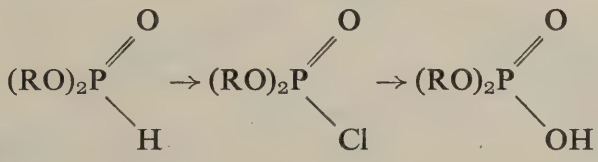


$$>P(O)H + IO_4^- + OH^- \rightarrow >P(O)O^- + IO_3^- + H_2O$$

One of the most successful methods for preparing dialkyl phosphates from the corresponding hydrogen phosphonate is oxidation with nitric oxide[638, 862]:

$$(RO)_2PO.H + NO \rightarrow (RO)_2PO_2H$$

Reaction with nitrosyl chloride in the presence of pyridine yields the corresponding tetra-alkyl pyrophosphate.[1077, 1542] An indirect method of oxidation to dialkyl phosphate involves chlorination to the phosphorochloridate followed by hydrolysis:



$$(RO)_2P(O)H \rightarrow (RO)_2P(O)Cl \rightarrow (RO)_2P(O)OH$$

### HALOGENATION

The dialkyl phosphites are readily chlorinated by elemental chlorine[706] or by sulphuryl chloride with or without solvent to give high yields of the corresponding dialkyl phosphorochloridates:

$$(RO)_2PO.H + SO_2Cl_2 \rightarrow (RO)_2PO.Cl + SO_2 + HCl$$

Chlorination with reagents such as *N*-chlorosuccinimide[1599] and *N*,*N*-dichlorobenzene sulphonamide[671] similarly yields the phosphorochloridate, but sulphur dichloride[709-10] and dimethylaminosulphenyl chloride[710,1078] (usually with a neutralizing agent such as pyridine) give a tetra-alkyl monothiopyrophosphate. Sulphur monochloride gives bis-dialkoxy-phosphinodisulphides,

$$(RO)_2PO—S—S—PO.OR_2{}^{1186}$$

Direct bromination with elemental bromine is unsatisfactory owing to the ready dealkylating action of the hydrogen bromide produced[902]; the dialkyl phosphorobromidate may, however, be prepared using *N*-bromosuccinimide.[639] Practically no reaction takes place at room temperature between dialkyl phosphites and iodine owing to the reduction of the phosphoroiodidate with hydrogen iodide,[700] $(RO)_2PO.H+I_2 \rightleftharpoons (RO)_2PO.I+HI$. For this reason the dialkyl phosphoroiodidates have been prepared by the action of iodine on the corresponding trialkyl phosphites.[700]

Pseudohalogens behave like chlorine, thiocyanogen forming dialkyl phosphorothiocyanatidate, $(RO)_2PO.NCS$.[640]

### REACTION WITH CARBONYL COMPOUNDS

Dialkyl α-hydroxy phosphonates are formed by the addition of dialkyl phosphites to aldehydes and ketones. Generally a basic catalyst[503,646,1685] has been used to catalyze the reaction, although free-radical catalysis has been reported.[645] Reaction with active aldehydes such as chloral will occur in the absence of a catalyst.[641,644,908,1192] With α-unsaturated aldehydes the products are the expected dialkyl 1-hydroxy-2-vinyl phosphonates,[642] but α-unsaturated ketones generally undergo primary addition of the dialkyl phosphite to the C=C double bond giving a γ-keto-phosphonate which may undergo reaction with a second molecule of dialkyl phosphite at the carbonyl group.[643] Keten and dialkyl phosphites react in the presence of boron trifluoride or sulphuric acid catalyst giving 1-acetoxy-vinyl phosphonates.[748] Diacetyl forms the expected 1-hydroxy-2-keto-phosphonate if the reaction is conducted at 100°, but at higher temperatures the product is an isomeric phosphate.[665] These reactions are shown in Chart XIII.

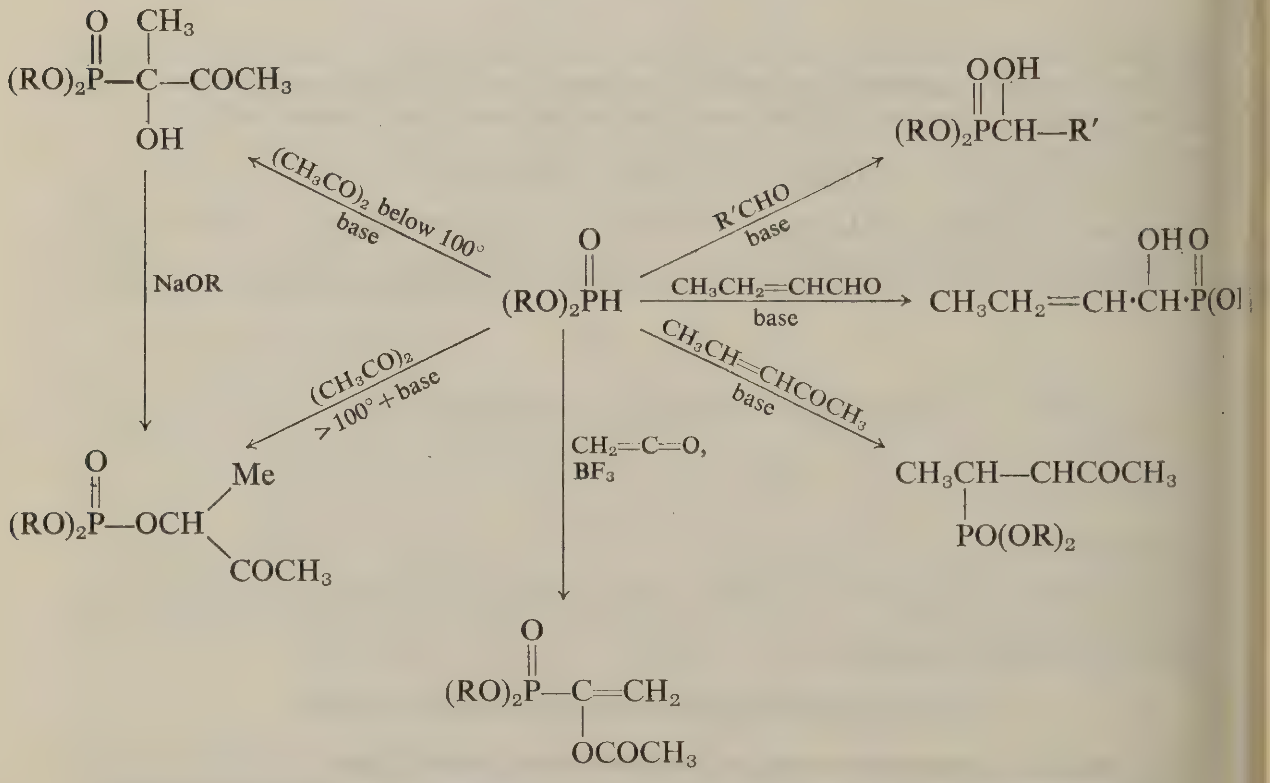


CHART XIII.—Some reactions of dialkyl phosphites with carbonyl compounds

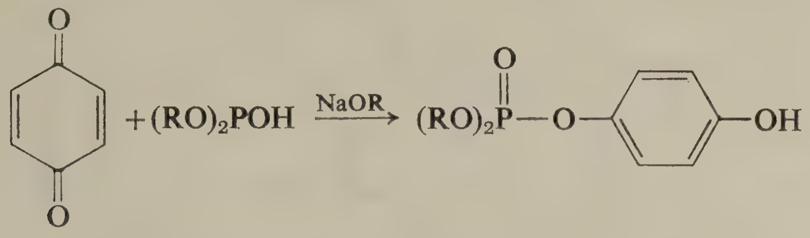
Orthoformic esters and dialkyl phosphites react without catalyst to form dialkyl dialkoxymethylphosphonates[2059]:

$$(RO)_2POH + CH(OR')_3 \xrightarrow{182°} (RO)_2PO.CH(OR')_2 + ROH$$

*p*-Benzoquinone reacts vigorously with dialkyl phosphites in the presence of sodium alkoxide catalyst to form dialkyl *p*-hydroxyphenyl phosphates[679]:



Naphthaquinone and chloranil[680] behave similarly.

With salts of dialkyl phosphite, carbonyl sulphide and carbon disulphide form salts of dialkyl phosphorothiocarbonic and dithiocarbonic acids, respectively; these can be isolated by conversion to their methyl esters by reaction with methyl iodide[750]:

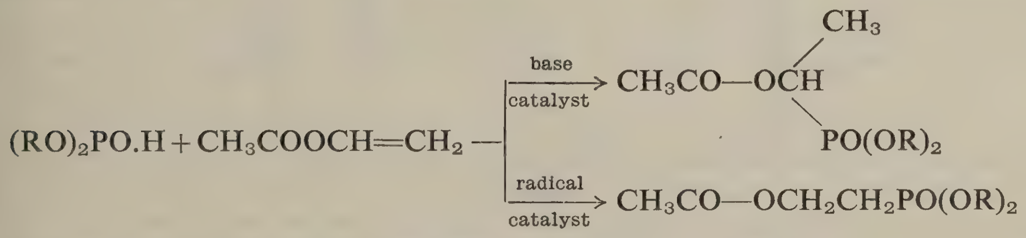
$$(RO)_2PONa + CS_2 \rightarrow (RO)_2PO.CS_2Na \xrightarrow{MeI} (RO)_2PO.CS.SMe$$

ADDITION TO UNSATURATED COMPOUNDS

The addition of dialkyl phosphites to non-activated olefins to form dialkyl alkylphosphonates takes place only in the presence of a free-radical catalyst. Examples of such olefins are simple alkenes[763] such as octene-1,[764,766] alkyl oleates,[658] $Et_3SiCH_2CH_2CH{=}CH_2$,[572] diallyl,[1091] and vinyl ethers.[1091,2400] $\gamma$-Radiation-induced additions of phosphites to a number of olefins are reported.[1688,2401-2]

$$R'CH{=}CH_2 + (RO)_2PO.H \xrightarrow[\text{catalyst}]{\text{radical}} R'CH_2CH_2PO(OR)_2$$

Olefins in which the C=C double bond is activated by an adjacent electron-attracting group, such as CO, CN, and $CO_2R$, undergo base-catalyzed addition of dialkyl phosphites, wherein the addition is similar to a Michael reaction and in a sense opposed to Markownikov's rule[648,682]; 2-substituted ethylphosphonates are formed. Generally, the attachment of substituent groups at the double bond slows down the reaction and necessitates the use of larger amounts of catalyst. In a number of cases the addition reactions have been carried out with radical-catalysts to form a product the same as that obtained in the base-catalyzed reaction.[765,1686] However, McConnell and Coover[1090] showed that with vinyl acetate the reactions proceed as shown below:

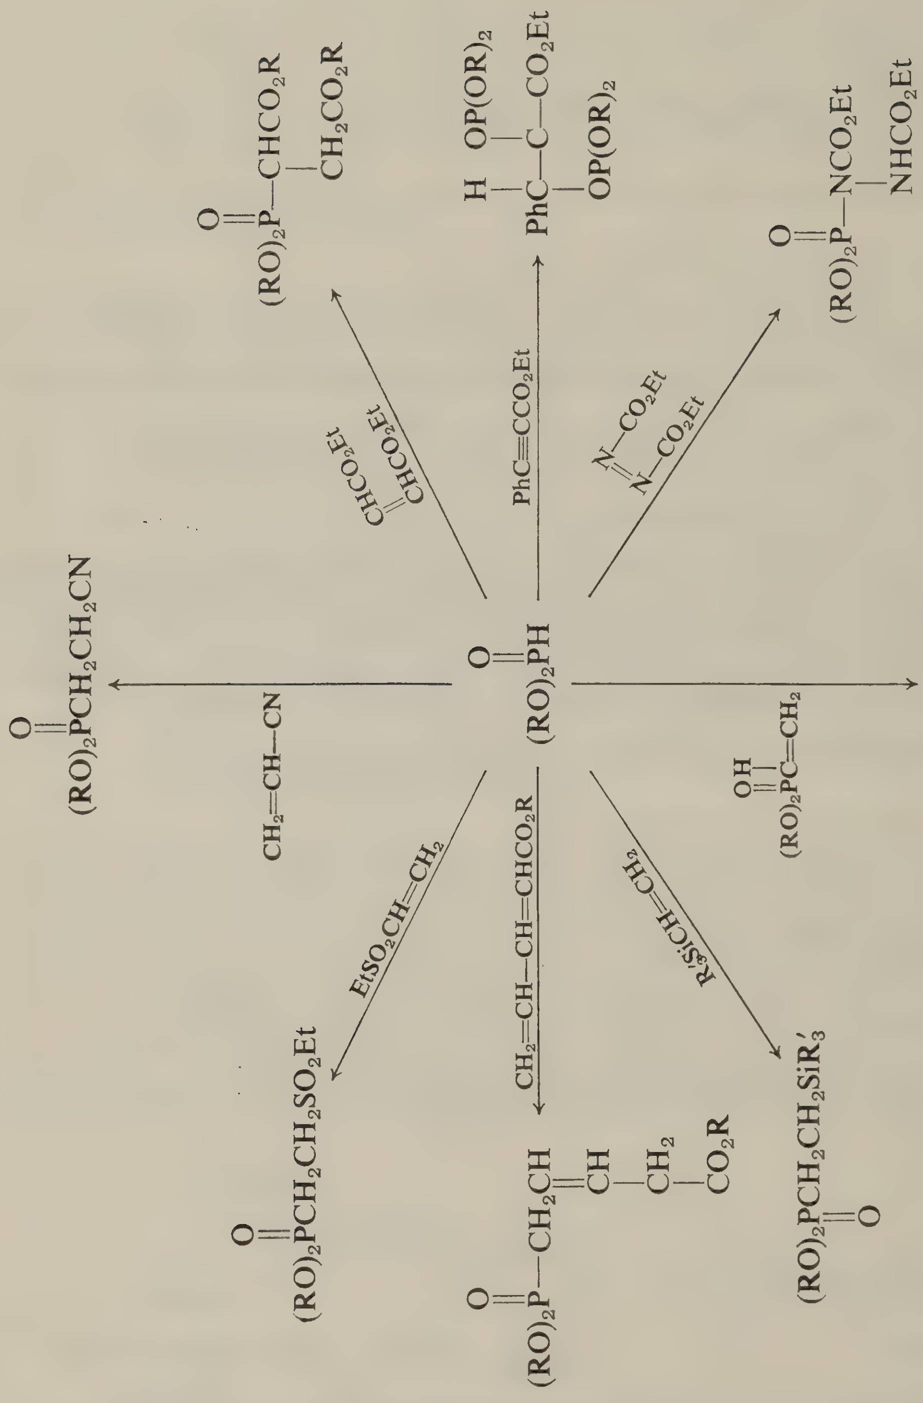


$$(RO)_2PO.H + CH_3COOCH{=}CH_2 \begin{cases} \xrightarrow[\text{catalyst}]{\text{base}} CH_3CO{-}OCH(CH_3)PO(OR)_2 \\ \xrightarrow[\text{catalyst}]{\text{radical}} CH_3CO{-}OCH_2CH_2PO(OR)_2 \end{cases}$$

Tetrafluoroethylene reacts with diethyl phosphite and benzoyl peroxide catalyst in an autoclave to form diethyl polyfluoroalkyl phosphonates, $H(CF_2CF_2)_nPO(OEt)_2$ where $n$ has an average value of 3.[1092,1477] $\gamma$-Radiation-induced addition of $(RO)_2POH$ to chlorofluoro-olefins proceeds:

$$(RO)_2PO.H + CFX{=}CX_2 \xrightarrow{\gamma\text{-radiation}} HX_2C{-}CFX{-}PO(OR)_2$$

(X = F or Cl, R = Me, Et, *n*-Pr)



$(RO)_2P(=O)H$
$CH_2{=}CH{-}CN$
$(RO)_2P(=O)CH_2CH_2CN$
$CHCO_2Et{=}CHCO_2Et$
$(RO)_2P(=O){-}CHCO_2R{-}CH_2CO_2R$
$PhC{\equiv}CCO_2Et$
$PhC(H){-}C(OP(OR)_2)(OP(OR)_2){-}CO_2Et$
$N(CO_2Et){=}N(CO_2Et)$
$(RO)_2P(=O){-}NCO_2Et{-}NHCO_2Et$
$(RO)_2P(=O)C(OH){=}CH_2$
$(RO)_2P(=O)CH_2CH_2P(=O)(OR)_2$
$R'_3SiCH{=}CH_2$
$(RO)_2P(=O)CH_2CH_2SiR'_3$
$CH_2{=}CH{-}CH{=}CHCO_2R$
$(RO)_2P(=O){-}CH_2CH{=}CH{-}CH_2{-}CO_2R$
$EtSO_2CH{=}CH_2$
$(RO)_2P(=O)CH_2CH_2SO_2Et$

CHART XIV.—Some reactions of dialkyl phosphites with unsaturated compounds

The apparent reactivity of the olefins is in the order:

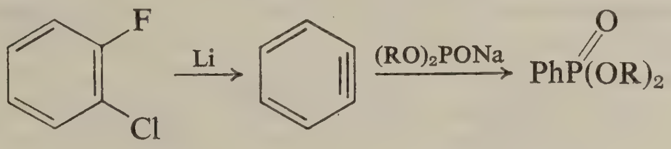
$$CFCl{=}CFCl > CFCl{=}CCl_2 > CF_2{=}CCl_2{}^{1687}$$

Examples of activated olefins which undergo base-catalyzed addition giving dialkyl 2-substituted ethyl phosphonates are as follows: esters of unsaturated acids such as maleic,[653, 1689] acrylic,[648, 1690] methacrylic,[653] cinnamic,[648, 650] benzylidenemalonic[652] and crotonic acids[648, 650]; α-unsaturated nitriles[662, 704] and amides,[653] unsaturated ketones[643, 664]; vinyl esters, such as vinyl acetate[651] and *iso*propenyl acetate[656]; esters of vinyl[655] and butadienyl phosphonic acid[1093]; vinyl sulphonic acid derivatives, such as ethyl vinyl sulphone,[649] dimethylaminovinyl sulphone[657] and vinyl sulphonyl fluoride[567] (no catalyst required); vinyl silicon compounds $CH_2{=}CHSiX_3$ ($X = R$ or OR,[659, 702] using a $(BuO)_2$ catalyst[1686]); α-nitro olefins,[649] and vinyl pyridines.[701]

Acetylenic esters such as methyl phenyl acetylenecarboxylate[654] and acetylenedicarboxylic ester[653] add two equivalents of dialkyl phosphite giving 1,2-(dialkoxyphosphinyl)ethane derivatives. Activated conjugated unsaturated compounds such as ethyl sorbate and hepta-3,5-diene-2-one undergo 1:4 addition giving 4-substituted but-2-enylphosphonates.[1093]

Similar addition reactions take place with Schiff's bases such as benzylideneaniline[663] and *N*-benzylidenepropylamine[660] and with *N*-methylenepiperidinium chloride,[705] giving substituted α-aminophosphonic esters. Diethyl azodicarboxylate[661] forms 1-dialkyloxyphosphinyl-1,2-dicarbethoxyhydrazine. Some base-catalyzed addition reactions are illustrated in Chart XIV.

The reaction of sodium diethyl phosphite with benzyne (formed *in situ* from the reaction of *o*-bromofluorobenzene with lithium) gives diethyl phenylphosphonate[749]; the same product is obtained in lower yield from triethyl phosphite. In a similar reaction ethyl diphenylphosphinite forms triphenylphosphine oxide:



FORMATION OF α-AMINOALKYL PHOSPHONATES

Fields[669] showed that dialkyl phosphites could be used in a Mannich-type reaction with an aldehyde and amine or a tetra-alkyl methylene diamine to give esters of α-aminoalkyl phosphonic acids. Thus, diethyl phosphite, formaldehyde, and diethylamine form diethyl diethylaminomethyl phosphonate:

$$(EtO)_2PO.H + HCHO + HNEt_2 \rightarrow (EtO)_2PO.CH_2NEt_2$$

Many variations of this basic reaction may be brought about by the use of other aldehydes, ketones, and amines. Of interest is the preparation of the aminobisphosphonate, $CH_3N[CH_2PO(OEt)_2]_2$, and aminotriphosphonate, $N[CH_2PO(OEt)_2]_3$, from the reaction of diethyl phosphite, formaldehyde, and methylamine or ammonia, respectively.[667]

In a related reaction the treatment of a dialkyl phosphite with an aldehyde or ketone and ammonia, usually in alcoholic media, at elevated temperature produces an α-aminophosphonate.[667–8, 681] Kabachnik *et al.* consider that in this reaction the α-hydroxyphosphonate is first formed at room temperature and reacts with ammonia on heating to give the α-amino compound[666, 670]:

$$(RO)_2PO.H + R'CHO \rightarrow (RO)_2PO.CH(OH)R' \xrightarrow[100°]{NH_3} (RO)_2PO.CH(NH_2)R'$$

THE TODD REACTION

Todd and his co-workers[672] found that a dialkyl phosphite, a polyhalogenated hydrocarbon, such as carbon tetrachloride, and an excess of ammonia or a primary or secondary amine react to form the corresponding dialkyl phosphoroamidate, a haloform, and the base hydrochloride:

$$(RO)_2PO.H + CCl_4 + 2R'_2NH \rightarrow (RO)_2PO.NR'_2 + CHCl_3 + R'_2NH,HCl$$

A number of halogenated hydrocarbons, such as $CBr_4$, $CHI_3$, $CHBr_3$, $CCl_3Br$, $C_2HCl_5$, $C_3Cl_8$, $C_4Cl_{10}$, $CCl_2{=}CH{-}CCl_3$, $Cl_2CH{-}CCl_3$, and $CFCl_2{-}CFCl_2$ are active, but $CHCl_3$, $CH_3{-}CCl_3$, $(CHCl_2)_2$, and $CCl_2{=}CCl_2$, are inactive.[673] Use of trichlorobromomethane gives particularly good yields of phosphoroamidates.[673] In the reaction between 2-aminoethanol and diethyl phosphite the reaction rate decreases in the following order with respect to halogenated hydrocarbon; $CCl_3Br > CCl_3CN \gg CCl_4 > CCl_3CO_2Et$.[676] The relative reaction rates of various amines with carbon tetrachloride and diethyl phosphite decrease in the series: diethylamine > tertiary butylamine > *cyclo*hexylamine > di-*iso*-propylamine > 2-aminoethanol.[676] Weakly basic amines, such as aniline, do not undergo the reaction except in the presence of a strong tertiary amine[672]; the reaction rate increases with the base strength of the tertiary amine and decreases with increasing size of the alkyl groups of the dialkyl phosphite.[675] It is believed that the reaction proceeds through intermediate formation of a dialkyl phosphorochloridate.[673, 675, 677] This view is supported by the isolation of diethyl phosphorochloridate in 81% yield from the reaction of diethyl phosphite, carbon tetrachloride and triethylamine.[677]

Various modifications of the Todd reaction have been carried out to form tetraalkyl pyrophosphate, dialkyl alkyl phosphate, dialkyl aryl phosphate, and dialkyl hydrazophosphonate. These are illustrated in Chart XV.

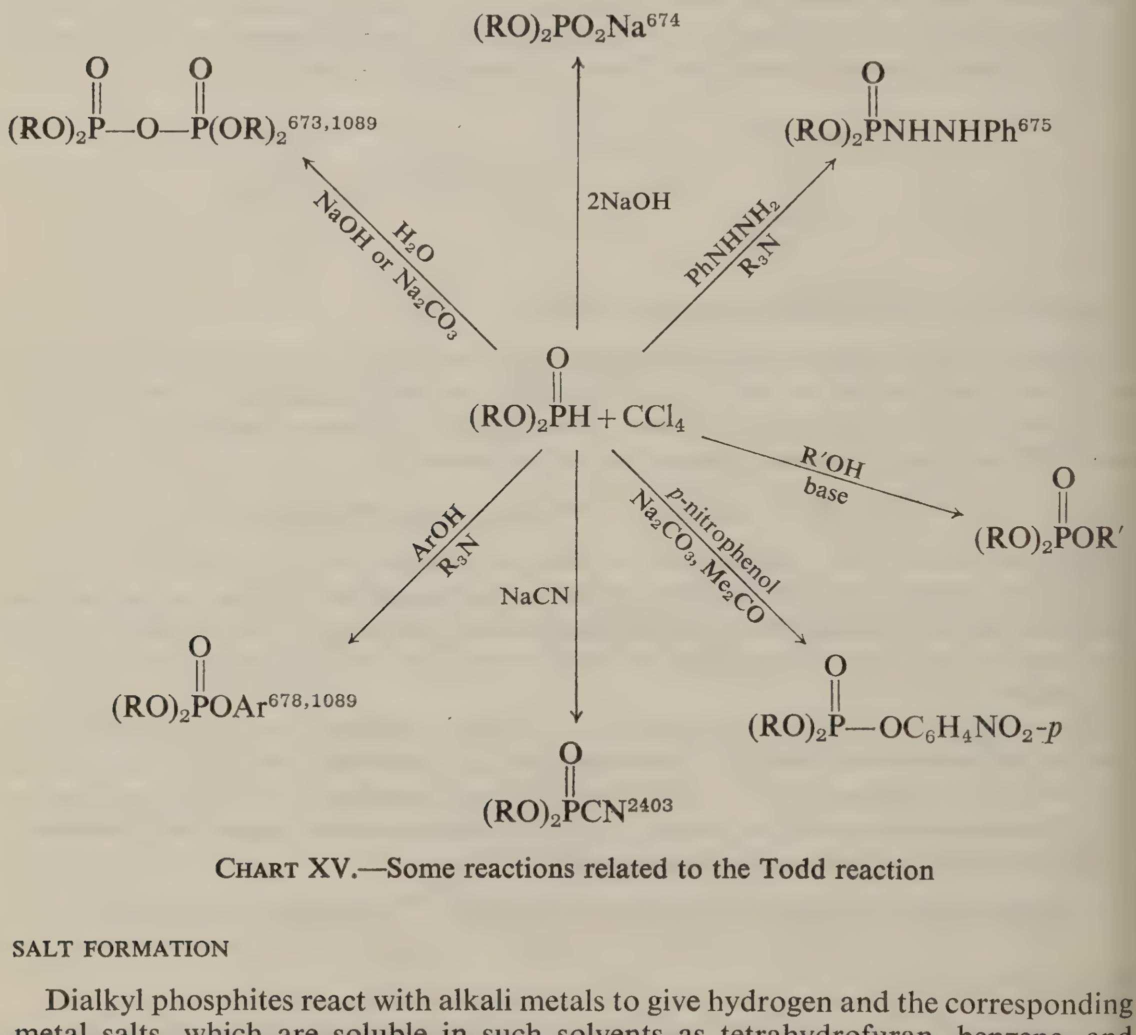


CHART XV.—Some reactions related to the Todd reaction

### SALT FORMATION

Dialkyl phosphites react with alkali metals to give hydrogen and the corresponding metal salts, which are soluble in such solvents as tetrahydrofuran, benzene, and petroleum ether. A better method of forming the sodium salt is treating the phosphite with sodium hydride in tetrahydrofuran solution[683]; this avoids the formation of phosphine by-products which result from reduction of the phosphite when the alkali metal is used. Salts may also be prepared using sodium alkoxides:

$$(RO)_2PO.H + M,\ MH,\ \text{or}\ MOR \rightarrow (RO)_2PO.M + \tfrac{1}{2}H_2,\ H_2,\ \text{or}\ ROH$$

Lithium and sodium salts are formed in low yield by heating a trialkyl phosphite with a lithium or sodium halide[684]:

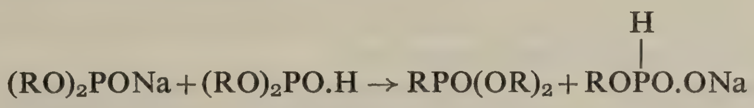
$$(RO)_3P + LiX \xrightarrow{\Delta} (RO)_2PO.Li + RX\uparrow$$

Magnesium salts have been prepared by treating a phosphite with magnesium in pyridine; halogenmagnesium salts are formed when a phosphite reacts with one equivalent of a Grignard reagent.[687] Silver salts may be prepared by treating the ester in aqueous solution, or suspension, with ammoniacal silver nitrate and then carefully neutralizing with nitric acid.[1691] Dialkoxyphosphinyl mercury salts are obtained from the dialkyl phosphites by treatment with a mixture of mercuric oxide and mercuric halide,[685] by treating the intermediate bis(dialkoxyphosphinyl) mercury with mercuric halide,[686] or by an Arbuzov-type reaction between a trialkyl phosphite and mercuric acetate[1083] :

$$(RO)_2PO.H + HgO \rightarrow [(RO)_2PO]_2Hg \xrightarrow{HgX_2} (RO)_2PO.HgX$$
$$(RO)_3P + Hg(OAc)_2 \rightarrow (RO)_2PO.HgOAc + ROAc$$

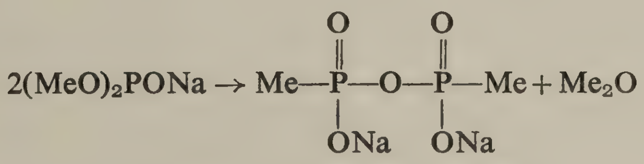
Stelling[690] examined the *X*-ray absorption spectrum of several salts of dialkyl phosphites. He concluded that the silver salt exists in the form $(RO)_2POAg$ and that the sodium salt exists in a form in which phosphorus is connected to four neighbouring atoms with sodium bonded to phosphorus. From a study of the infra-red spectrum of the lithium, sodium, potassium and silver salts of several dialkyl phosphites, Daasch[691] concluded that there is no evidence for the structure $[(RO)_2PO]Na$ and favours a structure having a covalent metal–oxygen bond.

Sodium salts of di-*n*-alkyl phosphites react with the parent dialkyl phosphites giving dialkyl alkyl phosphonates and sodium alkyl hydrogen phosphite[688-9]; the reaction proceeds at a significant rate above 60°[689]:



$$(RO)_2PONa + (RO)_2PO.H \rightarrow RPO(OR)_2 + RO\overset{\overset{H}{|}}{P}O.ONa$$

Analogous reactions of the secondary alkyl esters are much slower and proceed by *O*-alkylation; thus sodium di-*sec*-butyl phosphite reacts with the parent phosphite giving tri-*sec*-butyl phosphite and sodium *sec*-butyl hydrogen phosphite.[688] Sodium dimethyl phosphite decomposes at 50° giving disodium dimethyl pyrophosphonate and dimethyl ether[689]:



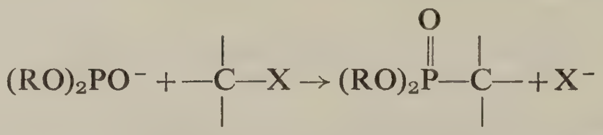
$$2(MeO)_2PONa \rightarrow Me{-}\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}{-}O{-}\underset{\underset{ONa}{|}}{\overset{\overset{O}{\|}}{P}}{-}Me + Me_2O$$

Although the dialkyl phosphites themselves undergo little reaction with sulphur in the absence of solvent (p. 985), the alkali-metal salts react exothermically in inert media with sulphur or selenium giving salts of the corresponding dialkyl phosphorothionate or selenoate.[692] A similar reaction may be carried out with sulphur by adding gaseous ammonia[693–4] or a tertiary amine[1266] to a cooled mixture of dialkyl phosphite and sulphur:

$$(RO)_2PO.H + S + NH_3 \rightarrow (RO)_2PS.ONH_4$$

REACTIONS OF SALTS OF DIALKYL PHOSPHITES

Alkali-metal salts of dialkyl phosphites are strong nucleophiles; they participate in many displacement reactions at electrophilic carbon centres giving dialkyl phosphonates:



$$(RO)_2PO^- + -\overset{|}{\underset{|}{C}}-X \rightarrow (RO)_2\overset{O}{\overset{\|}{P}}-\overset{|}{\underset{|}{C}}- + X^-$$

Reactions with numerous alkyl halides, with esters of sulphonic[683, 717] and sulphuric acids[715, 1105] and with Mannich bases[985] have been reported. The relative reaction rates towards primary *n*-alkyl compounds are $RI > RBr > ROSO_2C_6H_4\text{-}p\text{-}CH_3 > RCl$.[683] However, alkyl iodides are rarely used owing to the ready dealkylation by sodium iodide of the phosphonate ester product, giving alkyl iodide and sodium monoalkyl phosphonate.[716, 718]

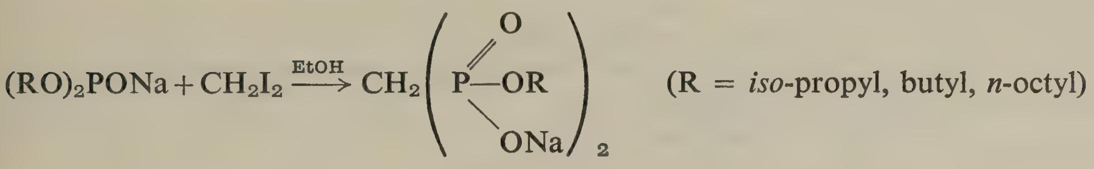
Generally, primary alkyl halides, particularly alkyl bromides,[712] give good yields of the corresponding phosphonate. Other primary halides which give the expected phosphonate (often in lower yield than obtained by the Arbuzov reaction) are amino-substituted halides such as 2-diethylaminoethyl chloride,[1187] trimethylsilylmethyl halides,[431, 732] arylmethyl halides such as benzyl chloride, benzyl bromide[719] and 7-chloromethyl benzanthracene[722]; halogenomethyl substituted heterocyclic compounds such as 2-chloromethyl pyridine[1699] and 2-chloromethyl quinoline[1094]; 1-(2-bromoethyl)piperidine[714]; tetrahydrofurfuryl bromide[714] and chloroacetonitrile.[727]

Secondary alkyl halides[364] and toluene sulphonates[717] give lower yields than those generally obtained from primary compounds. Diphenylmethyl bromide undergoes reductive coupling with sodium diethyl phosphite, giving a high yield of tetraphenylethane; the chloride gives but a poor yield of the expected phosphonate.[719] The reaction fails with *tert*-alkyl halides.[364]

Aryl halides such as chloro- and bromo-benzene, 2-chloro- and 2-bromopyridine fail to react; iodobenzene with sodium diethyl phosphite gives a moderate yield of sodium monoethyl phenyl phosphonate.[716] Successful reactions have been reported for a few heterocyclic halides such as 2-chloro-4,6-dimethylpyrimidine[740] and 2-chloroquinoline[741] giving dialkyl-4,6-dimethyl pyrimidyl phosphonate and dialkyl 2-quinolinyl phosphonate respectively.

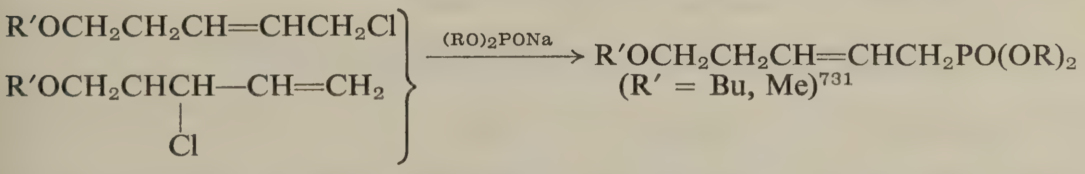
Ethyl chloroformate,[726] ethyl chloroacetate,[726–7] and $\alpha$- and $\gamma$-bromoethyl acetoacetates,[721] yield the expected phosphonic esters; dialkyl chloromethylphosphonates yield tetra-alkyl methylenediphosphonates.[723–4] Acetyl halides yield acetoxymethylenediphosphonates which result from addition of sodium dialkyl phosphite to the initially formed $\alpha$-ketophosphonate followed by acetylation.

Primary aliphatic $\alpha$-$\omega$ dihalides can react with two equivalents of sodium dialkyl phosphite giving a tetra-alkyl $\alpha$-$\omega$ alkyl diphosphonate,[723, 742] but the reaction of compounds having primary and secondary halogen atoms follows no set pattern. Thus, in $CNCHBr\text{–}CH_2Br$[713] the primary bromine atom is replaced and hydrogen bromide is then lost to yield $CNCH{=}CHPO(OR)_2$, but in $EtOCHCl\text{–}CH_2Cl$[744] the secondary chlorine atom is replaced giving $(EtO)_2OP(CHOEt)CH_2Cl$. Several 1,2-dihalogeno-compounds undergo dehalogenation. Ethylene dibromide and sodium diethyl phosphite give ethylene and a mixture of diethyl phosphite, triethyl phosphate, tetraethyl pyrophosphite, tetraethyl pyrophosphate, and tetraethyl ethylene-1,2-diphosphonate.[1714] 1,2-Dibromoethylbenzene gives styrene,[713] 9,10-phenanthrene dibromide gives phenanthrene,[720] and $(Me_2CBr)_2$ gives $Me_2C{=}CMe_2$ [713]; the nature of the phosphorus-containing product is not known. Methylene dihalides give generally poor yields of tetra-alkyl methylenediphosphonates,[723, 745] reaction of methylene di-iodide with sodium dialkyl phosphites gives moderate yields of disodium dialkyl methylenediphosphonates[1696]:



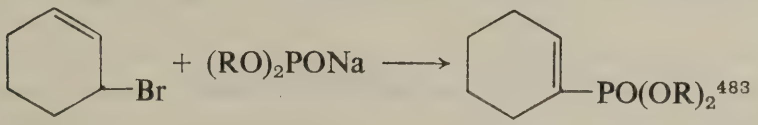
$$(RO)_2PONa + CH_2I_2 \xrightarrow{EtOH} CH_2\left(\begin{array}{l}\quad O\\ P—OR\\ \quad ONa\end{array}\right)_2 \quad (R = \textit{iso}\text{-propyl, butyl, } n\text{-octyl})$$

In the presence of an excess of dialkyl phosphites allyl halides react with sodium dialkyl phosphite giving dialkyl allylphosphonate[728] but with sodium dialkyl phosphite and allyl chloride (or allyl bromide) the products are propane-1,2-diphosphonates[728, 743]; this is possibly due to migration of the C=C double bond from the 2- to the 1- position in the initially-formed allyl phosphonate, followed by phosphite addition. Allylic rearrangements and carbon–carbon double- or triple-bond migration have been demonstrated in reactions of allylic halides and propargyl bromide:



$$\left.\begin{array}{l}R'OCH_2CH_2CH=CHCH_2Cl\\ R'OCH_2\underset{Cl}{\underset{|}{C}}HCH—CH=CH_2\end{array}\right\} \xrightarrow{(RO)_2PONa} R'OCH_2CH_2CH=CHCH_2PO(OR)_2$$

(R′ = Bu, Me)[731]

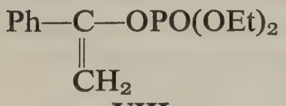


$CH\equiv C—CH_2Br + (RO)_2PONa \xrightarrow{THF} CH_3C\equiv C—PO(OR)_2$[2404]

α-Halogenocarbonyl compounds react anomalously. Thus, sodium dialkyl phosphite and ω-halogenoacetophenones can react to give either the expected phosphonate, **VII**, the rearranged vinyl phosphate ester, **VIII**, or the epoxyphosphonate, **IX**, or mixtures of these compounds, depending on the reaction conditions and the halogen atom replaced[729-30]:

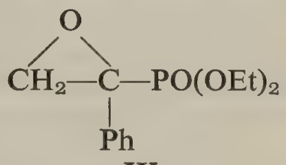
$PhCOCH_2PO(OEt)_2$

**VII**



$Ph—\underset{CH_2}{\underset{\|}{C}}—OPO(OEt)_2$

**VIII**



**IX**

The reaction of triarylmethyl halides with salts of dialkyl phosphites has been studied mainly by Arbuzov and co-workers. Early work with triphenylmethyl bromide and sodium dialkyl phosphites gave no phosphonate; the products isolated were triphenylmethane and a 'tetraethyl subphosphite', $((EtO)_2PO)_2$.[1095] Recently, *p*-alkoxy-substituted triphenylmethyl bromides have been shown to give high yields of the corresponding dialkyl phosphonates on reaction with sodium diethyl phosphate. Electron spin resonance measurements on the reacting solutions gave free-radical concentrations in the range $10^{15}$–$10^{17}$/ml. of solution.[1096] Silver salts of ethyl and *sec*-alkyl phosphites react immediately with triphenylmethyl halides giving dialkyl triphenylmethyl phosphites, but the silver salts of di-*n*-alkyl phosphites (except ethyl) yield dialkyl triphenylmethylphosphonates.[738]

In a manner formally similar to nucleophilic attack of dialkyl phosphite ions on carbon centres, the salts also participate in displacement reactions on sulphur, nitrogen,[1097] selenium, silicon,[732] and arsenic,[736] giving phosphorothiolate, phosphoroamidate, phosphoroselenoate, silicophosphonic and arsenophosphonic esters, respectively:

$$(RO)_2PONa + R'{-}SX \rightarrow (RO)_2PO.SR' + NaX$$

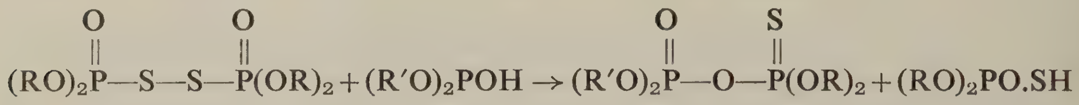
(X = SR,[735,737] Cl,[746] —CN,[747,1286] —NR$_2$,[1697] —SO$_2$R,[734] —SO$_2$Na[734])

$$(RO)_2PONa + R'_2AsCl \rightarrow (RO)_2PO.AsR'_2$$

$$(RO)_2PONa + R'_3SiCl \rightarrow (RO)_2PO.SiR'_3$$

$$(RO)_2PONa + R'NHBr \rightarrow (RO)_2PO.NHR' + NaBr$$

Dialkyl phosphites and dialkyl thionophosphites react with acyl disulphides in the absence of a base[735]:



$$(RO)_2\overset{O}{\overset{\|}{P}}{-}S{-}S{-}\overset{O}{\overset{\|}{P}}(OR)_2 + (R'O)_2POH \rightarrow (R'O)_2\overset{O}{\overset{\|}{P}}{-}O{-}\overset{S}{\overset{\|}{P}}(OR)_2 + (RO)_2PO.SH$$

In benzene solvent $(RO)_2POH$ and perhalogenomethyl mercaptans react to form *O*,*O*-dialkyl-*S*-perhalogenomethyl phosphorothioates:

$$(RO)_2POH + CCl_2FSCl \rightarrow (RO)_2PO.SCFCl_2 + HCl$$ [1695]

MISCELLANEOUS REACTIONS OF DIALKYL PHOSPHITES

In the presence of a base catalyst, dialkyl phosphites react with isocyanates[751,1224] and isothiocyanates[752-3] giving carbamoyl and thiocarbamoyl phosphonates, respectively:

$$(RO)_2PO.H + R'NCX \xrightarrow{\text{base}} (RO)_2PO.CX.NHR' \qquad (X = O, S)$$

When β-propiolactone and sodium diethyl phosphite react together both acyl–oxygen and alkyl–oxygen fissions occur giving diethyl α-keto-3-hydroxypropyl phosphonate and diethyl 2-carboxyethyl phosphonate, respectively.[755] When heated with a diethyl phosphite without catalyst acyl–oxygen fission predominates and the end-product, formed by further addition of dialkyl phosphite to the keto-compound, is tetraethyl 1,3-dihydroxypropylidene diphosphonate.[754]

Epoxy compounds react with sodium dialkyl phosphites[755] or dialkyl phosphites with boron trifluoride as catalyst[757] giving 2-hydroxyethylphosphonates. With a basic catalyst propylene oxide gives a diphosphonate. This may result from dehydration of the initially-formed hydroxypropylphosphonate to the propenephosphonate followed by addition of dialkyl phosphite.[656]

Aryl and heterocyclic diazonium salts and dialkyl phosphites form highly coloured dialkyl azophosphonates[758] which may be converted to the corresponding hydrazo-compounds by a variety of reducing agents[759]:

$$ArN_2^+X^- + (RO)_2POH \xrightarrow{\text{NaOAc}} ArN{=}N{-}PO(OR)_2 \xrightarrow{\text{Zn/HOAc}} ArNH{-}NHPO(OR)_2$$

Dialkyl phosphites react with carboxylic acids without catalysts giving high yields of corresponding carboxylic ester and phosphorous acid; both alkyl groups on the dialkyl phosphite can be utilized[938]:

$$(RO)_2POH + 2R'CO_2H \rightarrow 2R'CO_2R + H_3PO_3$$

Phenols yield the alkylphenyl ether.

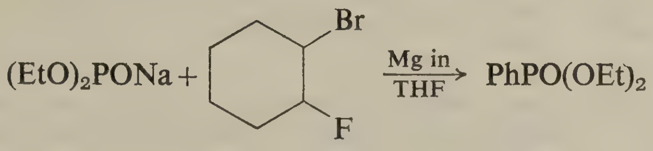
The alkylating properties of dialkyl phosphites are also exhibited in reactions with various sulphur compounds; thus thiourea gives an *S*-alkyl *iso*thiouronium monoalkyl phosphite,[760] and ammonium thiocyanate an alkyl isothiocyanate[762]; xanthates form the esters.[761]

Orthoformates and the lower dialkyl phosphites react to form acetals of formylphosphonic esters[1694]:

$$(RO)_2PO.H + CH(OR')_3 \rightarrow (RO)_2PO.CH(OR')_2 + R'OH$$

Diethyl phosphite and methyl benzoate react in the presence of di-*tert*-butyl peroxide to form diethyl *iso*-butyl phosphonate and diethyl (*p*-carbomethoxyphenyl) phosphonate.[1708] The reaction has been extended to polycyclic aromatic and heterocyclic compounds, such as naphthalene, anthracene, phenanthrene, dibenzofuran, and carbazole, to give the corresponding phosphonic esters in 51–96% yield.[1709]

Diethyl phenylphosphonate is formed by the interaction of sodium diethyl phosphite or triethyl phosphite with benzyne generated *in situ* by the action of magnesium on *o*-bromofluorobenzene in tetrahydrofuran solvent[749]:



### Dialkyl Hydrogen Phosphonothionates (dialkyl thionophosphites), $(RO)_2PS.H$

These compounds, in contrast to the dialkyl phosphites, are not easily prepared, and methods of synthesis have been published only during the last decade. Dialkyl hydrogen phosphonothionates are prepared (*a*) in low yield (*ca.* 20%)[609] admixed with a variety of other sulphur-containing organophosphorus compounds, by the action of alcohols on the lower sulphides of phosphorus,[635] (*b*) from dialkyl phosphorochloridites by the action of hydrogen sulphide in the presence of a weak tertiary organic base such as pyridine,[609, 634] (*c*) from dialkyl *N,N*-diethylphosphoroamidites by the action of hydrogen sulphide,[596] and (*d*) by treating dialkyl phosphites with phosphorus pentasulphide.[608] Mixed ethyl alkyl hydrogen phosphonothionates have been prepared by transesterification of diethyl hydrogen phosphonothionate with higher alcohols, using phosphoric acid as catalyst[1101]:

$$
\begin{gathered}
P_4S_6 + ROH \rightarrow (RO)_2PS.H \\
(RO)_2P{-}Cl + H_2S \xrightarrow{\text{base}} B,HCl + (RO)_2PS.H \\
(RO)_2PNEt_2 + H_2S \rightarrow (RO)_2PS.H + Et_2NH \\
(RO)_2PO.H \xrightarrow{P_2S_5} (RO)_2PS.H \\
(EtO)_2PS.H + ROH \rightarrow RO(EtO)PS.H + EtOH
\end{gathered}
$$

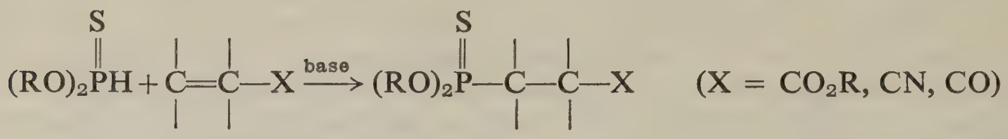
The lower dialkyl hydrogen phosphonothionates, unlike their oxygen analogues, are sparingly soluble in, and are not decomposed by, water.[609] However, in many respects the chemistry of the two classes of compound is similar and many of the typical reactions of dialkyl phosphites have been shown to take place with the phosphonothionates. Thus, chlorination with sulphuryl chloride[569] or with carbon tetrachloride and a base[697, 1611] yields dialkyl phosphorochloridothionate; thiocyanogen forms a dialkyl phosphorothiocyanatothionate.[640] Dialkylamino sulphenyl chloride reacts to form a tetra-alkyl trithiopyrophosphate[1078, 1099–1100]:

$$(RO)_2PS.H + SO_2Cl_2 \rightarrow (RO)_2PS.Cl + HCl + SO_2$$

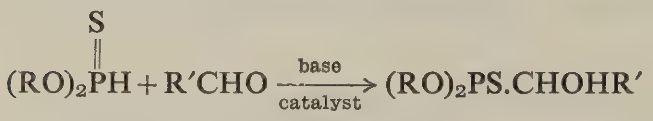
$$(RO)_2PSH + QSCl \rightarrow (RO)_2PS.SQ + HCl \rightarrow (RO)_2PS.SCl + QHCl \xrightarrow[\text{base, B}]{(RO)_2PSH} (RO)_4P_2S_3 + B,HCl$$

(Q = aliphatic, aromatic or heterocyclic secondary amine.)[1099]

In the presence of a base catalyst, hydrogen phosphonothionates add to the carbon–carbon double bond of many activated unsaturated compounds such as esters of maleic,[654] crotonic,[654] cinnamic,[654] acrylic,[654] and alkylidene malonic[695] acids and α-β unsaturated ketones and nitriles,[699] giving dialkyl β-substituted alkyl phosphonothionates. Similar addition takes place with the C=N double bond in anils.[1101] Aldehydes, ketones and α-β unsaturated aldehydes react to form dialkyl α-hydroxyalkyl phosphonothionates[639, 699]; in the presence of ammonia the product is a dialkyl α-aminoalkyl phosphonothionate:



$$(RO)_2\overset{S}{\overset{\|}{P}}H + \overset{|}{\underset{|}{C}}{=}\overset{|}{\underset{|}{C}}-X \xrightarrow{\text{base}} (RO)_2\overset{S}{\overset{\|}{P}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-X \qquad (X = CO_2R,\ CN,\ CO)$$

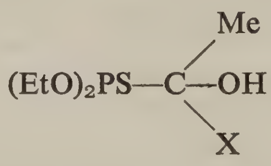


$$(RO)_2\overset{S}{\overset{\|}{P}}H + R'CHO \xrightarrow[\text{catalyst}]{\text{base}} (RO)_2PS.CHOHR'$$

An interesting difference between dialkyl phosphites and dialkyl hydrogen phosphonothionates is found in the reaction with chloral; the phosphite gives the expected 1-hydroxy-2,2,2-trichloroethyl phosphonate but the phosphonothionate product loses hydrogen chloride and rearranges to yield a dialkyl β,β-dichlorovinyl phosphorothiolate[609, 1098]:

$$(RO)_2PO.H + CCl_3CHO \rightarrow (RO)_2PO.CHOHCCl_3$$
$$(RO)_2PS.H + CCl_3CHO \rightarrow (RO)_2PS.OCH{=}CCl_2 \rightarrow (RO)_2PO.SCH{=}CCl_2$$

Carbonyl compounds of the type $CH_3COX$ ($X = PO(OEt)_2$, $CO_2Et$, $COCH_3$, Ph) react exothermically with diethyl thiophosphites in the absence of catalyst to form



If heated in the presence of sodium alkoxide, the compounds where X is $(EtO)_2PO$, $CO_2Et$ or $COCH_3$, undergo rearrangement to phosphates or phosphorothiolates, while the compounds where X = Ph are cleaved to $(EtO)_2PSH$ and $PhCOCH_3$.[1698]

Alkali-metal salts of dialkyl phosphorothionites are less soluble in organic media such as toluene than the corresponding salts of dialkyl phosphites.[697] Sodium diethyl thiophosphite is stated by Pudovik and Tarasova to decompose at 100°–110° giving triethyl phosphite and disodium *O*-ethyl phosphorodithioite[1692]:

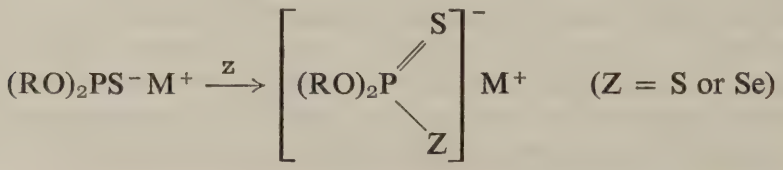
$$2\,(EtO)_2PSNa \xrightarrow{100\text{–}110^\circ} (EtO)_3P + EtOP(SNa)_2$$

The same workers report the following decomposition for sodium diethyl phosphite:

$$(EtO)_2PONa \xrightarrow{\Delta} (EtO)_3P(\text{trace}) + EtPO(OEt)_2 + EtPO(ONa)_2$$

Although the esters themselves are weak nucleophiles the sodium and potassium salts are strongly nucleophilic[634] and also exhibit the typically unsaturated character of trivalent phosphorus compounds. They react rapidly with alkyl halides giving dialkyl alkylphosphonothionates,[696, 768] with acyl halides giving dialkyl acylphosphonothionates, and readily add sulphur or selenium forming the corresponding dithio or selenothiophosphate[610, 636]:

$$(RO)_2PS^-M^+ \xrightarrow{R'X} R'PS.(OR)_2 + MX \qquad (X = \text{halogen})$$



### Dialkyl Hydrogen Phosphonoselenoates (dialkyl selenophosphites) $(RO)_2PSe.H$

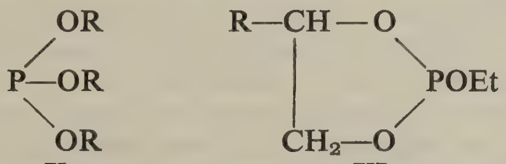
These compounds have been obtained by the action of hydrogen selenide on dialkyl phosphorochloridites in the presence of a tertiary organic base[769]:

$$(RO)_2PCl + H_2Se + R_3N \rightarrow (RO)_2PSe.H + R_3N.HCl$$

They react vigorously with sulphuryl chloride forming dialkyl phosphorochloridoselenoates, and undergo base-catalyzed addition to acrylonitrite giving dialkyl 2-cyanoethyl phosphonoselenoates.[769]

### Phosphorous Acid Triesters, $(RO)_3P$

Trialkyl phosphites are colourless liquids which are fairly readily oxidized by atmospheric oxygen. The lower members, particularly trimethyl phosphite, possess an unpleasant carbylamine-type odour. The lower members are soluble in, and are slowly hydrolyzed by, water; solubility and rate of hydrolysis decrease with increasing molecular weight. The hydrolysis is retarded by bases[770] and is strongly accelerated by acids.[781, 861] In pure water the hydrolysis is mildly catalyzed by dialkyl hydrogen phosphite, the first product of hydrolysis.[770] Hydrolysis of trialkyl phosphites derived from optically active alcohols shows that both acid- and base-catalyzed reaction involves P–O bond fission.[784] Phosphites in which the phosphorus atom forms part of a 1,3-dioxalane ring (XI) are rapidly hydrolyzed by water. When R = H, ring fission occurs leading to ethyl 2-hydroxyethyl hydrogen phosphite, but when R = –OEt, –CH$_2$OEt or –CH$_2$Cl, the ring is preserved and a substituted ethylene hydrogen phosphonate results[781]:



X XI

In contrast to trialkyl phosphites the rate of hydrolysis of triphenyl phosphite is accelerated by bases.[770]

The spectra of trialkyl phosphites indicate the structure X.[613] The relationship between parachor and structure in trialkyl phosphites, trialkyl phosphates, and trialkyl phosphorothionates, has been investigated by Arbuzov and Vinogradova.[771–3] They conclude that the phosphates carry all three alkyl chains in parallel positions, whereas in trialkyl phosphites only two of the alkyl chains are parallel. Heats of mixing of di- and tri-alkyl phosphites with chloroform are given by Kosolapoff.[774] Surface-tension values, determined by the method of maximum bubble pressure,[772] and dipole moments determined from dielectric constant measurements in carbon tetrachloride[776] are given by Arbuzov and co-workers. Atomic refractivities of phosphorus, oxygen and chlorine, in trialkyl phosphites and phosphorochloridites and in the corresponding phosphates and phosphorochloridates are given by Kabachnik *et al.*[777, 779] Bond and molar refractions of a large number of organophosphorus compounds are given by Sayre.[778]

The heats of formation of trimethyl phosphite and triethyl phosphite have been derived from the heats of esterification of phosphorus trichloride by methyl alcohol and ethyl alcohol in *cyclo*hexane solution.[780] They are:

$$\Delta H_f^\circ\,[P(OMe)_3, \text{liq.}] = -175{\cdot}0 \text{ kcal./mole}$$

and

$$\Delta H_f^\circ\,[P(OEt)_3, \text{liq.}] = -204{\cdot}1 \text{ kcal./mole}$$

The mean bond dissociation energies $\bar{D}$(P–OR) were calculated to lie within the range 79–82 kcal./mole. Mass spectra of trialkyl phosphites and dialkyl hydrogen phosphites have been recorded[782] and related to their radiolytic decomposition in the liquid phase.[783]

### PREPARATION

Although the reaction of phosphorus trihalides with sodium alkoxides formed the basis of the classical work by Arbuzov[820, 904] on the preparation of trialkyl phosphites, this method is rarely used today owing to the formation of by-products.[1, 813] Use of magnesium alkoxides in place of sodium alkoxides gives poor yields of trialkyl phosphites.[788]

The most general and widely used method of preparing trialkyl phosphites is by interaction of a phosphorus trihalide, usually the trichloride, with a hydroxy-compound or a mercaptan[1, 237, 848] in the presence of three equivalents of a tertiary organic base, B. Unsymmetrical tertiary phosphites[813, 819, 844] and mixed oxygen-sulphur esters[853] may be obtained using a phosphorochloridite or phosphorodichloridite in place of phosphorus trichloride:

$$3ROH + PCl_3 + 3B \rightarrow (RO)_3P + 3B,HCl$$

In its normal form the reaction is conducted by adding phosphorus trichloride to a stirred, cooled solution of a slight excess of the hydroxy-compound in an inert solvent such as benzene, petroleum ether or methylene dichloride and tertiary amine at 10°–15°. The product is filtered to remove base hydrochloride and the solution distilled under reduced pressure to obtain the phosphite. Bases such as pyridine, tributylamine, dimethylaniline or diethylaniline, have been used.[1, 785, 786, 812, 815, 817]

Industrially, the preparation of trialkyl phosphites is generally conducted using ammonia as the neutralizing base rather than an organic amine. Methods have been described in which the reaction of phosphorus trichloride and alcohol is conducted in a solvent at a temperature which is sufficiently low (−25°C.) to prevent dealkylation by hydrogen chloride, followed by neutralization at −25° with dry ammonia[787]; the simultaneous reaction of phosphorus trichloride and alcohol with a balanced stream of ammonia so as to maintain the pH of the mixture at 7–8·5, using a visual indicator such as methyl red, has also been described.[814, 818] Use of ammonium carbamate as neutralizing base is also suggested.[816]

Triaryl phosphites are not dearylated by hydrogen chloride and are prepared by reaction of phosphorus trichloride with a slight excess of a phenol at somewhat elevated temperatures.[821–3] Phenols of higher molecular weight usually react satisfactorily in the presence of a catalytic amount of magnesium chloride.[823] No product other than triaryl phosphite is formed in the reaction. Trialkyl and triaryl phosphorotrithiolites are similarly prepared[1]; the reaction is catalyzed by pyridine hydrochloride. The phosphites derived from certain strongly electronegatively substituted alcohols are not dealkylated by hydrogen chloride and may be prepared in the absence of bases; examples are: $CH_3CHCN.OH$,[804] $(CH_3)_2CCN.OH$,[879] $CCl_3.CH_2OH$,[799] and $CF_3CH_2OH$.[1481] The hydroxyl group in 1,1,1,3,3,3-hexachloropropane-2-ol is so deactivated that it does not react with phosphorus trichloride except in the presence of pyridine, when it yields the tertiary phosphite.[798]

### *Transesterification*

Trialkyl phosphites undergo an uncatalyzed exchange reaction when heated with aliphatic alcohols to yield mixtures of tertiary phosphites containing different alkyl groups; the relative amounts of these are determined by the proportion of reagents used[800]:

$$R'OH + (RO)_3P \rightleftharpoons R'OP(OR)_2 + ROH$$
$$R'OH + R'OP(OR)_2 \rightleftharpoons (R'O)_2POR + ROH$$

The transesterifications are catalyzed by bases, e.g. sodium alkoxide, and less efficiently by acids such as phosphoric acid. Difficulty is experienced in the isolation of the products if the boiling points of the exchanging and exchanged alcohol are too close[845]; use of trimethyl phosphite with higher alcohols gives good yields of the higher trialkyl phosphite[876]:

$$(MeO)_3P + 3ROH \xrightarrow{\text{base}} (RO)_3P + 3MeOH$$

Transesterification of triaryl phosphites with aliphatic alcohols has been used to prepare mixed alkyl-aryl phosphites[803, 813, 819, 871] and trialkyl phosphites. Since the displaced phenol may be reconverted to triaryl phosphite by direct reaction with phosphorus trichloride, this method provides a route to the trialkyl phosphites which avoids the use of an organic base or ammonia. Three methods have been described: (*a*) use of a high-boiling alcohol[803] or mercaptan[846] using base[846] or diphenyl phosphite[1701] as catalyst and removal of the phenol by distillation under vacuum, (*b*) use of a low-boiling alcohol such as methanol and fractionation of the trimethyl phosphite from the phenol,[801] and (*c*) treating triphenyl phosphite with 6–9 moles of an alcohol and sufficient sodium or potassium hydroxide to convert all the phenol to metal phenoxide, which is then removed by water washing.[802] For example,

$$(a)\ (PhO)_3P + C_{12}H_{25}SH \xrightarrow{\text{NaOPh}} (PhO)_2PSC_{12}H_{25} \rightarrow PhOP(SC_{12}H_{25})_2 \rightarrow P(SC_{12}H_{25})_3$$

$$(b)\ (PhO)_3P + CH_3OH(\text{excess}) \xrightarrow{\text{NaOPh}} (CH_3O)_3P\uparrow + 3PhOH$$

$$(c)\ (PhO)_3P + CH_2{=}CH{-}CH_2OH + 3NaOH \rightarrow (CH_2{=}CH{-}CH_2O)_3P + 3NaOPh + 3H_2O$$

The transesterification of trivalent phosphorous esters has been reviewed by Petrov *et al.*[2398]

### *Miscellaneous Methods*

Trialkyl phosphites have been prepared by interaction of phosphorus trichloride with alkali-metal salts of alkyl carbonic acids; possibly there are formed intermediate substances such as $(ROCO_2)_3P$ which lose carbon dioxide giving the product.[806] Butoxytrimethyl silane undergoes an exchange reaction with phosphorus trichloride in the presence of a catalytic amount of pyridine hydrochloride[805]:

$$3Me_3SiOBu + PCl_3 \xrightarrow{C_5H_5N.HCl} (BuO)_3P + 3Me_3SiCl\uparrow$$

The reaction of tetraethyl silicate with phosphorus trichloride gives ethyl phosphorodichloridite and diethyl phosphorochloridite but no triethyl phosphite.[807] Ethyl orthopropionate and phosphorus trichloride react to give a mixture of triethyl phosphite and diethyl-1,1-diethoxypropylphosphonate.[807]

Good yields of trialkyl phosphites,[808] alkyl arylphosphites,[570] alkyl and aryl trithiophosphites[570] and diesters of phosphonous and phosphonodithious acids[570] are obtained by reaction of the appropriate dialkyl amides of trivalent phosphorous acids with alcohol, phenol, or mercaptan:

$$P(NMe_2)_3 + 3ROH \rightarrow P(OR)_3 + 3Me_2NH$$
$$RP(NEt_2)_2 + 4PhSH \rightarrow RP(SPh)_2 + 2PhSH,Et_2NH$$

Unsymmetrical phosphites are obtained by adding an alcohol or phenol to an acyl phosphite and triethylamine at room temperature[1702]:

$$(RO)_2P{-}OCOCH_3 + R'OH + Et_3N \rightarrow (RO)_2P{-}OR' + CH_3CO_2H,Et_3N$$

Trivinyl phosphite, mixed alkyl-vinyl phosphites, and divinyl phosphonites have been prepared from phosphorus trichloride, phosphorochloridite or phosphonous dichloride, respectively, by reaction with mercury, acetaldehyde, and triethylamine[789-90]:

$$PCl_3 + Hg(CH_2CHO)_2 \rightarrow P(OCH{=}CH_2)_3$$

Dialkyl phosphites are not further alkylated by diazoalkanes, but diphenyl phosphite and diazomethane react to form diphenyl methyl phosphite.[615] Reduction of trialkyl phosphorothionates with sodium affords the trialkyl phosphite[809]:

$$(RO)_3PS + 2Na \rightarrow (RO)_3P + Na_2S$$

Benzoic acid reacts with phosphorus trichloride and pyridine giving tribenzoyl phosphite, but aliphatic carboxylic acids are said to yield the acyl halide as primary product[811]:

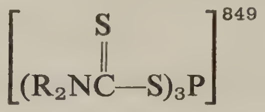
$$3PhCO_2H + PCl_3 + 3C_5H_5N \rightarrow (PhCOO)_3P + 3C_5H_5N{,}HCl$$

Organic disulphides react with white phosphorus at 200° giving trialkyl phosphorotrithioites[847,1189]:

$$6RSSR + P_4 \rightarrow 4(RS)_3P$$

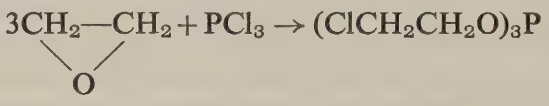
The same products are obtained in >90% yield by the reaction of white phosphorus and disulphides in the presence of strongly basic catalysts under mild conditions in aprotic solvents such as dimethyl formamide or dimethyl sulphoxide.[2062]

Dialkyl aminodithiocarbamates and phosphorus trichloride react to form tris(dialkylaminothiocarbamyl) phosphorotrithioites[849]:



$$\left[(R_2N\overset{\overset{\displaystyle S}{\|}}{C}{-}S)_3P\right]^{849}$$

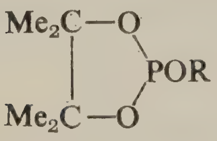
Phosphorus trichloride or tribromide reacts readily with alkylene oxides giving tris(2-halogenoalkyl) phosphites[834-5,1104]:



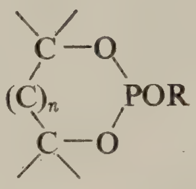
$$3\underbrace{CH_2{-}CH_2}_{O} + PCl_3 \rightarrow (ClCH_2CH_2O)_3P$$

Phosphine and trifluoromethyl sulphenyl chloride react to form a mixture of $(CF_3S)_2PH$ and $(CF_3S)_3P$.[1703]

Tertiary phosphites of numerous primary and substituted primary alcohols and phenols have been prepared.[1] Secondary alcohols generally give poorer yields. Phosphites of tertiary alcohols such as *tert*-butanol are difficult to prepare[593]; tri-*tert*-butyl phosphite[850-1] readily eliminates *iso*butylene on heating at 80°–90°. In contrast, the di-*tert*-alcohol, tetramethyl ethylene glycol, readily forms the cyclic phosphite **XII** on reaction with an alkyl phosphorochloridite and pyridine. A number of cyclic phosphites (2-alkoxy-1,3,2-dioxaphospholanes) **XIII**, have been prepared

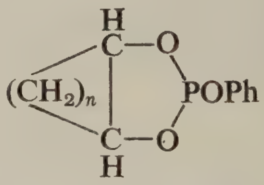


**XII**



*n* = 0, 1, 2

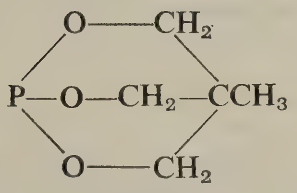
**XIII**



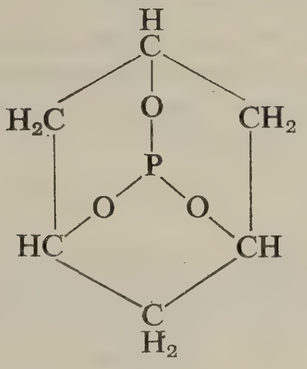
*n* = 3, 4

**XIV**

by Arbuzov and co-workers[781,796-7,828] from the corresponding cyclic phosphorochloridites (1-chloro-1,3,2-dioxaphospholanes). Similar compounds, R = Ph, *n* = 0,1,2,3, have been obtained by Rydon[871] by transesterification of aliphatic glycols with triphenyl phosphite; polymeric by-products which range from oils (from the lower glycols) to a rubber-like solid (with hexane-1,6-diol) are also formed. Compounds **XIV** result from transesterification with *cis-cyclo*pentane-1,2-diol and *cis-cyclo*hexane-1,2-diol. Other novel cyclic phosphites which have been prepared are 1-methyl-4-phospha-3,5,8-trioxabi*cyclo*(2,2,2)-octane[794] **XV**, and related compounds,[1108] and phospha-2,8,9-trioxa-adamantane **XVI**.[795,876,1102] Dipole moments of **XV** and **XVI** and their corresponding phosphates and thionophosphates are recorded.[876]

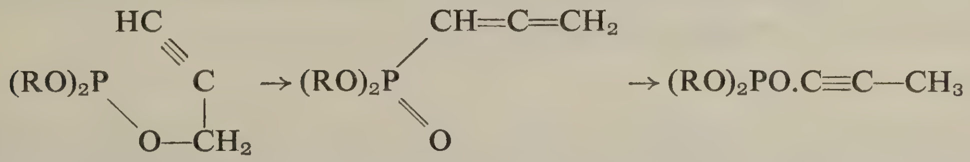


**XV**

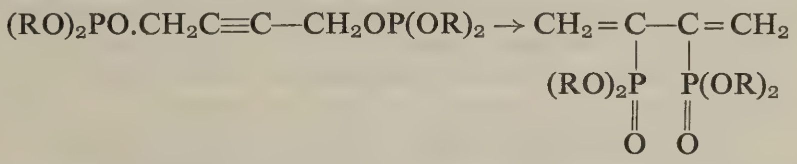


**XVI**

Allyl and benzyl groups are readily removed from phosphorous esters by dealkylation with hydrogen chloride or amine hydrochlorides. Tribenzyl phosphite has not been described. Dialkyl alkynyl phosphites derived from primary α-acetylenic alcohols such as propargyl alcohol readily undergo rearrangement on heating, giving dialkyl 1,2-propadienylphosphonate and dialkyl 1-propynephosphonate[792,1103]:

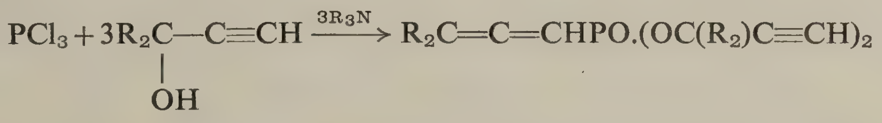


The tetra-alkyl diphosphite from butyne-1,4-diol rearranges exothermically at room temperature giving tetra-alkyl 2,3-diphosphonobutadiene[793]:

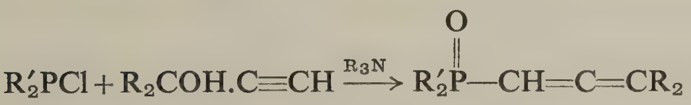


$$(RO)_2PO.CH_2C{\equiv}C{-}CH_2OP(OR)_2 \rightarrow CH_2{=}\underset{\underset{\displaystyle O}{\|}}{\underset{|}{\overset{}{C}}}\!\!\!\!\!\!\!\!\!\!\phantom{x}{-}C{=}CH_2 \quad [C_2: (RO)_2P(=O),\ C_3: P(=O)(OR)_2]$$

Tertiary α-acetylenic alcohols react with trivalent phosphorus compounds ($R_2PCl$, $RPCl_2$, $PCl_3$) in the presence of organic base giving allenic pentacovalent phosphorus compounds (phosphine oxide, phosphinate ester, phosphonate ester, respectively)[791]:



$$PCl_3 + 3R_2\underset{\underset{\displaystyle OH}{|}}{C}{-}C{\equiv}CH \xrightarrow{3R_3N} R_2C{=}C{=}CHPO.(OC(R_2)C{\equiv}CH)_2$$



$$R_2'PCl + R_2COH.C{\equiv}CH \xrightarrow{R_3N} R_2'\overset{\overset{\displaystyle O}{\|}}{P}{-}CH{=}C{=}CR_2$$

### REACTIONS OF TERTIARY PHOSPHITES

#### *Complex Formation*

Trialkyl and triaryl phosphites combine with many metal halides and pseudo halides to give co-ordination complexes which are frequently crystalline and have characteristic melting points. Complexes of the following types have been described {L = $(RO)_3P$ or $(PhO)_3P$}: L,CuX (X = Cl, Br, I, CNS[400, 855] and CN[854]); 2L,CuX (X = Cl, Br, I,[855] CN[854]); LL′,CuX (where L = $(PhO)_3P$, L′ = $(RO)_3P$, $C_5H_5N$ or $Ph_3As$, X = halogen)[940]; L,AgX (X = Cl, Br, I)[855]; L,AuCl[855]; L,$PtCl_2$[855]; L,$(HgCl_2)_2$[855]; L,$HgX_2$ (X = Cl, Br, I)[855]; $L_4$Pt,$PtCl_2$[857, 861]; $L_4$,M (where L = $(EtO)_3P$, M = Co, Ni).[810, 2405] In many cases the same complexes can be synthesized by reacting an alcohol or phenol with the appropriate complex of phosphorus trichloride with the metal halide.[855, 859] Cryoscopic molecular weight determinations on a number of complexes have been carried out by Arbuzov.[855]

The complex of trimethyl phosphite and cuprous chloride, $(MeO)_3P,CuCl$, which may be prepared from the phosphite directly or by methanolysis of the $PCl_3,CuCl$ complex, undergoes isomerization and decomposition at 200°, giving dimethyl methyl phosphonate[928]:

$$(MeO)_3P,CuCl \xrightarrow[\text{Dowtherm}]{200^\circ \text{ in}} MePO(OMe)_2$$

The preparation of complexes of trialkyl phosphite and borine has been investigated by Reetz and Katlafsky.[858] They found the trialkyl phosphites to be strong Lewis bases (in the case of tri-*iso*propyl phosphite, of the same strength as trimethylamine). The complexes may be obtained by the reaction:

$$NaBH_4 + CO_2 + P(OR)_3 \rightarrow NaOCHO + (RO)_3P,BH_3$$

The relative stability order of borine co-ordination complexes with various trivalent phosphorus compounds is given as[860]:

$$PCl_3 < PH_3 < PF_3 < PR_3 < P(OR)_3 < P(NR_2)_3$$

Trialkyl phosphites give no colour with carbon disulphide, thus differing in this respect from phosphonous diesters which give red solutions and from tertiary phosphines which form red crystalline adducts.[411]

### *Oxidation*

Although direct oxidation by oxygen to corresponding phosphates has been reported for certain specific tertiary phosphites such as tris-1-cyano-*iso*propyl,[879] tris-*p*-chlorophenyl,[880] and triallyl phosphites,[1188] this method fails with triethyl phosphite[872] and is of little practical value for the preparation of phosphates. Photochemically induced oxidation of a variety of trialkyl phosphites is reported to proceed readily[867, 1190] but with trimethyl and triaryl phosphites the oxidation is unsatisfactory.[1190] Unsaturated tertiary phosphites are reported to be oxidized by air in the presence of alumina catalyst[1704]; trithiophosphites can be oxidized by air at 110°C. to about 80% completion and then by hydrogen peroxide to about 95% completion.[1124] Methods involving "wet" oxidation are generally not satisfactory owing to extensive hydrolysis of the phosphite. Reagents which have been used successfully to oxidize tertiary phosphites are ozone,[865–6] sulphur dioxide with phosphorus tribromide as catalyst,[1681] sulphur trioxide in liquid sulphur dioxide solution,[874] sulphur trioxide alone,[1494] aqueous hydrogen peroxide in slightly alkaline solution,[864] nitrogen tetroxide,[872] nitrous oxide,[873] manganese dioxide,[871] mercuric oxide,[870, 871] lead tetraacetate,[889] aqueous chloramine *T*,[637] organic peroxides,[881] and hydroperoxides,[118, 881, 875] peracids such as perbenzoic acid, and *tert*-butyl hypochlorite.[114]

Complexes of the type $(ArO)_3P,O_3$ have been described by Thompson[866] as intermediates in the oxidation of triaryl phosphites by ozone. The products isolated from reaction of tertiary phosphites and dialkyl peroxides are consistent with a free-radical reaction mechanism which involves the formation of an intermediate phosphoranyl radical by the addition of alkoxy-radical to the phosphite (cf. the review 'Radical Reactions of Organophosphorus Compounds'[2314]):

$$RO\cdot + (RO_3)P \rightarrow (RO)_3\dot{P}{-}OR \xrightarrow{\text{fast}} (RO)_3PO + R\cdot$$

The reaction with alkyl hydroperoxides giving phosphate and alcohol has been formulated as an ionic process.[875, 881]

Trialkyl phosphites are excellent deoxygenating reagents,[355] the phosphite itself being oxidized to phosphate. Examples of some compounds which are reduced by trialkyl phosphites are given below:

epoxides → olefins[883]
isocyanates → isonitriles[884]
phthalic anhydride → biphthalyl[885-6]
pyridine *N*-oxide → pyridine[355, 887-8]
diaryloyl peroxides → diaryloyl esters[869]
nitrosobenzene → azoxybenzene[868]
hydroperoxides → alcohols
*O*-nitrostyrenes → 2-substituted indoles[2055]

*Formation of Thiono- and Selenono-phosphates*

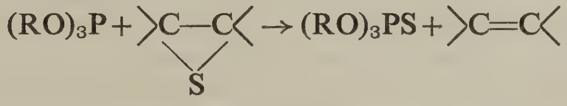
Trialkyl phosphorothionates are readily formed by the addition of sulphur to trialkyl phosphites[1, 399, 1289, 771]; selenium adds less readily to give the phosphoroselenonate:

$$(RO)_3P + S \text{ or } Se \rightarrow (RO)_3PS \text{ or } (RO)_3PSe$$

Triaryl phosphites and aryl phosphorochloridites readily desulphurize $PSCl_3$[1184]:

$$(PhO)_3P + PSCl_3 \rightarrow (PhO)_3PS + PCl_3$$
$$PhOPCl_2 + PSCl_3 \rightarrow PhOPSCl_2 + PCl_3$$

Phosphorothionates also result from reaction with an episulphide,[127, 890] the episulphide being reduced stereospecifically to the corresponding olefin[126, 893]:



Under the influence of free-radical initiators alkane thiols react with trialkyl phosphite yielding the trialkyl phosphorothionate and a hydrocarbon.[881, 894] Rabinowitz and Walling[881, 895] conclude that direct attack of thiyl radicals on phosphorus occurs giving an intermediate tetravalent phosphoranyl radical $(RO)_3\dot{P}\text{–}SR'$ which subsequently breaks down with C–S bond fission to phosphorothionate and an alkyl radical which can perpetuate a chain-reaction:

$$RS\cdot + (RO)_3P \rightarrow (RO)_3\dot{P}\text{—}SR \rightarrow (RO)_3P{=}S + R\cdot$$
$$R\cdot + RSH \rightarrow RH + RS\cdot$$

Dialkyl disulphides react under free-radical conditions giving the thioether and phosphorothionate[881]; in contrast, at higher temperatures in the presence of free-radical inhibitors, reaction proceeds by an ionic Arbuzov-type reaction giving an *S*-alkyl dialkyl phosphorothioate and an unsymmetrical thioether.[896] The two modes of reaction are shown below.

$$(RO)_3PS + R'SR' \xleftarrow[R'S-SR']{\text{radical catalyst}} (RO)_3P \xrightarrow[R'S-SR']{\text{heat}} (RO)_2PO.SR' + RSR'$$

Diacyl disulphides such as diacetyl disulphide,[1004] dibenzoyl disulphide[896] and bis(diethoxyphosphinyl) disulphide react with trialkyl phosphite giving trialkyl phosphorothionate and diacylsulphide. Thiocyanogen behaves similarly.[1004] A modified Arbuzov reaction has been suggested[896, 1004]:

$$(RO)_3P + XSSX \rightarrow [(RO)_3P\text{—}S\text{—}X]^+SX^- \rightarrow (RO)_3PS + X_2S$$
$$(X = CH_3CO,\ PhCO,\ (EtO)_2PO,\ CN)$$

*Reaction with Halogens*

Dialkyl phosphorochloridates may be readily prepared by passing dry chlorine into ice-cold trialkyl phosphite.[700] Other reagents which may be used are sulphuryl chloride,[897] phosgene,[1127] and oxalyl chloride[901]:

$$(RO)_3P \xrightarrow[(COCl)_2,\ COCl_2]{Cl_2,\ SO_2Cl_2} (RO)_2PO.Cl$$

The reported formation of compounds of the type $(RO)_2PO.COCl$ and $[(RO)_2PO]CO$ by reaction of dialkyl phosphite and phosgene[1026] has been questioned by Petrov *et al.*[1634] Reaction with bromine gives the less stable dialkyl phosphorobromidates.[706, 902] Very unstable dialkyl phosphoroiodidates have been obtained in ethereal solution by the action of iodine on ice-cold phosphite.[700]

Sulphur monochloride[898] and sulphur dichloride[899] react with trialkyl phosphites forming both dialkyl phosphorochloridite and trialkyl phosphorothionate, and with triaryl phosphites to give triaryl phosphorothionate and triaryl phosphite dichlorides[900]:

$$S_2Cl_2 + 3(RO)_3P \rightarrow 2(RO)_3PS + RCl + (RO)_2PO.Cl$$
$$SCl_2 + 2(RO)_3P \rightarrow (RO)_3PS + RCl + (RO)_2PO.Cl$$

The reaction between triaryl phosphites and halogens (Cl, Br, I) has been clarified by the work of Rydon and Tonge.[924] The reaction of triphenyl phosphite with halogens proceeds in several stages, the first two of which are[924-5]:

$$2(PhO)_3P + X_2 \rightarrow (PhO)_2PX + (PhO)_4PX \qquad (X = Cl, Br, I)$$
$$(PhO)_2PX + (PhO)_4PX + X_2 \rightarrow 2(PhO)_3PX_2$$

Exchange of cation and anion amongst the dimeric forms of triphenoxyphosphorus dihalides can lead to the formation of all or any of the possible phenoxy-halides $(PhO)_nPX_{(5-n)}$. From a study of the alcoholysis and hydrolysis of these compounds, prepared either by addition of halogen to the phosphite or by the action of phosphorus pentachloride on phenol, it was concluded that the chloro- and bromo-compounds are dimeric polyhalogenopolyphenoxyphosphonium polyphenoxypolychlorophosphates, $[(PhO)_xPX_{(4-x)}]^+[(PhO)_yPX_{(6-y)}]^-$, or mixtures of such compounds, whereas the iodides are monomeric phosphonium compounds

$$[(PhO)_nPI_{(4-n)}]^+I^-$$

Triphenyl phosphite dihalides have been used as reagents for the preparation of alkyl halides[984]:

$$(PhO)_3PX_2 + ROH \rightarrow (PhO)_3PO + RX + HX$$

Triphenyl phosphite polyiodides $(PhO)_3PI^+I_n^-$ have been reported by Forsman and Lipkin.[1005] Reaction of triphenyl phosphite with ammonia and iodine gives $[PhO)_3P{-}N{=}P(OPh)_3]^+I^-$.[1005]

*The Michaelis–Arbuzov Reaction*

One of the classical phenomena of organophosphorus chemistry is the reaction, discovered by Michaelis and Kaehne[903] and developed by Arbuzov,[904] in which a trialkyl phosphite is heated with an alkyl halide to form a dialkyl alkylphosphonate and a new molecule of alkyl halide.[1, 911] In its simplest form, interaction of *n*-alkyl halide with a tri-*n*-alkyl phosphite, the reaction may be written:

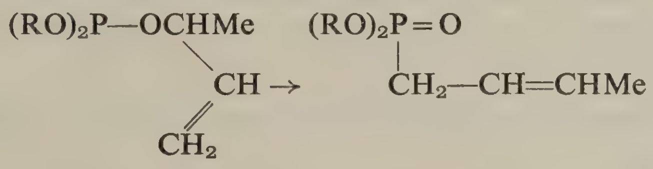
$$R'X + (RO)_3P \rightarrow [(RO)_3\overset{+}{P}{-}R']X^- \rightarrow (RO)_2PO.R' + RX$$

The reaction is generally believed to proceed by two consecutive bimolecular nucleophilic displacement reactions. In the first, trivalent phosphorus attacks the alkyl halide with fission of the C–X bond to form an alkyl trialkoxyphosphonium halide; in the second, the halide ion attacks one of the alkoxy-groups of the intermediate phosphonium salt.[717,896,905,907–10,918] The general observation that, with respect to alkyl halide, the reaction rate decreases in the order RI > RBr > RCl, and primary halide > secondary halide, and the low reactivity of *cyclo*hexyl *p*-toluenesulphonate with triethyl phosphite have been advanced in support of the mechanism of the first stage of reaction.[717,905] Overall reaction rates have been measured by a number of workers.[912–5,936–7,1109] Reaction of tris-2-octyl phosphite from optically active 2-octanol with ethyl bromide or with acetyl chloride gives optically inverted 2-bromo-octane and 2-chloro-octane, respectively, indicating the $S_N2$ character of the second reaction step.[905]

Physico-chemical evidence for the existence of the intermediate quasiphosphonium salts has been advanced by Arbuzov and co-workers[917–8,933] and by Abramov,[919,923,926] and is strongly supported by the isolation of salt-like quasiphosphonium halides from the reaction of triaryl phosphite,[903,916] diesters of phosphonous acids,[421,920,1723] and esters of phosphinous acids[421,2387–8] with alkyl halides and by the formation of quasiphosphonium fluoroborates from the reaction of trialkyl phosphites with carbonium-ion tetrafluoroborates.[921–2]

No exchange of radio-active phosphorus takes place between triethyl phosphite and diethyl ethyl phosphonate indicating that the reaction is irreversible.[927]

Trialkyl phosphites have been isomerized to the corresponding alkyl dialkyl phosphonates by heating at 250° without catalyst[1105] and at lower temperatures by the Arbuzov reaction using catalytic amounts of reagents such as methyl iodide,[813,931] dimethyl sulphate,[813] ethyl toluene sulphonate[717] or sodium iodide.[929] Diphenyl alkylphosphonates are formed by heating $(PhO)_3P$, an alcohol, and a catalytic amount of sodium iodide.[930] Allyl dialkyl phosphites undergo a Claisen-type rearrangement on heating, giving 2-propenyl phosphonates[932]:



Phosphites which contain halogenoalkyl substituents readily undergo isomerization on being heated; thus tris-2-chloroethyl phosphite rearranges to bis-(2-chloroethyl) 2-chloroethyl phosphonate.[934]

### *Scope of the Arbuzov Reaction*

(*a*) The phosphorus component

The Arbuzov reaction occurs between a wide range of trivalent phosphorous esters and alkyl halides. The following classes of esters participate: mixed trialkyl phosphites,[844] trialkyl phosphorothionites and dithionites,[853,1595] aryl dialkyl and diaryl alkyl phosphites,[914] vinyl dialkyl and divinyl alkyl phosphites,[789–90] dialkyl phosphoramidites[863,1595,878,941–2,1087] and alkyl phosphorodiamidites,[943,946,2406] diesters of phosphonous[415–8,840] and phosphonodithious acids,[945] esters of phosphinous[526,920] and phosphinothious acid,[944] and esters of pyrophosphorous acid.

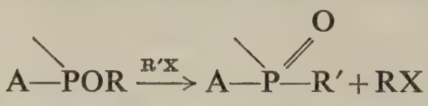
In a number of these reactions moderately stable intermediate quasiphosphonium salts have been isolated.[421,920,941,943,945,1723]

The effects of substituents attached to the phosphorus atom on the reaction rate are generally in accordance with the predicted electron-donating or electron-attracting effect of the substituent on the electron density at the phosphorus atom. Thus, the reaction rate increases in the series:

$$ArOP(OAlk)_2 < AlkOP(OAlk)_2 < AlkP(OAlk)_2$$

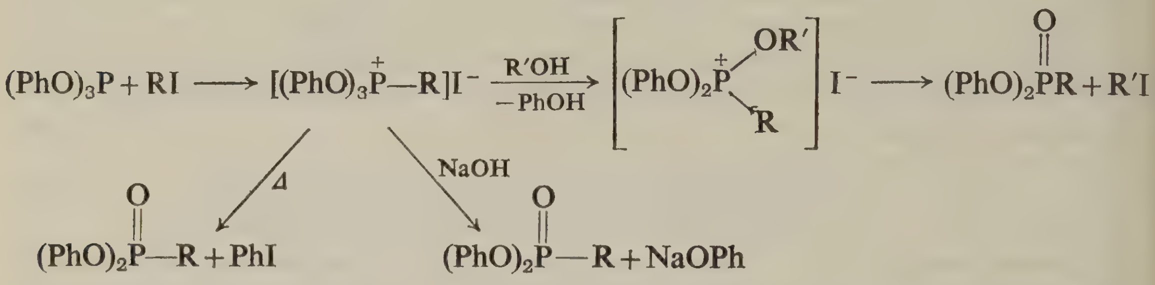
In the series of compounds $(EtO)_3P$, $EtP(OEt)_2$, $Et_2POEt$, the relative reaction times with ethyl iodide are 1214 : 12 : 1.[915]

In mixed trialkyl phosphites the smallest alkyl group is eliminated as alkyl halide,[844] in mixed phenyl alkyl phosphites, vinyl alkyl phosphites and alkyl phosphoroamidites the alkyl group is always eliminated:



$$\text{A—POR} \xrightarrow{\text{R}'\text{X}} \text{A—}\overset{\text{O}}{\text{P}}\text{—R}' + \text{RX} \qquad (\text{A} = \text{phenyl, vinyl, R}_2\text{N})$$

Triaryl phosphites, trivinyl phosphites, and trialkyl trithiophosphites do not undergo the Arbuzov reaction. Triaryl phosphites form moderately stable quasi-phosphonium salts which may be converted to diaryl alkylphosphonates by treatment with an alcohol[813] or with aqueous alkali or by heating at 200°[914]:



Diphenyl phenylphosphonite and phenyl diphenylphosphinite behave similarly.[421] The first reaction sequence above has been developed by Rydon[813] as a convenient route for the preparation of alkyl halides.

Trivinyl phosphite decomposes on being heated with methyl iodide at 120°.[790] Trithiophosphites form crystalline adducts with alkyl halides[852] and these adducts were shown by Divinskiĭ, Kabachnik and Sidorenko[947] to be the products of alkylation at a sulphur atom. The adducts decompose on heating giving dialkyl dithiophosphorous halides (*S,S*-dialkyl phosphorohalidodithioites):

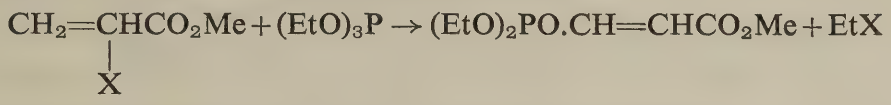
$$(\text{RS})_3\text{P} + \text{RX} \rightarrow (\text{RS})_2\text{P—}\overset{+}{\text{S}}\text{R}_2\text{X}^- \xrightarrow{\Delta} (\text{RS})_2\text{PX} + \text{RSR}$$

### (*b*) The alkyl halide

Trialkyl phosphites undergo the Arbuzov reaction with a wide range of alkyl halides to form the corresponding phosphonic acid esters.[1, 2] The phosphonic esters have been thus obtained in good yield from the following halogen compounds: low molecular-weight and long-chain primary alkyl halides[948, 715]; arylalkyl halides such as benzyl halides and their nuclear substituted derivatives[958, 973, 1085]; halogenomethyl naphthalene and halogenomethyl substituted heterocyclic compounds [1111]; halogenomethyl ethers such as chloromethyl benzyl ether[949]; $\omega$-halogeno esters[2406] such as $\beta$-bromopropionic ester[983]; $\omega$-bromoundecanoates[961]; $\omega$-halogen substituted quaternary ammonium compounds[968]; halogenohydrins such as epibromohydrin[656]; and chloromethyl cyanide.[1722] The reaction proceeds less well with secondary alkyl halides and generally good yields of phosphonate are obtained only with secondary halides which also carry an $\alpha$-activating group such as $\alpha$-bromo fatty acid esters,[721, 954, 962–3] $\alpha$-halogenoacetamide,[460, 960] diesters of $\alpha$-halogenomethylphosphonic acid,[745] bromoacetal[975] and chloroacetonitrile.[975] Diphenylmethyl bromide and 9-bromofluorene[964] react well; a free-radical reaction mechanism has been suggested for the reaction of these bulky halides.[964] Triarylmethyl halides form the expected triarylmethylphosphonates.

Aromatic halogen compounds do not undergo the Arbuzov reaction but a number of chlorosubstituted heterocyclic compounds such as 9-chloroacridine[1112] and 5-chloropyrimidine yield the expected phosphonates. In chlorotriazines the chlorine atom is replaced by the diethyl phosphono-group by reaction with triethyl phosphite[1086]; thus cyanuric chloride (2,4,6-trichlorotriazine) forms 2,4,6-tris-diethyl phosphonotriazine.[966] Cyanogen chloride or bromide and tertiary alkyl phosphites form dialkyl cyanophosphonates.[967, 1721]

Compounds having halogen attached to a carbon–carbon double bond react with difficulty. α-Halogenoacrylic esters and triethyl phosphite react with rearrangement giving diethyl 2-(carboxymethyl)vinylphosphonate[959]:

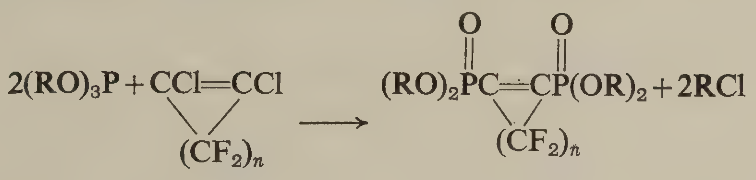


$$CH_2{=}\underset{\displaystyle X}{\underset{|}{C}}HCO_2Me + (EtO)_3P \rightarrow (EtO)_2PO.CH{=}CHCO_2Me + EtX$$

Perfluorovinylphosphonates have been obtained by the reaction of trialkyl phosphite with perfluoro*cyclo*butene, perfluoro*iso*butylene, and perfluoropropylene[971]:

$$(EtO)_3P + (CF_3)_2C{=}CF_2 \rightarrow (CF_3)_2C{=}CF{-}PO.(OEt)_2 + EtF$$

1,2-Dichloroperfluoro*cyclo*alkenes react with triethyl phosphite with displacement of both chlorine atoms to give tetra-alkyl perfluoro-1-*cyclo*alkene-1,2-diphosphonates.[2065] In contrast, saturated chlorofluorohydrocarbons react anomalously to give olefin and dialkyl phosphorofluoridate[2066]:

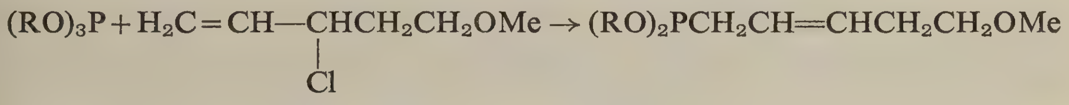


$$(RO)_3P + F(CF_2CFCl)_nF \longrightarrow F(CF{=}CF)_nF + (RO)_2POF + RCl$$

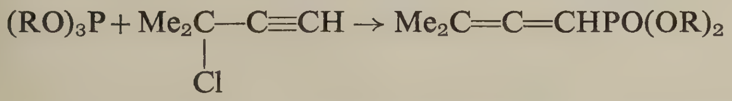
Aromatic imidoyl chlorides form the expected dialkyl phenyliminobenzyl phosphonates.[2408] Acetylenic halides such as phenyl chloroacetylene[715, 2407] and 1-bromo-3-butene-1-yne[1110, 957] form the corresponding alkynylphosphonates:

$$BrC{\equiv}C{-}CH{=}CH_2 + (RO)_3P \rightarrow (RO)_2PO.C{\equiv}C{-}CH{=}CH_2$$

Allyl halides and propargyl halides in which the halogen atom is attached to a primary carbon atom as in allyl chloride,[953] propargyl bromide[955] and 1-bromobut-2-yne[1110] form the expected phosphonate. When the halogen atom is attached to a secondary or tertiary carbon atom a rearranged product can result. Thus 3-chloro-1-methoxypent-4-ene gives 5-methoxy-pent-2-enyl phosphonate and 3-methyl-3-chlorobut-1-yne gives 3-methylbuta-1,2-dienyl phosphonate[956]:

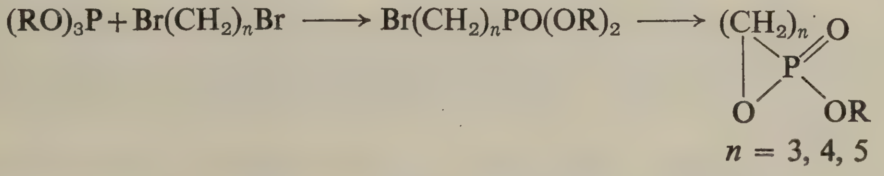


$$(RO)_3P + H_2C{=}CH{-}\underset{\displaystyle Cl}{\underset{|}{C}}HCH_2CH_2OMe \rightarrow (RO)_2PCH_2CH{=}CHCH_2CH_2OMe$$



$$(RO)_3P + Me_2\underset{\displaystyle Cl}{\underset{|}{C}}{-}C{\equiv}CH \rightarrow Me_2C{=}C{=}CHPO(OR)_2$$

Compounds containing two primary halogen atoms such as α-ω dihalogenoalkanes[976] and bis-halogenomethyl ether[950] react with an excess of trialkyl phosphite giving good yields of the bis-phosphonate ester. With an excess of halogen compound ethylene dibromide forms a 2-bromoethyl phosphonate,[977] but with higher α-ω dibromides the initially formed ω-bromoalkyl phosphonate undergoes cyclization to form a phospholane derivative.[965] A similar alkylation has been demonstrated by Laughlin between dimethyl methylphosphonate and dodecyl bromide[952]:



$$MePO(OMe)_2 + C_{12}H_{25}Br \longrightarrow MePO(OMe)OC_{12}H_{25}$$

Methylene di-iodide and trialkyl phosphites react to form the dialkyl iodomethylphosphonate,[745] which can react with a further equivalent of trialkyl phosphite giving a tetra-alkyl methylenediphosphonate. Methylene dibromide reacts more slowly and it is necessary to conduct the reaction under pressure.[812] The reaction of methylene dichloride with trialkyl phosphites has not been reported.

Chloroform is reported not to react with triethyl phosphite even under vigorous conditions[364,458,980]; in the presence of benzoyl peroxide reaction occurs giving diethyl dichloromethylphosphonate. Carbon tetrachloride reacts with trialkyl phosphites at temperatures lower than those required for simple alkyl halides, giving high yields of trichloromethylphosphonates[844,979–80]; similarly trichlorofluoromethane gives $CFCl_2PO(OR)_2$.[1002] The reaction with carbon tetrachloride has been shown by Griffin[363] to proceed by a radical-chain process. Similar radical-chain processes have been suggested[982] for the reaction of trialkyl phosphites with trichlorobromomethane and carbon tetrabromide[1008] and for the benzoyl peroxide catalyzed reactions of dibromomethane, bromodichloromethane, bromochloromethane, and chloroform.[982] Support for the homolytic nature of the reaction of carbon tetrachloride with triethyl phosphite has been advanced by Cadogan.[355]

In some cases olefin formation occurs during the Arbuzov reaction. Formation of small amounts of olefin and dialkyl phosphite takes place when 1-halogenoalkanes having an activating group in the 2-position are reacted with trialkyl phosphite.[909] The preparative use of trialkyl phosphites as dehydrohalogenating agents has been described.[974] 3-Chloro*cyclo*pent-1-ene reacts with trialkyl phosphite to form *cyclo*pentadiene but with sodium diethyl phosphite giving the expected diethyl *cyclo*pent-2-enyl phosphonate.[969]

Dehalogenation occurs with certain polyhalogen compounds, e.g., phenanthrene-9,10-dibromide[720] and hexachloroethane[970] give phenanthrene and tetrachloroethylene respectively.

Chloro-urea and trialkyl phosphites react to form esters of ureido-phosphoric acid[2161]:

$$(RO)_3P + ClNHCONH_2 \rightarrow NH_2CONHPO(OR)_2 + RCl$$

*Reactions related to the Arbuzov Reaction*

A variety of compounds which contain polarized or easily polarizable linkages, which can undergo reaction with a nucleophile with displacement of an anion, will undergo reaction with trialkyl phosphite in an Arbuzov-type reaction:

$$(RO)_3P + A{-}X \rightarrow [(RO)_3\overset{+}{P}A]X^- \rightarrow (RO)_2PO.A + RX$$

Such reactions occur with molecular chlorine, bromine,[902] or iodine,[1005] alkyl sulphonate esters,[717] acyl halides,[508,725,745,990] carboxylic acid anhydrides,[997,1009] Mannich base salts,[985–6] *N*-alkyl[996] and *N*,*N*-dialkyl[995–6] carbamoyl chlorides and thiocarbamoyl chlorides,[998] sulphenyl[841,898,1003] and sulphonyl halides,[994,999] alkyl isothiocyanates and alkyl isoselenocyanates,[988] *N*,*N*-dialkylamino-sulphenyl chlorides,[1084] *N*-chloroamines,[993] *N*-chloro-benzamide and *N*-chloro-benzamidine,[1081] alkyl hypochlorites,[992] disulphides,[896,999] bis(dialkyloxythiophosphonyl) disulphides,[1605] alkyl alkanethiolsulphonates,[987] diselenides[1002] and bisdialkoxyphosphinyl diselenides,[1002] organosilicon halides,[989] and mercuric acetate.[1083] Disulphides of formula $RSSCCl_3$ and tertiary phosphites are reported to form compounds with the formula $RSSC[PO(OR)_2]_3$.[1707] Some of these reactions are shown in Chart XVI.

The quasiphosphonium salts formed as intermediates in these reactions are difficult to isolate. Recently, relatively stable crystalline double salts of the type $[(RO)_3PSR]^+SbCl_6^-$ have been obtained by Hilgetag and Teichmann from the reaction of lower trialkyl phosphites with alkyl sulphenyl chlorides in the presence of $SbCl_5$.[1003]

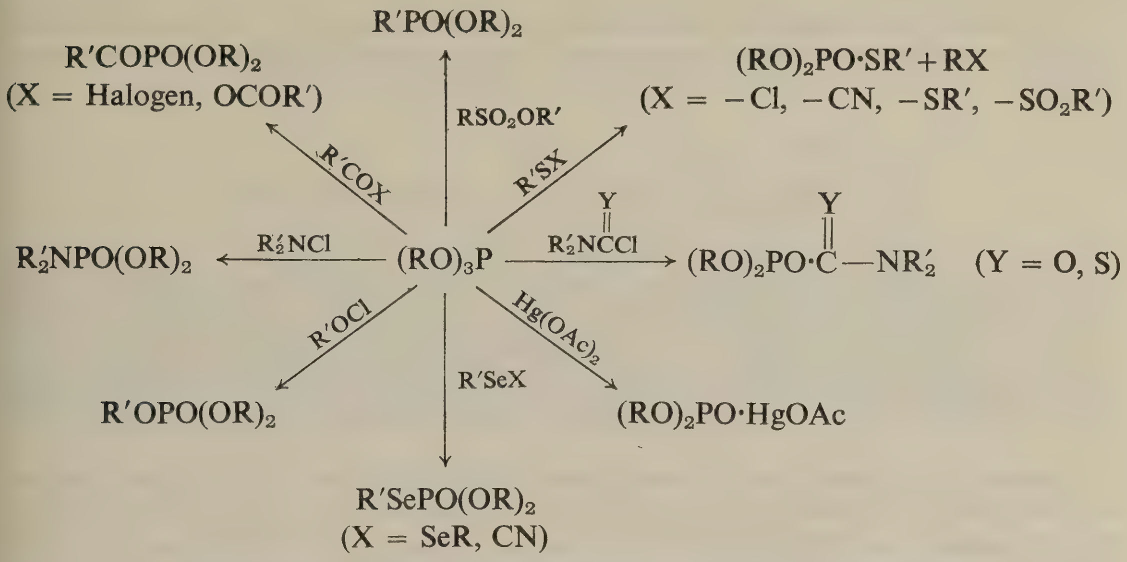


CHART XVI.—Some reactions related to the Arbuzov reaction

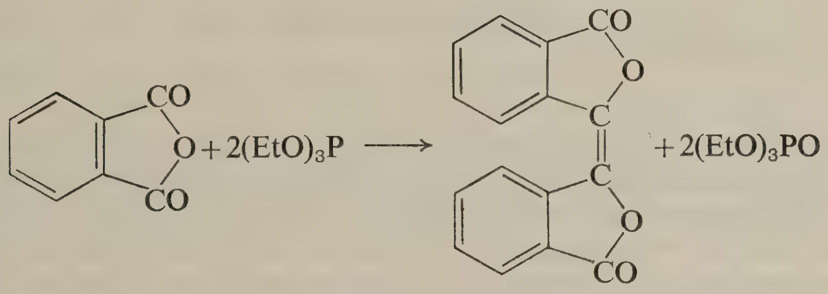
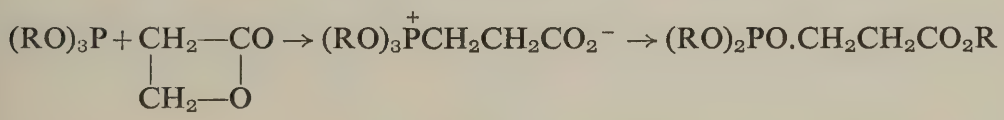
In contrast to the reaction of aliphatic acid anhydrides, phthalic anhydride reacts with trialkyl phosphites giving biphthalyl[885]; if the reaction is conducted in the presence of dialkyl phosphite the product is phthalide 3-phosphonate:



Lactones such as $\beta$-propiolactone and $\gamma$-valerolactone react at the alkyl rather than the acyl carbon atom giving charged intermediates which undergo transalkylation to yield $\omega$-dialkyl phosphonocarboxylic esters[755, 1061]:

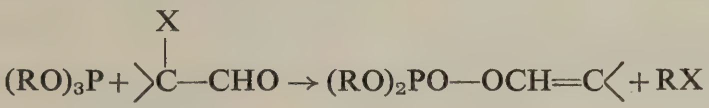


$$(RO)_3P+\begin{array}{l}CH_2\text{—}CO\\ |\qquad\quad |\\ CH_2\text{—}O\end{array}\rightarrow (RO)_3\overset{+}{P}CH_2CH_2CO_2^- \rightarrow (RO)_2PO.CH_2CH_2CO_2R$$

By contrast, the sodium dialkyl phosphonates react at both alkyl and acyl carbon atoms giving a mixture of products.[755]

THE PERKOW OR ANOMALOUS ARBUZOV REACTION

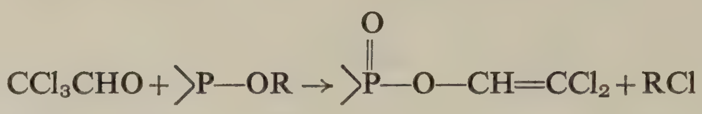
Perkow *et al.* in 1952[1010] found that $\alpha$-halogenoaldehydes did not react with trialkyl phosphites by the Arbuzov–Michaelis reaction but that a new type of rearrangement occurred yielding a dialkyl vinyl phosphate:



$$(RO)_3P+{>}\overset{X}{\overset{|}{C}}\text{—}CHO\rightarrow(RO)_2PO\text{—}OCH{=}C{<}+RX$$

The historical development leading to the recognition of the Perkow reaction, its scope and limitations, and possible reaction mechanisms have been reviewed by Lichtenthaler.[1007]

Like the Arbuzov reaction, the Perkow reaction has proved to be a general reaction for trivalent phosphorus compounds of the type R′R″POR. Reactions with chloral,



$$CCl_3CHO + \rangle P{-}OR \rightarrow \rangle \overset{O}{\overset{\|}{P}}{-}O{-}CH{=}CCl_2 + RCl$$

have been reported for the following: trialkyl and mixed trialkyl phosphites,[1013] aryl dialkyl phosphites,[1013] diaryl alkyl phosphites,[1013] *O*,*O*,*S*-trialkyl phosphorothioites,[1033] dialkyl phosphoramidites,[1030, 1191] alkyl phosphorodiamidites,[1030] dialkyl esters of phosphonous acids,[419, 1031] *O*-alkyl-*N*,*N*-dialkyl phosphonamidites,[419] alkyl esters of phosphinous acids,[419] and alkyl ethylene, tri- and tetra-methylene phosphites.[1013, 1032]

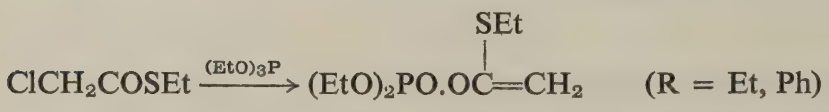
Frequently it is found that a given halogen compound reacts by both the Arbuzov and the Perkow reactions giving a mixture of products. Structural factors, the nature of the halogen and temperature have a marked influence on the relative extents of the two reactions.[1017] Whereas α-monohalogen,[946, 1013] α-dihalogen,[1013–5] and α-trihalogen[908, 1010, 1013, 1016] aldehydes react with trialkyl phosphites to give exclusively the vinyl phosphates, α-halogenoketones give mixtures of vinyl phosphate and ketoalkyl phosphonate.[1012, 1017–8] Thus chloro-, bromo- and iodo-acetones give mixtures of *O*,*O*-dialkyl-2-ketopropyl phosphonate and dialkyl 1-methylvinyl phosphate[1017]:

$$(RO)_3P + XCH_2COCH_3 - \begin{cases} \rightarrow (RO)_2PO.CH_2COCH_3 + RX & \text{(Arbuzov)} \\ \rightarrow (RO)_2PO.{-}OC(CH_3){=}CH_2 + RX & \text{(Perkow)} \end{cases}$$

Chloroacetone reacts predominantly by the Perkow reaction, bromoacetone gives a mixture of products and iodoacetone yields predominantly the phosphonate. Higher reaction temperatures favour the occurrence of the Arbuzov reaction over the Perkow reaction.[1017] Ketones in which the halogen atom is attached to a secondary carbon atom react to a significantly greater extent by the Perkow reaction than those having halogen on a primary carbon atom.[729, 1012, 1018] Ketones having more than one halogen attached to the α-carbon atom,[946, 1018] and 2-halogeno-1,3-diketones,[1022–3] react almost exclusively by the Perkow reaction.

Marked effects of structure on the course of reaction have been observed with α-halogen derivatives of fatty acids. Ethyl chloroacetate and α-halogenoacetamides[460, 960] react by the Arbuzov reaction giving phosphonate products whereas *S*-esters of α-chlorothiolacetate[1028, 1724] give largely the product formed by the Perkow reaction:

$$ClCH_2COY \xrightarrow{(EtO)_3P} (EtO)_2PO.CH_2COY \qquad (Y = NH_2, NEt_2, OEt)$$

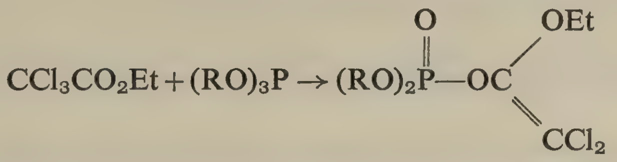


$$ClCH_2COSEt \xrightarrow{(EtO)_3P} (EtO)_2PO.O\overset{SEt}{\overset{|}{C}}{=}CH_2 \qquad (R = Et, Ph)$$

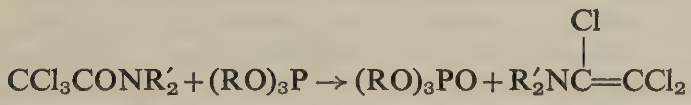
α-Halogen acetoacetates and acetoacetamides react according to the Perkow reaction[1007, 1013, 1023, 1027] as do diethyl chloro- and diethyl dichloro-malonates, ethyl cyanoacetate,[1025] and α-chloro-α-diethyl phosphonoacetone,[1027] but diethyl bromomalonate can react either by the Perkow[1020] or the Arbuzov[1024] reaction depending on the reaction conditions.

Ethyl trichloroacetate undergoes the Perkow reaction giving a dialkyl 1-alkoxy-

2,2-dichlorovinyl phosphate,[960, 1013, 1020] but with trichloroacetamides the major reaction products are trialkyl phosphate and a trichlorovinylamine[1021]:



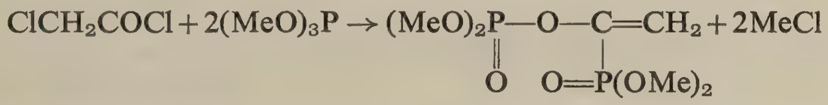
$$CCl_3CO_2Et + (RO)_3P \rightarrow (RO)_2\overset{\overset{O}{\|}}{P}—OC(OEt)=CCl_2$$



$$CCl_3CONR'_2 + (RO)_3P \rightarrow (RO)_3PO + R'_2N\overset{\overset{Cl}{|}}{C}=CCl_2$$

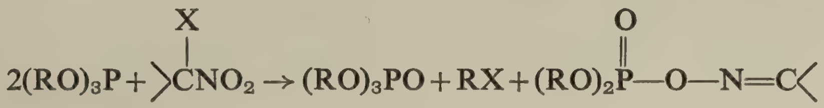
*sym*-Dichlorotetrafluoroacetone $(CF_2Cl)_2CO$ and trialkyl phosphites undergo the Perkow reaction but perfluoroketones give dialkyl phosphorofluoridate.[1725]

α-Halogenoacyl halides react with two molecules of trialkyl phosphite giving dialkyl 1-(dialkyl phosphono)vinyl phosphates,[1018, 1026] e.g., chloroacetyl chloride and trimethyl phosphite react according to the equation:



$$ClCH_2COCl + 2(MeO)_3P \rightarrow (MeO)_2\underset{\underset{O}{\|}}{P}—O—\underset{\underset{O=P(OMe)_2}{|}}{C}=CH_2 + 2MeCl$$

The reaction of α-halogenonitroparaffins such as trichloronitromethane and 1-bromo-1-nitropropane has been shown by Allen[972, 1029] to give phosphoric esters of oximes:



$$2(RO)_3P + {>}\overset{\overset{X}{|}}{C}NO_2 \rightarrow (RO)_3PO + RX + (RO)_2\overset{\overset{O}{\|}}{P}—O—N=C{<}$$

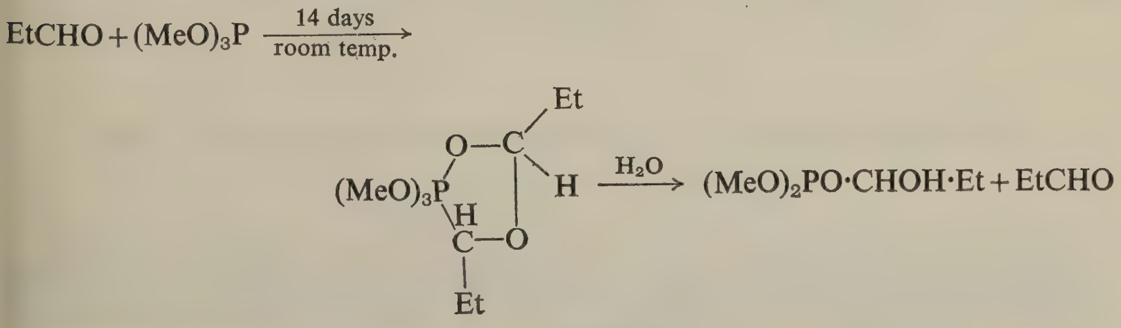
THE REACTION OF TRIALKYL PHOSPHITES WITH CARBONYL COMPOUNDS AND α-β UNSATURATED ACIDS

When aliphatic aldehydes and trialkyl phosphites are heated together in a sealed tube at 100°–170° for several hours, an Arbuzov-type reaction occurs giving a charged intermediate in which the negative charge appears on oxygen rather than on a displaced anion. This intermediate undergoes trans-alkylation to form a dialkyl 1-alkoxyalkyl phosphonate[1039]:

$$(RO)_3P + R'CHO \rightarrow [(RO)_3\overset{+}{P}CH(R')—O^-] \rightarrow (RO)_2PO.CH(OR)R'$$

Tri-*n*-propyl phosphite and benzaldehyde[1040] react to give a poor yield of di-*n*-propyl α-propoxybenzyl phosphonate; furfural yields trialkyl phosphate and difurylethylene,[1040] a reaction reminiscent of the reaction of phthalic anhydride.[885]

Ramirez and co-workers[1055] have isolated the tetraoxyalkyl phosphorane (**XVII**) in 60% yield from the reaction of trimethyl phosphite and propionaldehyde (3 moles). They consider that the initial 1 : 1 complex formed by addition of the phosphite to the carbonyl carbon of the aldehyde undergoes addition of a second mole of aldehyde giving the precursor of the oxyphosphorane. Hydrolysis of **XVII** yields dimethyl 1-hydroxypropyl phosphonate and propionaldehyde:



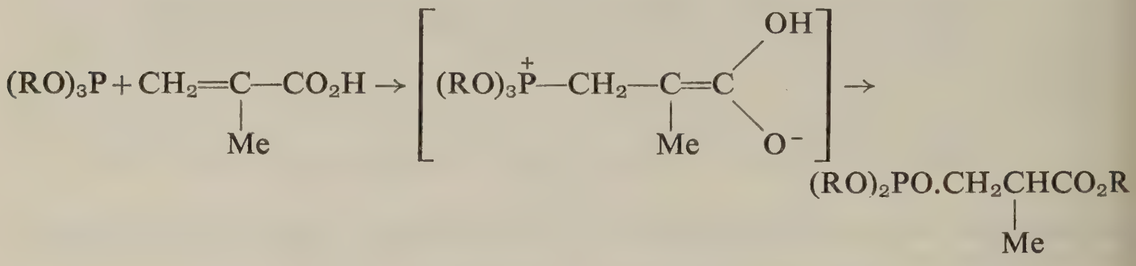
**XVII**

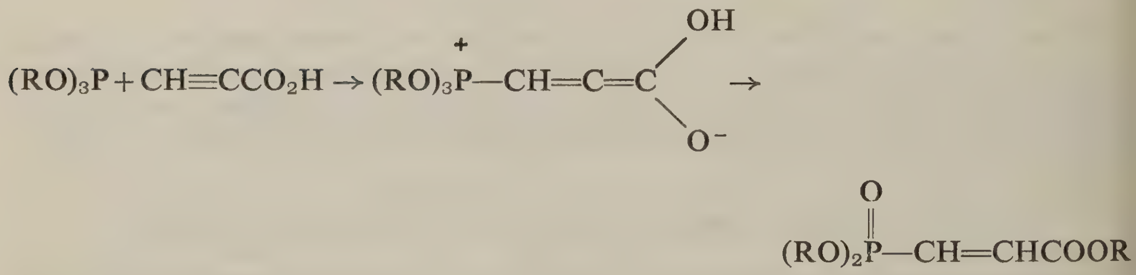
Acetone[1710] and 4-methyl-(4-dichloromethyl)-*cyclo*hexadiene-1-one[1711] are reported to be inert to triethyl phosphite. Certain aromatic ketones react with tertiary phosphites giving diarylmethylphosphonic esters,[1712] e.g.,

$$Ph_2CO + 2(RO)_3P \rightarrow Ph_2CHPO(OR)_2 + (RO)_3PO + C_3H_7 \qquad (R = \textit{iso}\text{propyl})$$

In a manner similar to the thermal reactions of aliphatic aldehydes, $\alpha$-$\beta$-unsaturated aldehydes[1041, 1044] such as acrolein and crotonaldehyde, and $\alpha$-$\beta$-unsaturated acids[1042-3] such as cinnamic acid and methacrylic acid, when heated with trialkyl phosphites, form charged intermediates in which the negative charge is transferred through the conjugated system to oxygen of the aldehyde or carboxyl group. Transalkylation results in dialkyl 3-alkoxyprop-2-enyl phosphonates and dialkyl 2-carbalkoxyethyl phosphonates, respectively. Acetylenic acids such as propiolic acid undergo the reaction at room temperature giving dialkyl 2-carbalkoxyvinyl phosphonates[1065]:

$$(RO)_3P + CH_2{=}CHCHO \rightarrow [(RO)_3\overset{+}{P}CH_2{-}CH{=}CH{-}O^-] \rightarrow (RO)_2PO.CH_2{-}CH{=}CHOR$$

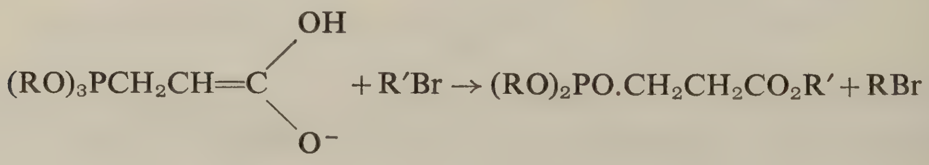




Dialkyl phosphonites react similarly with methacrylic acid giving an ester of an unsymmetrical phosphinic acid.[1045, 1062]

Kukhtin and Kamaĭ showed the rate of reaction of $(RO)_3P$ with methacrylic acid at 50° to be dependent on the nature of the solvent[1046]: polar solvents accelerate the reaction, whereas weakly polar solvents retard the reaction in comparison with the rate without solvent.

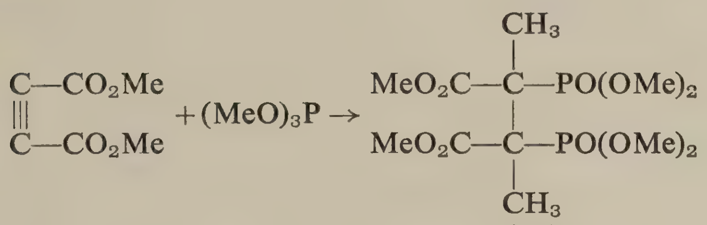
In a related reaction the combined effect of trialkyl phosphite and an alkyl halide on an $\alpha$-$\beta$-unsaturated acid yields a dialkyl 2-carbalkoxyethyl phosphonate[1046-7] by alkylation of the charged intermediate with alkyl halide:



Telomers having molecular weights ranging from several hundred to two thousand result from the reaction of triethyl phosphite and methacrylic acid in the presence of benzoyl peroxide at room temperature.[1048]

The thermal reaction of trialkyl phosphites with non-activated acetylenes proceeds through the formation of a dipolar intermediate (I) which collapses by an internal *cis* $\beta$-elimination (R = ethyl, butyl) to form olefin and vinyl phosphonate (II). Normally **II** undergoes attack by a second molecule of phosphite to form an alkylene-1,2-bis phosphonate.[2410] Dimethyl acetylenedicarboxylate and trimethyl phosphite form 2,3-bis-carbomethoxy-2,3-(dimethylphosphono)butane (III)[2409]:

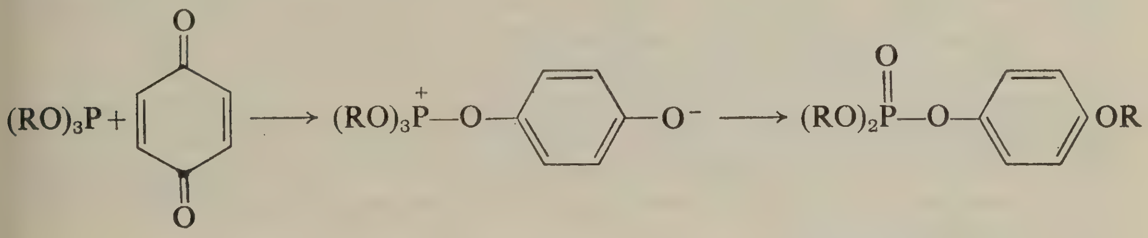
$$RC{\equiv}CH + P(OR)_3 \rightarrow \underset{\text{(I)}}{R\overset{-}{C}{=}CH\overset{+}{P}(OR)_3} \rightarrow \underset{\text{(II)}}{RCH{=}CHPO(OR)_2} + \text{olefin}$$



$$\begin{array}{l} C{-}CO_2Me \\ \| \! | \\ C{-}CO_2Me \end{array} + (MeO)_3P \rightarrow \begin{array}{c} CH_3 \\ | \\ MeO_2C{-}C{-}PO(OMe)_2 \\ | \\ MeO_2C{-}C{-}PO(OMe)_2 \\ | \\ CH_3 \end{array}$$

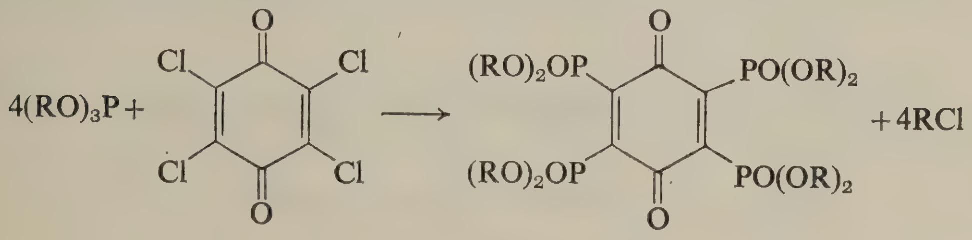
(III)

Tri(primary-alkyl) phosphites and *p*-quinones (Q) such as *p*-benzoquinone[1053] and chloranil[1054] react to give charged intermediates which undergo transalkylation yielding a dialkyl *p*-alkoxyaryl phosphate. If the reaction is conducted in the presence of water the intermediate (except that from duroquinone) is hydrolyzed to trialkyl phosphate and the quinol ($QH_2$)[1053]:



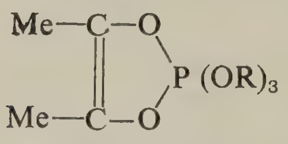
$$(RO)_3P + Q + H_2O \longrightarrow (RO)_3PO + QH_2$$

Tri(*sec*-alkyl) phosphites and chloranil react forming carbon-phosphorus rather than oxygen-phosphorus bonds, the product being a quinone 2,3,5,6-tetraphosphonate[1060]:

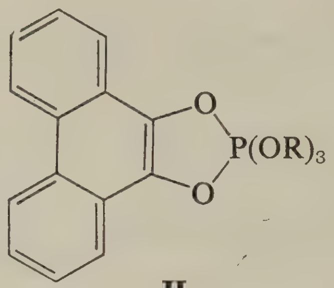


## PENTAOXOPHOSPHORANES

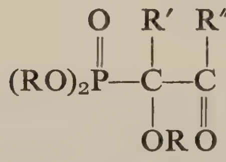
Trialkyl phosphites react at substantially room temperatures with *o*-quinones such as *o*-benzoquinone,[1066] 1,2-naphthaquinone,[1066] and phenanthraquinone,[1049, 1052] with $\alpha$-diketones such as diacetyl,[1041, 1056] benzil,[1049] and 2,3-pentanedione,[1049] and with α-ketoaldehydes to give colourless 1 : 1 adducts. Triaryl phosphites yield similar adducts if the reaction is conducted at about 100°.[1049, 1052, 1067–8] From a careful analysis of the results of Raman, infra-red, $^{31}P$ and $^{1}H$ nuclear magnetic resonance spectroscopy, and dipole moment measurements, Ramirez and Desai[1049, 1052, 1715] confirmed that the adducts are derivatives of pentaoxophosphorane. The diacetyl and phenanthraquinone adducts have structures **I** and **II**, respectively:



**I**



**II**

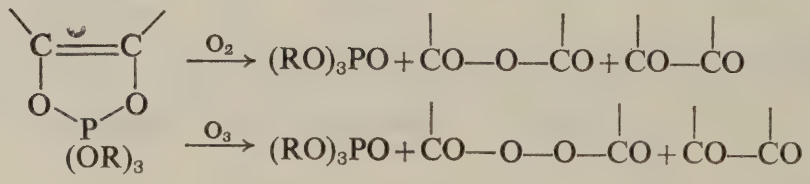


$$(RO)_2P(=O)-C(R')(OR)-C(R'')=O$$

**III**

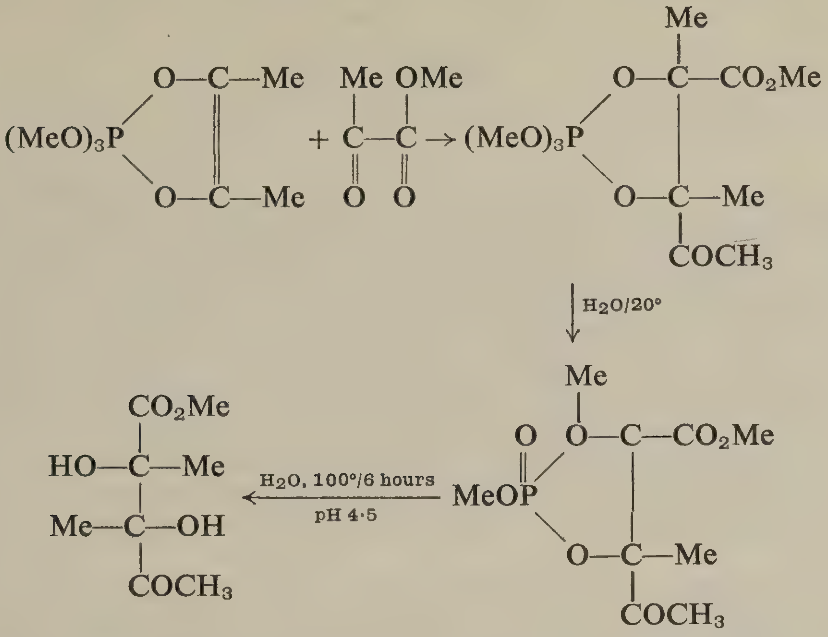
Structures of type **I** were first proposed by Kukhtin[1056] and by Birum and Dever.[1069] Although alternative structures such as **III** ($R=R'=R''=CH_3$) have been suggested by Kukhtin[1058–9] and co-workers for the reaction product of trimethyl phosphite with diacetyl, more recent work [1057, 1064, 1066] confirms the existence of compounds of type **I** and suggests that **III** ($R', R''=(CH_2)_4$, $R=Et$) is formed when *cyclo*hexanedione and triethyl phosphite interact at 120°–130°. On the other hand, near room temperature the product is an oxyphosphorane of type **I**. The formation, structure and reactions of cyclic pentaoxyphosphoranes are surveyed by Ramirez.[1716, 2411]

The pentaoxyphosphoranes do not undergo the alkyl group translocation which occurs with the adducts of trialkyl phosphites and *p*-quinones.[1052] Hydrolysis proceeds readily giving dialkyl α-ketophosphonates or dialkyl α-quinol phosphates from **I** and **II**, respectively.[1052, 1067] The adducts derived from diketones react with oxygen giving a mixture of the original diketone and an acid anhydride[1063]; ozonation of the phenanthraquinone–trimethyl phosphite adduct (**IV**, R = Me) gives a good yield of biphenoyl peroxide, trimethyl phosphate, and some phenanthraquinone[1080]:



**IV**

The 1 : 1 adduct of trimethyl phosphite and diacetyl has been shown to react further with diacetyl to give two diastereoisomeric forms of a 2 : 1 adduct having a cyclic oxophosphorane structure with a new 1,3-dioxophospholane ring system.[1051] Pyruvic acid and propionaldehyde behave similarly with the 1 : 1 adduct.[1050] On mild hydrolysis with water at 20° the ring system of the 1,3-dioxophospholane remains intact, giving a cyclic phosphate, which may be hydrolyzed under more vigorous conditions.[1715] The reactions of methyl pyruvate which lead to the formation of *DL*-threomethyl-α,β-dimethyl α,β-dihydroxylevulinate are shown below:



Non-cyclic pentaoxyphosphoranes are less well-known. Pentaphenoxyphosphorane, $(PhO)_5P$, is reported to be formed from $(PhO)_3PCl_2$ and phenol.[1718–9] (see also page 1077). Pentaethoxyphosphorane results from the reaction between triethyl phosphite and diethyl peroxide; it is unstable and decomposes slowly to diethyl ether, triethyl phosphate, and ethanol.[1717]

$$(EtO)_3P + EtO\text{—}OEt \xrightarrow[\text{temperature}]{\text{15 days at room}} (EtO)_5P$$

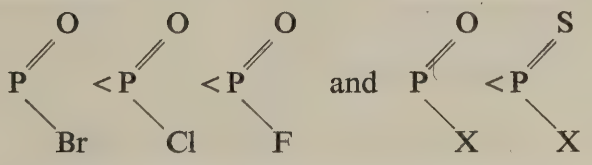
Reaction with carboxylic acid, phenol and acetylacetone, gives the ethyl ester of the acid, ethyl phenyl ether and ethyl enol ether respectively, together with triethyl phosphate.[2412]

## DERIVATIVES OF PHOSPHORIC ACID

### Esters of Phosphorohalidic Acids and Phosphorothionohalidic Acids

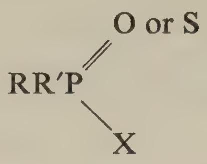
An extensive series of ester halides of phosphoric and thiophosphoric acid is known in which one or two of the halogen atoms in $POX_3$ or $PSX_3$ (X = F, Cl, Br, I) are replaced by alkoxy-, or mercaptide groups.

The lower alkyl and aryl derivatives are colourless liquids which can generally be distilled under vacuum. Vapour pressure data for a number of dialkyl phosphorofluoridates[1127, 1315] and several aryl phosphorochloridates[948, 1371] are recorded. As a class these compounds undergo fairly ready hydrolysis to the corresponding acids. The stability of the P-halogen bond in $(RO)_2POX$ or $(RO)_2PSX$ increases in the series:



Compounds of the type $(ArO)_2POF$ or $(ArO)_2PSF$ are stable in water.[1137] The hydrolysis of dialkyl phosphorochloridates to dialkyl phosphates is catalyzed by formdimethylamide.[1173]

The rates of hydrolysis of ethyl phosphorodichloridate[1035] and a number of dialkyl phosphorohalidates have been examined[438, 498, 549, 550, 1156, 1158] frequently in relation to the effect of substituents on the mechanism of hydrolysis of compounds having the general structure:



(R, R′ can be alkyl, arylalkoxyl, alkylamino, dialkylamino; X = halogen or alkoxy). The results of much of this work are collated and discussed by Hudson[1076] and are reviewed.[1171] Substitution at the phosphoryl centre normally proceeds by a bimolecular displacement mechanism with a transition state similar to an $S_N2$ displacement on carbon. Thus, Dostrovsky and Halmann demonstrated a rate sequence, $F^- > OH^- > OPh^- > EtOH > PhS^- > CH_3CO_2^-$, for the reaction of di-*iso*-propyl phosphorochloridate with anionic reagents[549] and later, in isotope studies, showed that no exchange occurs between the phosphoryl oxygen and $^{18}O$ labelled water during the hydrolysis of $(EtO)_2POCl$.[1285] In the reaction of *O*,*O*-diphenyl phosphorochloridothionate with various nucleophilic anions, the reactivities of the oxy-anions $RO^-$ and sulphur anions $RS^-$, closely follow the p*K* values of the conjugate acids.[1166-7]

Dialkyl phosphorofluoridates are extremely toxic, acting to inhibit cholinesterase. Such compounds, particularly di-*iso*propyl phosphorofluoridate (DFP), were developed as nerve gases during World War II.[1154,1172] The structural effects required to give high toxicity are discussed by Saunders.[1159] Kinetics of hydrolysis of dialkyl phosphorofluoridates,[1176] particularly DFP[438,1158,1161-4] and related toxic compounds such as sarin[1158,1160-2,1174-5,1185] and *O*-*iso*propyl methylphosphonofluoridate, have been extensively studied. Fission of the P–F bond in DFP is catalyzed by acids and bases[1164] and is accelerated by basic oxy-anions such as hydroperoxide ion,[1169] hypochlorite,[1168] and salts of oximes[1178] and of hydroxamic acids[1160,1162,1170,1230,1232] by metal ions and metal-ion complexes, particularly those of Cu(II),[1233-5] and by enzymes.[1165]

## PREPARATION

The most commonly used and simplest method of preparing phosphorohalidate esters is by reaction of an alcohol, phenol or mercaptan with an oxy- or thiono-halide of phosphorus. The ease of reaction, and the experimental technique used to obtain the product, are governed largely by three factors: (i) the nucleophilic power of the reagent towards the phosphoryl group, ROH > ArOH > RSH; (ii) the reactivity of the P–X bond in the phosphorus oxy- or thiono-halide, $POBr_3 > POCl_3 > POF_3$ and PO.X > PS.X; and (iii) the ease of dealkylation of the resulting ester by hydrogen halide formed as by-product, HBr > HCl ≫ HF(zero) and *tert*-alkyl > benzyl > *sec*-alkyl > *n*-alkyl > aryl (zero). Thus, with two active reactants such as a primary alcohol and phosphoryl chloride the chlorine atoms are rapidly replaced at essentially room temperature, whereas with less reactive pairs of compounds such as thiophosphoryl fluoride and a phenol, or phosphoryl chloride and a mercaptan[1206] it is necessary to use a tertiary organic base condensing agent. As a first approximation, the formation of primary or secondary ester halide depends on the molar proportions of reagents used as indicated by the idealized equations:

$$ROH + POCl_3 \rightarrow ROPOCl_2 + HCl \tag{1}$$

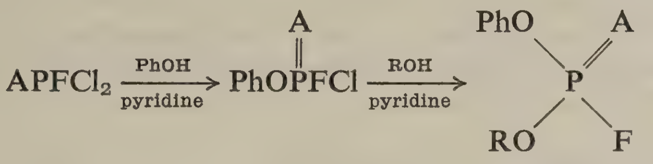
$$2ROH + POCl_3 \rightarrow (RO)_2POCl + 2HCl \tag{2}$$

Lower primary alkyl phosphorodichloridates can generally be prepared in satisfactory yield by reaction (1) carried out using an excess of phosphoryl chloride at below room temperature; the success of the preparation depends on complete removal of hydrogen chloride before distillation.[1,599,967,1133,1180] With alcohols of higher molecular weight, substantially pure alkyl phosphorodichloridates are obtained by interaction of stoichiometric amounts of alcohol and phosphoryl chloride at below 15° in vacuum.[1128,1180] The preparation of phosphorodichloridates or chloridates derived from secondary, tertiary or aryl alkyl alcohols is unsatisfactory owing to dealkylation,[1] as is the preparation of phosphorobromidates by direct reaction in the absence of a base.[902] Reaction (2) is unsuitable for the preparation of dialkyl phosphorochloridates owing to difficulties of separation from the mixture of products formed.[1181]

Dialkyl phosphorochloridates are best prepared by chlorinating the corresponding dialkyl phosphite; the bromidates may be obtained similarly but are best prepared by the action of bromine on trialkyl phosphite; for iodidates the tertiary phosphite route is essential. Phenols require temperatures higher than those for alcohols for reaction (usually at reflux) with phosphoryl chloride. Under these conditions a mixture of products forms[1139,1141] even when an excess of phosphoryl chloride is used. Phenyl phosphorodichloridate[1231] and diphenyl phosphorochloridate[1236] are readily prepared from phenol and phosphoryl chloride and can be separated easily by fractional distillation. The formation of aryl phosphorodichloridates is catalyzed by substances such as aluminium chloride,[1146,1502] salts of group I metals,[1139] calcium chloride,[1130,1134] magnesium chloride or oxide,[1] magnesium,[1126] and iron.[1140] The yield of dichloridate relative to chloridate is reduced by the presence of electron-withdrawing substituents such as chlorine in the aromatic nucleus.[1146]

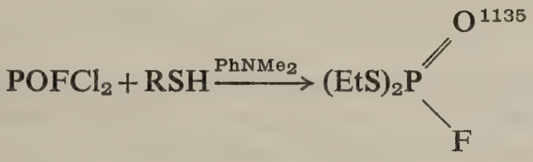
Phosphorofluoridates and chloridofluoridates have been prepared by taking advantage of the lower reactivity of the fluorine atom in phosphoryl chlorofluorides (equations 3, 4 and 5), by metathesis from the corresponding chlorides (equation 6),[1,967,1154,1177,1488] and from pyrophosphoric esters and hydrogen fluoride (equation 7).[1179]

(3)

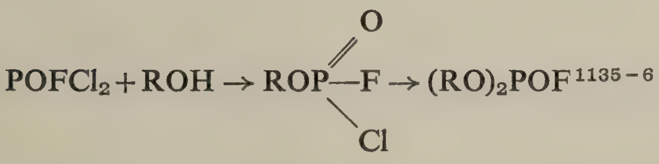


(A = O, S)[1136-8]

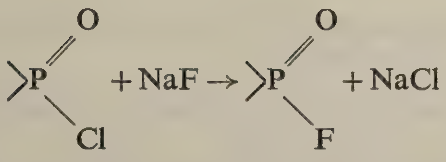
(4)



(5)

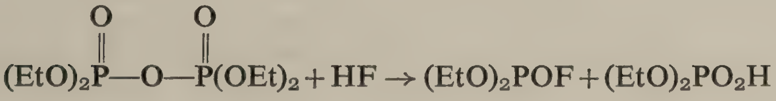


(6)



$$—POCl_2 + 2NaF \rightarrow —POF_2 + 2NaCl$$

(7)

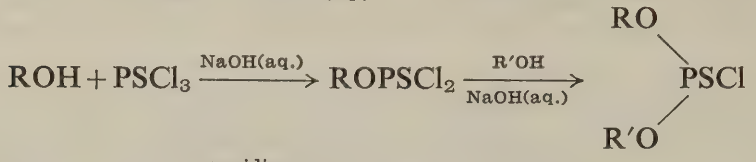


$$(EtO)_2\overset{\overset{O}{\|}}{P}—O—\overset{\overset{O}{\|}}{P}(OEt)_2 + HF \rightarrow (EtO)_2POF + (EtO)_2PO_2H$$

Thiophosphoryl chlorides react much more sluggishly with alcohols than does phosphoryl chloride, and the reaction is fairly readily restricted to the formation of alkyl phosphorodichloridothionates,[1,1152] indeed, formation of dialkyl phosphorochloridothionates and aryl phosphorodichloridothionates generally necessitates the use of a base[1230] such as aqueous alkali,[1148-50] sodium alkoxide,[1151] aluminium alkoxide[1147] or a tertiary amine[1206]:

$$ROH + PSCl_3 \rightarrow ROPSCl_2 + HCl$$

$$ArOH + PSCl_3 + NaOH_{(aq.)} \rightarrow ArOPSCl_2 + NaCl + H_2O$$



$$ROH + PSCl_3 \xrightarrow{NaOH(aq.)} ROPSCl_2 \xrightarrow[NaOH(aq.)]{R'OH} (RO)(R'O)PSCl \qquad (R, R' = \text{alkyl, aryl})$$

$$PSCl_3 + 2RSH \xrightarrow{pyridine} (RS)_2PSCl + 2HCl$$

*O*-Aryl phosphorodichloridothionates can be prepared from phenols and thiophosphoryl chloride using a catalyst such as magnesium, cuprous or phosphorous chloride, or with pyridine as a hydrogen acceptor, or from the aryl phosphorodichloridite by the reaction $ArOPCl_2 + PSCl_3 \rightarrow ArOPSCl_2 + PCl_3$.[1682] Phosphorochloridates give rather low yields of phosphorochloridothionates by treatment with phosphorus pentasulphide.[1733]

$$EtOPOCl_2 + P_2S_5 \xrightarrow[5\ hr.]{150°} EtS\text{—}PSCl_2$$

$$PhOPOCl_2 + P_2S_5 \xrightarrow[6\ hr.]{140\text{–}150°} PhOPSCl_2 + (PhO)_2PSCl + (PhO)_3PS$$

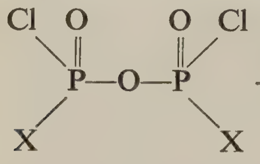
MISCELLANEOUS METHODS

Lower alkyl phosphorodichloridates have been obtained by reaction of phosphoryl chloride with trialkyl phosphates[1,600]; the method is unsatisfactory for higher alkyl compounds and for the preparation of dialkyl phosphorochloridates.[600] A high yield of diethyl phosphorochloridate is claimed from the reaction of triethyl phosphate with phosphorus pentachloride[1143]:

$$2POCl_3 + (BuO)_3PO \rightarrow 3BuOPOCl_2$$

$$PCl_5 + (EtO)_3PO \rightarrow (EtO)_2POCl + POCl_3 + EtCl$$

Pyrophosphoryl chloride and *sym*-dichlorodifluoropyrophosphoric acid react with alcohols with preferential fission of the P–O–P bond to give alkyl phosphorodichloridates[1144-5] and alkyl phosphorochloridofluoridate[1484] respectively:



$$Cl(X)P(O)\text{—}O\text{—}P(O)(X)Cl + ROH \rightarrow ROPO.XCl + HOPOXCl \qquad (X = Cl, F)$$

Alkyl or aryl phosphorohalidothionates are readily obtained by adding elemental sulphur to phosphorohalidites[1,1283]:

$$(RO)_nPX_{(3-n)} + S \rightarrow (RO)_nPSX_{3-n} \qquad (n = 1, 2;\ X = Cl, Br;\ R = \text{alkyl, aryl})$$

Alkyl phosphorochloridothioites, $RSPCl_2$ and $(RS)_2PCl$, add sulphur similarly. Frequently elemental sulphur can be replaced by thiophosphoryl chloride, which readily donates its sulphur atom to tertiary phosphites or phosphorohalidites.[1184]

Dialkyl or diaryl phosphorochloridothionates are readily obtained by chlorination of *O,O*-dialkyl(or aryl) phosphorodithioic acids or their salts, using reagents such as chlorine,[1239,1241-2] sulphur monochloride,[1238-9] sulphur dichloride,[1238] phosphorus pentachloride,[1153,1239] or sulphuryl chloride[1240]

$$2(RO)_2PS_2H + 3Cl_2 \rightarrow 2(RO)_2PSCl + S_2Cl_2 + 2HCl$$

Gerrard[1182] investigated the reaction of alcohols with phosphorus pentachloride. Primary alcohols give a mixture of alkyl phosphorodichloridate, dialkyl phosphorochloridate and alkyl chloride; secondary alcohols give higher yields of alkyl halide and olefin by-products; tertiary alcohols give almost 100% alkyl chloride. The initial chloro-esters of the type $ROPCl_4$ could not be isolated.

*S*-Alkyl phosphorodichloridothiolates are formed by the reaction of phosphorus trichloride with sulphenyl chlorides in liquid sulphur dioxide. Methyl dichlorophosphine affords *S*-alkyl methyl phosphonochloridothiolates[2417]:

$$PCl_3 + RSCl \xrightarrow[\text{at } -50°]{SO_2} RSPOCl_2$$

Reactions of dialkyl phosphorochloridates are shown in Chart XVII.

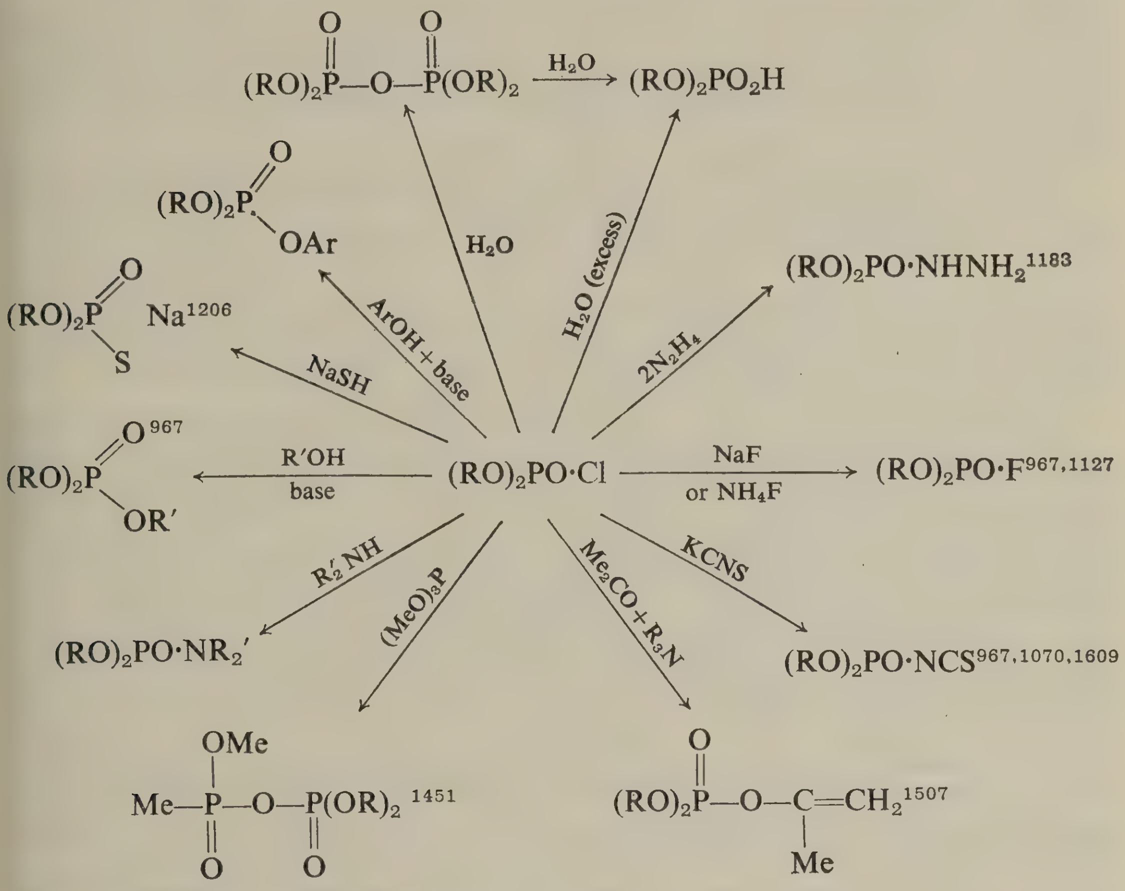


CHART XVII.—Reactions of phosphorochloridates

## ESTERS OF PHOSPHORIC ACID (AND CONDENSED PHOSPHATES AND THEIR THIO-ANALOGUES)

Esters of phosphoric acid, the condensed orthophosphates and sulphur-containing analogues form an important part of organophosphorus chemistry. Naturally occurring phosphates such as sugar phosphates, phospholipids, phosphoproteins, nucleic acids, and coenzymes, play a major role in life processes. Structural formulae of a number of the naturally occurring compounds are given by Van Wazer[3] and Hutt.[1515] Developments in the chemistry of the biologically important compounds are reviewed by Khorana,[1586] who has reported the total synthesis of coenzyme *A*.[1557] In commerce, esters of phosphoric acid have found numerous applications, most important of which are uses as plasticizers,[1516, 1530] insecticides,[1246–7, 1250, 1274, 1482, 1516, 1606] petrol and oil additives,[1216, 1218, 1243–5, 1530] extractants for metal ions,[1404, 1516–24] and as flotation agents.[1278]

There is a number of reviews concerned with phosphorylation. These may, broadly speaking, be divided into those concerned with methods[185,1193–4,1197,1200] and those concerned more with the mechanistic features of the reactions involved.[1076,1195–6]

## Mono- and Di-esters of Phosphoric Acid

### PROPERTIES

Mono- and di-esters of phosphoric acid are strong di- and mono-basic acids, respectively. The lower monoalkyl acids are stronger than phosphoric acid and the lower dialkyl acids are stronger than the monoalkyl acids; for $H_3PO_4$, $MeOPO_3H_2$, and $(MeO)_2PO_2H$, the $pK'a_1$ values are 1·97, 1·54, and 1·29 respectively.[1115] Acid strength decreases somewhat with increasing size of the alkyl substituent.[1115] Amongst the strongest phosphoric acids are the glucose 3-, 4- and 6-phosphates. Ionization constants of a number of the acids are collated by Van Wazer[3] and are correlated in terms of the Hammett $\sigma$ function of the substituent groups by Kabachnik.[1269,1274]

Association due to hydrogen-bonding is stronger in alkyl phosphoric acids than in carboxylic acids.[1403] The monobasic acids, bis(2-ethylhexyl), dibutyl, and bis(*p*-1,1,3,3-tetramethylbutylphenyl) phosphoric acids are dimeric in benzene solution, whilst the dibasic acids mono(2-ethylhexyl) and mono[*p*-(1,1,3,3-tetramethylbutyl) phenyl] phosphoric acids are polymeric. In carbon tetrachloride solution these acids show no non-associated hydroxyl spectral bands.[1403] Dimerization constants of dibutyl phosphates in organic solvents have been evaluated in connection with the use of monoacidic phosphates as extractants for metals.[1728–31]

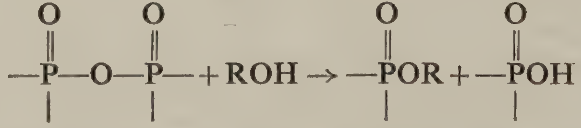
Aliphatic mono- and di-esters of phosphoric acid are syrupy liquids; the extreme water solubility of the lower alkyl acids decreases with increasing size of the alkyl substituent and from the mono- to the di-esters. Aromatic mono- and di-phosphates are frequently solids which may be crystallized from water.[1,1236] When absolutely pure (free from water, hydrogen chloride or dinitrogen tetroxide) the lower dialkyl phosphates are said to be stable at 100° and can be distilled under high vacuum.[1117–8] Acid ethyl phosphate decomposes slowly on storage; at 200° it gives triethyl phosphate and a residue of pyro- and meta-phosphoric acid esters.[1119] At 176° monobutyl phosphate undergoes extensive decomposition giving orthophosphoric acid and condensed phosphates; dibutyl phosphate is more stable but disproportionates to give approximately equal amounts (16%) of monobutyl and tributyl phosphate.[1448] Thermal decomposition of di-*n*-butyl, *sec*-butyl and *iso*butyl phosphates at 215°–302° gives butenes as the only volatile product. The volatiles from di-*n*-butyl phosphate consist of butene-1 (28%), *cis*-butene-2 (32%) and *trans*-butene-2 (40%).[1120]

The detailed crystal structure of dibenzyl phosphate has been determined by *X*-ray diffraction.[1121]

### PREPARATION

#### *Use of Anhydrides*

The earliest recorded organophosphorus compounds, crude mixtures of alkyl phosphoric acids, were prepared in 1820 by Lassaigne[1122] by heating alcohols with syrupy phosphoric acid. Anhydrides of orthophosphoric acid or its esters react with alcohols with fission of P–O–P linkages forming an ester and an acid:



$$-\underset{|}{\overset{\overset{O}{\|}}{P}}-O-\underset{|}{\overset{\overset{O}{\|}}{P}}-+ROH\rightarrow-\underset{|}{\overset{\overset{O}{\|}}{P}}OR+-\underset{|}{\overset{\overset{O}{\|}}{P}}OH$$

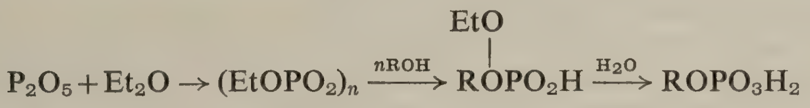
One of the simplest and commercially most important applications of this reaction is heating phosphorus pentoxide with alcohols to give approximately equimolar amounts of mono- and di-esters of phosphoric acid. The overall reaction may be written:

$$P_2O_5 + 3ROH \rightarrow (RO)_2PO_2H + ROPO_3H_2 \qquad \text{(plus traces of } H_3PO_4\text{)}$$

The reaction is generally carried out without solvent at temperatures of 30°–80°, in which range the product composition is not appreciably affected by temperature.[1330] At higher temperature some decomposition of the products occurs[1,1197] especially when secondary alcohols have been used. Colourless products are obtained by adding a small amount of hypophosphorous acid or its salts to the reactants.[1198,1329] The presence of water in the phosphorus pentoxide or alcohol leads to products having a higher monoalkyl phosphate content.[1330,1477] Products prepared in mineral oil dispersions are claimed to have low orthophosphoric acid contents.[1328]

The classical method of separating mono- and di-alkyl phosphates of lower molecular weight involved conversion of the acids into the calcium or barium salts followed by fractional crystallization from water[1,1335–6,1441]; the salts of the dialkyl phosphate are more soluble. Separation of the $C_7$–$C_{12}$ acids has been achieved by extracting the calcium or magnesium salts with a non-polar hydrocarbon to remove the salt of the dialkyl phosphate,[1331] or by extraction of the sodium salts with water to remove sodium monoalkyl phosphate.[1332] Mixtures of $C_1$–$C_9$ acids are separated by liquid–liquid extraction.[1333–4,1403–4] Bis-heptafluorobutyl phosphate may be isolated by direct distillation of the reaction mixture from phosphorus pentoxide and heptafluorobutanol.[1478–9]

'Polyphosphoric acid', a mixture of phosphorus pentoxide and 85% phosphoric acid, and the condensed phosphates obtained by heating 85% phosphoric acid, have been used extensively, particularly by Cherbuliez and co-workers, to prepare monoalkyl phosphates from substituted alcohols.[1335–8,1475] Trialkyl phosphates and phosphorus pentoxide react to give a mixture of products which is claimed, depending on the proportions of reactants used, to be predominantly alkyl metaphosphate $[(ROPO_2)_n]$, hexa-alkyl tetraphosphate $(RO)_6P_4O_4$, penta-alkyl tripolyphosphate $(RO)_5P_3O_5$ or tetra-alkyl pyrophosphate; these on hydrolysis yield mono- and/or di-alkyl phosphates.[1197,1339] The chloroform-soluble 'ethyl metaphosphate' (p. 1055) which may be prepared, following Langheld,[1398,1405] by interaction of phosphorus pentoxide and diethyl ether in chloroform, can be used to prepare phosphates from alcohols of high molecular weight.[1398,1406–7] The overall reactions may be written:



$$P_2O_5 + Et_2O \rightarrow (EtOPO_2)_n \xrightarrow{nROH} \overset{EtO}{R\overset{|}{O}PO_2H} \xrightarrow{H_2O} ROPO_3H_2$$

Monoalkyl phosphates of higher alcohols are readily prepared by reaction of the alcohol and pyrophosphoric acid[1727,2060]:

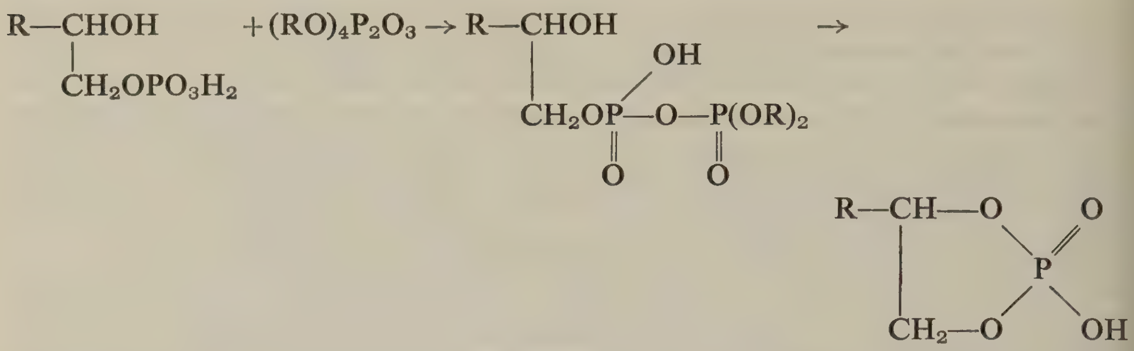
$$ROH + H_4P_2O_7 \rightarrow ROPO_3H_2 + H_3PO_4$$

Tetra-esters of pyrophosphoric acid cause phosphorylation of alcohols, usually in the presence of a base, to give mixed tertiary phosphates[1415] which, by suitable choice of substituents on the pyrophosphate, can be converted into monoalkyl phosphate by selective removal of two ester groups:

$$R'OH + (RO)_4P_2O_3 \xrightarrow{\text{base}} (RO)_2PO_2H + (RO)_2PO.OR' \rightarrow R'OPO_3H_2$$

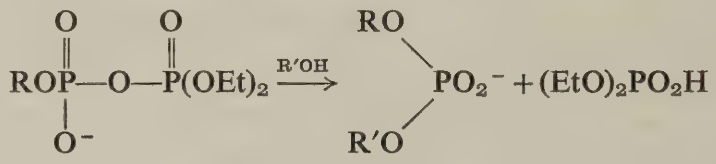
The mixed tertiary phosphates can be, and generally are, prepared by use of phosphorochloridates rather than the equivalent pyrophosphate. Alcohols can be phosphorylated with tetra-*p*-nitrophenyl pyrophosphate at room temperature in the absence of a base.[1384] One *p*-nitrophenyl group may be removed from the resulting alkyl di-(*p*-nitrophenyl) phosphate by mild alkaline hydrolysis, the second by more vigorous alkaline hydrolysis or by the action of snake venom[1410]; both *p*-nitrophenyl groups are removed by hydrogenolysis over Adams catalyst.[1384]

An interesting application of pyrophosphates is in the synthesis of cyclic phosphates from β-hydroxysubstituted phosphates. Riboflavin-4′,5′-phosphate is prepared from riboflavin-5′-phosphate with $(PhO)_4P_2O_3$ or $(PhCH_2O)_4P_2O_3$.[1411] Such reactions may be written:



Similarly a 2′- (or 3′-) nucleotide phosphate (as the trioctylamine or tridecylamine salt) with $(PhO)_4P_2O_3$ yields the nucleotide 2′,3′ cyclic phosphate.[1347] The same cyclization may be effected using trifluoroacetic anhydride[1347, 1411–2]; transient formation of a mixed anhydride of trifluoroacetic acid and the monosubstituted phosphate has been suggested.[1412–3]

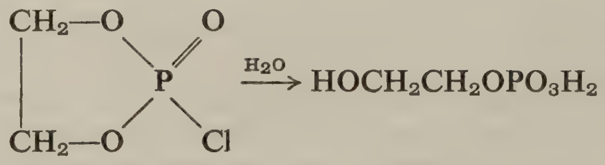
Trisubstituted pyrophosphates can cause phosphorylation of alcohols giving unsymmetrical phosphoric acid diesters[1440]:

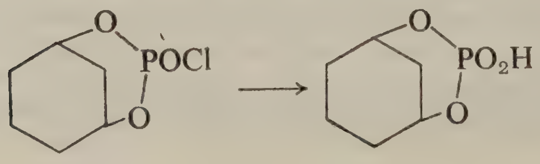


*Use of Phosphoryl Halides*

Although mono- and di-substituted phosphates can be produced by aqueous hydrolysis of the corresponding phosphorohalidates,[1, 1144, 1194, 1341, 1447–8] the method is not generally successful or practical since secondary reactions, such as hydrolysis of the ester linkages, occur so readily in the acid medium.[1194] Mono-*p*-*tert*-butyl phenyl phosphate of high purity may be obtained from the corresponding dichloridate by gradual addition of 2 moles of water at 85°–90° and removal of the hydrogen chloride formed by means of a stream of inert gas and/or reduced pressure.[1342] Frequently the phosphorohalidate, or the crude product obtained from hydroxy-compounds and phosphoryl chloride, is hydrolyzed by adding it to aqueous alkali thus giving a salt of the corresponding phosphoric acid.[620, 1117, 1448, 1525] The free acid can be obtained by adding phosphorochloridate to a suspension of the calculated amount of silver oxide in water.[1447] Dialkyl peroxyphosphates, $(RO)_2PO.OOH$, are formed by the action of pyridine and aqueous hydrogen peroxide on dialkyl phosphorochloridates.[1470]

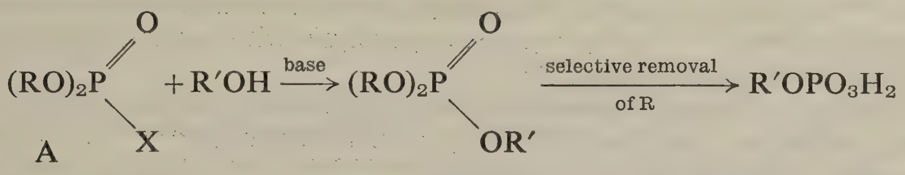
Cyclic ester halidates derived from 1,2-diols generally undergo ring fission on hydrolysis to form diol-monophosphate,[1343] but those derived from 1,3-diols give the normal product[1344]:





A number of phosphates have been obtained by adding an alcohol to phosphoryl chloride in the presence of water,[1] or to phosphoryl chloride in wet pyridine.[1345–6] Under these conditions species such as $Cl_2PO_2H$, $ClPO_3H_2$, pyrophosphoryl chloride and condensed phosphoric acid chloroanhydrides are the actual phosphorylating agents.

The most generally used procedure, particularly for mono- or di-phosphates of complex alcohols, is the reaction of an alcohol with a phosphorylating agent carrying protecting groups to give, usually, a tertiary phosphate from which the protecting groups are removed selectively:

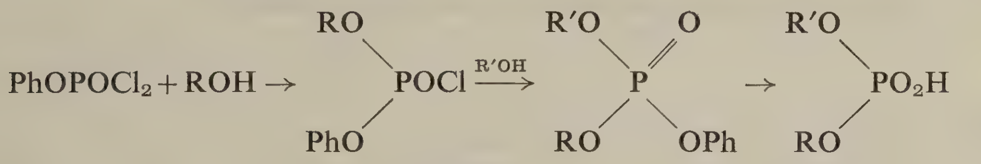


A

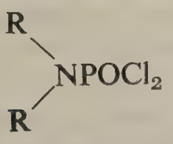
$$ROPOX_2 + 2R'OH \xrightarrow{\text{base}} ROPO(OR')_2 \rightarrow (R'O)_2PO_2H$$

B

Typical reagents, A and B respectively, are diphenyl phosphorochloridate, which has been used extensively for preparing sugar phosphates,[1193, 1236, 1348–9] and phenyl phosphorodichloridate, which is probably the most generally useful reagent for preparing symmetrical dialkyl phosphates.[1350] Unsymmetrical diesters, particularly in the phospholipid series,[1351] have been prepared from phenyl phosphorodichloridate by the following reaction sequence:



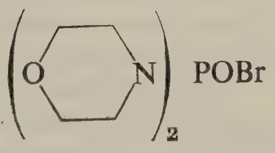
Dibenzyl phosphorochloridate has been used extensively by Todd and co-workers, particularly in the nucleotide field.[672, 1193, 1352] The reagent readily phosphorylates most primary hydroxyl groups in pyridine or, better, in 2,6-lutidine solutions[620, 1354] but is less satisfactory with secondary hydroxyl groups.[1355] It reacts with salts of phenols but not readily with the phenols themselves.[1352] Other reagents in this class, which have found specific rather than wide application are *p*-nitrophenyl phosphorodichloridate,[1356] di-*p*-bromobenzyl phosphorochloridate,[1358] di-*p*-nitrobenzyl phosphorochloridate,[1357] di-*p*-iodobenzyl phosphorochloridate,[1357] bis-(2-chloroethyl) phosphorochloridate,[1359] and bis-(2-cyanoethyl) phosphorochloridate.[1360] Similar reagents are the phosphoramidic halides,[1361–3] **I** and **II**. Amongst these compounds phosphorobromidic dimorpholide, **III**, is the most successfully used reagent.[1364]



**I**

$(R_2N)_2POCl$

**II**



**III**

### *Methods of removing the Protecting Groups*

In the preparation of complex phosphates the choice of the phosphorylating agent, and hence the mode of removing the protecting groups from the intermediate triester, is determined to a large extent by the stability of the organic residue in the final phosphate. For example, in the synthesis of nucleotides factors such as alkali lability of the 6-amino groups in cytosine, the acid lability of purine glycosidic bonds, and the catalytic reduction of pyrimidine rings must be taken into account.

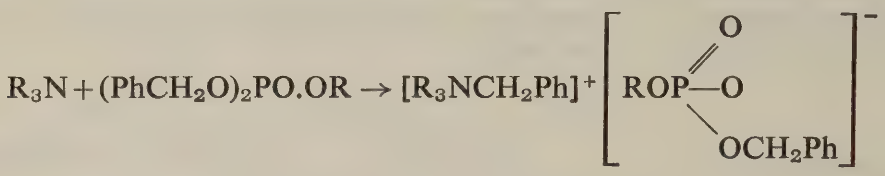
The phenyl group in monophenyl triesters may be removed by hydrogenation over platinum catalyst,[1350–1] or by alkaline hydrolysis[1365]:

$$(RO)_2PO.OPh \xrightarrow{H_2/Pt} (RO)_2PO_2H + C_6H_{12}$$

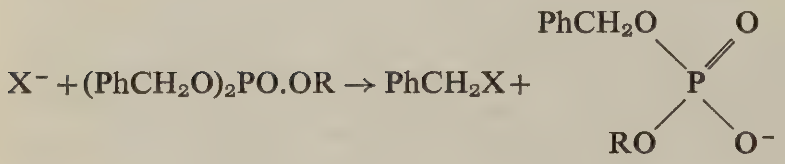
Aryl diethyl phosphates are soluble in liquid ammonia; the aryl group may be removed as aromatic hydrocarbon by reduction with lithium or sodium in ammonia solution.[1089] In diphenyl esters both phenyl groups are removed by hydrogenation over platinum,[1236, 1348–9] or by vigorous hydrolysis with barium hydroxide[1366] or with sodium carbonate solution.[1381]

The four main methods of removing protecting benzyl groups are: by hydrogenation over palladium catalysts,[1352, 1367] by acid hydrolysis,[1354, 1368] by nucleophilic displacement reactions and by phenolysis.[1366, 1369] In the last of these methods diphenyl benzyl phosphate gives diphenyl phosphate and a mixture of *o*- and *p*-benzylphenol in a ratio of 1·22:1, when heated in phenol with a catalytic amount of acid.

Particular attention has been paid by Todd and co-workers to the selective removal of one benzyl group from dibenzyl tertiary esters. Although this can be achieved by partial acid hydrolysis using dilute sulphuric acid[1354] or aqueous acetic acid,[1384] or by hydrogenolysis in the presence of a basic inhibitor,[1352, 1370] the most satisfactory and widely used methods involve nucleophilic displacements such as:

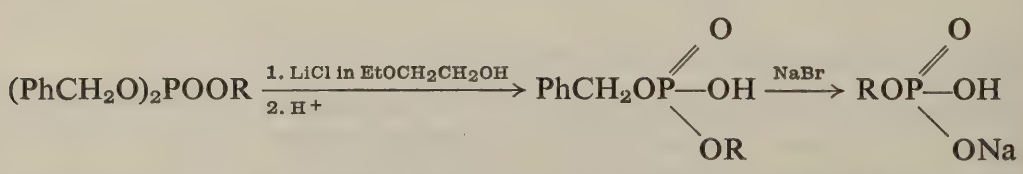


and:



(where X = Cl, OAc, NO$_3$, CNS, I)

The earliest work[620, 1372–3] using tertiary amines such as *N*-methylmorpholine and triethylamine demonstrated that neutral benzyl and substituted benzyl esters are selectively monodebenzylated giving a stable quaternary ammonium salt of a benzyl alkylphosphate. Later work with dibenzyl phosphite and tribenzyl phosphate demonstrated dealkylation by base hydrochlorides[1355] and led to the use of organic solutions of metal salts such as lithium chloride[1373–4] or potassium acetate. Thus tribenzyl phosphate is rapidly converted into lithium dibenzyl phosphate when treated with a solution of lithium chloride in ethoxyethanol at 100°. More effective reagents are sodium and barium iodides[1376, 1446, 1537, 1547] and lithium and barium thiocyanates.[1375] The use of hydrazine is reported.[1376] Two benzyl groups can be removed from ethyl dibenzyl phosphate or dibenzyl phenyl phosphate by the route[1358]:



Both 2-chloroethyl groups in a bis(2-chloroethyl)alkyl phosphate are removed by treatment with metallic sodium in dioxan.[1359] 2-Cyanoethyl groups are very smoothly removed by mild alkaline hydrolysis[1360, 1379]:

$$\mathrm{ROPO(OCH_2CH_2Cl)_2 \xrightarrow{Na} ROPO(ONa)_2 + 2C_2H_4 + 2NaCl}$$
$$\mathrm{ROPO(OCH_2CH_2CN)_2 \xrightarrow{Ba(OH)_2} ROPO_3Ba + 2CH_2{=}CHCN + 2H_2O}$$

Phosphoramidic esters can be hydrolyzed with acid.[1362, 1364, 1380]

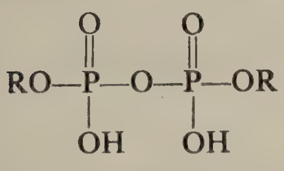
### *Use of Carbodi-imides and Related Compounds*

Carbodi-imides are of importance for the ease with which they convert acids to their anhydrides. In the organophosphorus field they have proved to be particularly valuable synthetic reagents, especially for the preparation of complex phosphates. Their use has resulted in new methods of preparation of esters of ortho-[1384–5, 1379, 1402] and pyro-[1382, 1384] phosphoric acids, cyclic phosphates,[1389–90] nucleotide coenzymes,[1391–2] and polynucleotides.[1393] The initial work by Khorana and Todd[1382] showed that under anhydrous conditions di*cyclo*hexyl (DCC) or di-*p*-tolyl carbodi-imide converts phosphate diesters to pyrophosphates; thus dibenzyl phosphate yields tetrabenzyl pyrophosphate quantitatively, while monophenyl phosphate gives *P,P′*-diphenyl pyrophosphate:

$$\mathrm{(RO)_2PO_2H + C_6H_{11}N{=}C{=}NC_6H_{11} \rightarrow (RO)_4P_2O_3 + (C_6H_{11}NH)_2CO}$$

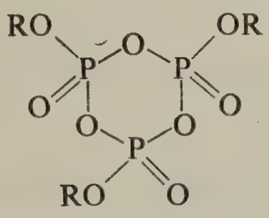
In the phosphoric acid ester field, esterification of phosphoric acid to dimethyl phosphate by reaction with an excess of methanol and DCC has been demonstrated.[1383] However, the major role of di-imides has been in the preparation of unsymmetrical diesters by condensing phosphoric acid monoesters with alcohols[1379, 1383, 1386, 1394, 1402, 1556] and of cyclic phosphates from phosphoric acid monoesters having suitably placed hydroxyl groups.[1390]

The work of Weimann and Khorana[1386] shows that monoalkyl phosphates react rapidly with DCC by way of the *P,P′*-pyrophosphate **IV** to form a trialkyl trimetaphosphate **V** which reacts slowly with alcohols giving an unsymmetrical dialkyl phosphate. Thus, ethyl phosphate and DCC in dioxan give triethyl trimetaphosphate which with methanol yields ethyl methyl phosphate in 85–90% yield. The initial formation of an *iso*urea phosphate VI, postulated by Khorana and Todd,[1382] has yet to be proven. The reaction of V with alcohols is catalyzed by DCC; thus for synthetic purposes a large excess of DCC completes the esterification in a short time[1387]:

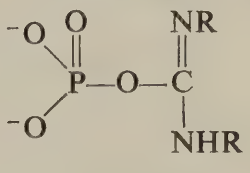


$$\mathrm{RO{-}\underset{OH}{\underset{|}{\overset{O}{\overset{\|}{P}}}}{-}O{-}\underset{OH}{\underset{|}{\overset{O}{\overset{\|}{P}}}}{-}OR}$$

**IV**

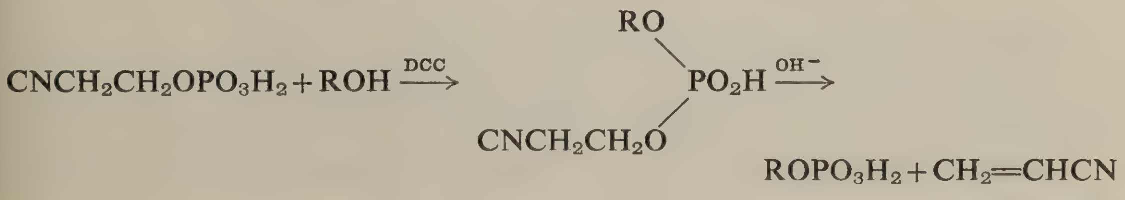


**V**

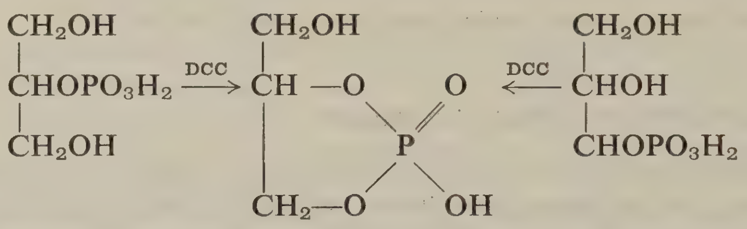


**VI**

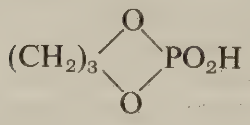
A useful procedure used to prepare $^{14}C$ labelled monomethyl phosphate and a number of nucleotide phosphates is the condensation of an alcohol with 2-cyanoethyl phosphate to form the alkyl 2-cyanoethyl phosphate which by mild hydrolysis gives monoalkyl phosphate[1379, 1555–6, 1558]:



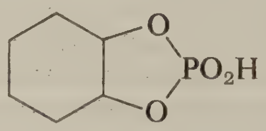
Using DCC, general methods have been developed for the preparation of 5-, 6- and 7-membered cyclic phosphates from 2-, 3- or 4-hydroxy-substituted monoalkyl phosphates, respectively.[1389-90, 1395, 1559] Glycerol α-[1395, 1397] or glycerol β-phosphate[1390] yields the same glycerol 1,2-cyclic phosphate **VII**; 3-hydroxypropyl phosphate gives the cyclic ester **VIII**[1389]; 2-hydroxy*cyclo*hexyl phosphate gives **IX**[1344]:



glycerol β-phosphate **VII** glycerol α-phosphate

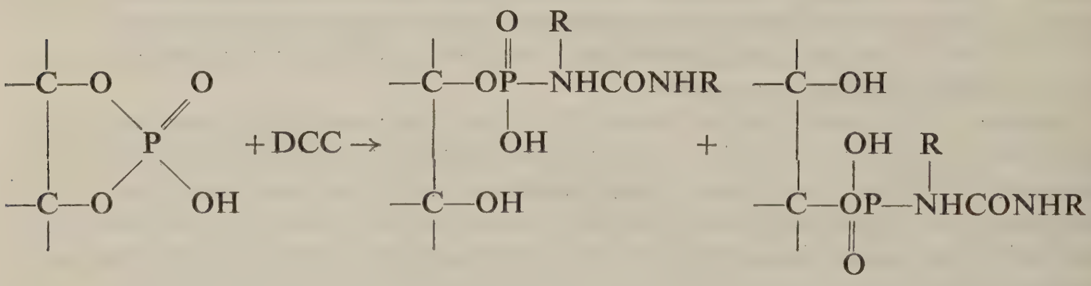


**VIII**



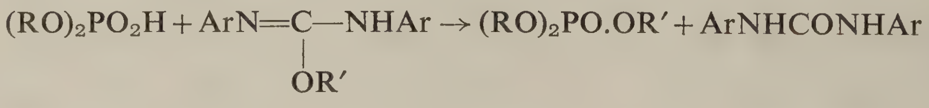
**IX**

The stereochemical requirements for cyclic phosphate formation are discussed by Khorana *et al.*[1386] 5-Membered cyclic phosphates, unlike the 6-membered compounds, undergo very ready hydrolysis and react with DCC forming *N*-phosphonyl urea phosphates[1389]:



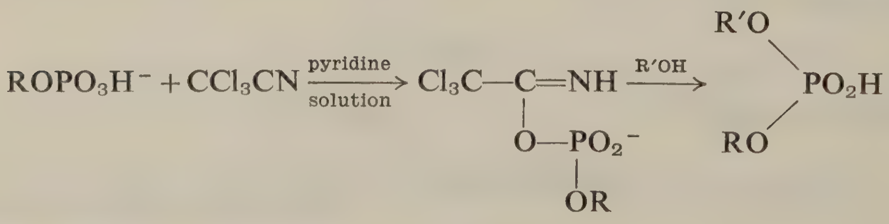
(R = $C_6H_{11}$)

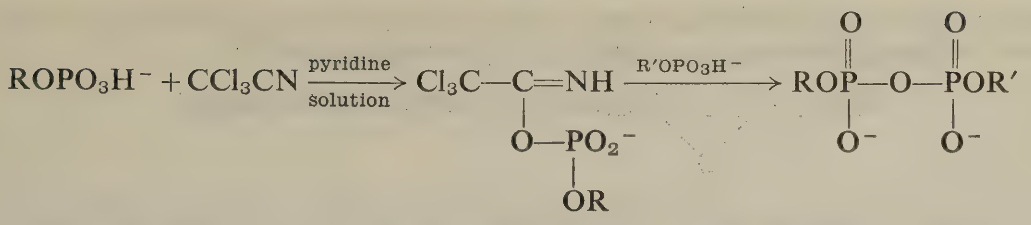
Tertiary phosphates may be prepared from secondary phosphates by reaction with an *N,N′*-diaryl-*O*-alkyl pseudourea ether (obtained from a diaryl carbodi-imide and a metal alkoxide)[1385]:



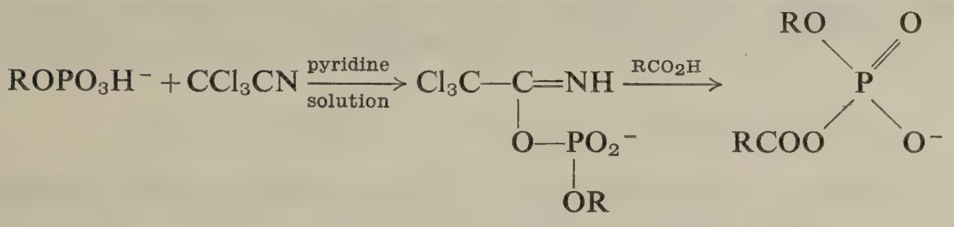
$$(RO)_2PO_2H + ArN{=}\underset{\displaystyle OR'}{\underset{|}{C}}{-}NHAr \rightarrow (RO)_2PO.OR' + ArNHCONHAr$$

The secondary acidic group in phosphoric acids is sufficiently nucleophilic to add to the nitrilo-group in trichloroacetonitrile (trichloromethyl cyanide) to form an intermediate imidoyl phosphate (cf.[1123]) formally similar to the postulated adducts formed with DCC (IX above). The intermediates react with alcohols giving unsymmetrical phosphoric diesters, with salts of monoalkyl phosphate giving *P,P′*-dialkyl pyrophosphates and with carboxylic acids giving acyl phosphates[1438-9, 1642]:

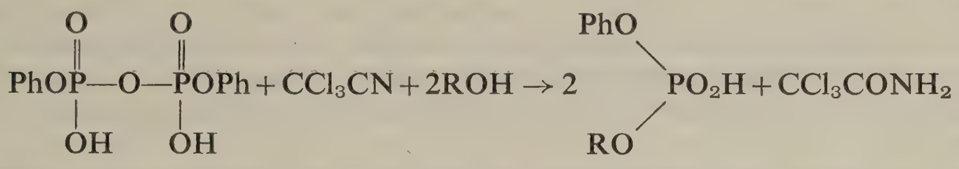




$$ROPO_3H^- + CCl_3CN \xrightarrow[\text{solution}]{\text{pyridine}} \underset{\substack{|\\ O-PO_2^-\\ |\\ OR}}{Cl_3C-C{=}NH} \xrightarrow{R'OPO_3H^-} RO\underset{O^-}{\overset{O}{P}}-O-\underset{O^-}{\overset{O}{P}}OR'$$



Phosphoric acid, benzyl alcohol, triethylamine, and trichloroacetonitrile react together similarly to give the triethylammonium salt of monobenzyl phosphate ($Et_3\overset{+}{N}H$ salt).[1439] *P,P′* diphenyl pyrophosphoric acid and alcohols react with trichloromethyl cyanide, giving alkyl phenyl phosphates[1643]:



*Miscellaneous Methods*

The reaction of alkyl halides with metal phosphates is one of the classical methods of obtaining phosphoric esters. In its original form reaction of silver phosphate with excess of alkyl halide affords a tertiary phosphate:

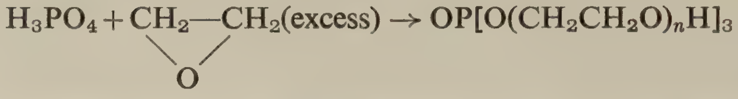
$$Ag_3PO_4 + 3RX \rightarrow 3AgX + (RO)_3PO$$

The reaction has found particular application in the preparation of sugar phosphates[1193]; thus glucose-1-phosphate has been obtained by reaction of acetobromoglucose with trisilver phosphate[1416] or with silver monophosphate[1417] (a mixture of $Ag_3PO_4$ and $H_3PO_4$). A more elegant approach has been the use of silver dibenzyl phosphate or silver diphenyl phosphate followed by removal of the protecting groups from the intermediate tertiary ester[1367, 1372, 1419, 1423] to yield the monoalkyl phosphate. Applications are for the preparation of sugar phosphates,[1418, 1427–8] phosphatidic acids,[1420–2] and uridine-5′-phosphate.[1429] Homogeneous reactions in hydrocarbon solvents may be advantageously employed if the silver salt of the diaryl phosphate is replaced by a trialkyl ammonium[1424–6, 1556, 1567] or quaternary ammonium salt.[1495]

Unlike trisilver phosphate, trisodium phosphate (or disodium phosphate and sodium hydroxide[1459]) reacts with alkyl halides[1431, 1434] or with alkyl sulphates[1432] to form mainly monoalkyl phosphates together with some dialkyl phosphates; disodium monoalkyl phosphates react similarly with alkyl halides affording sodium dialkyl phosphates[1433]:

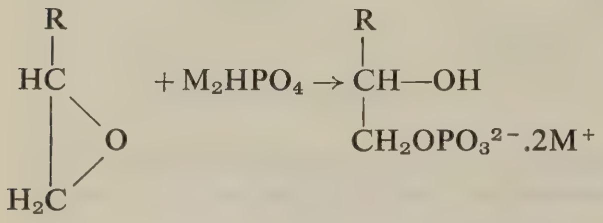
$$Na_3PO_4 + RX(\text{excess}) \rightarrow ROPO_3Na_2 + (RO)_2PO_2Na$$

Phosphates having an acidic hydrogen atom react with epoxides to give β-hydroxyalkyl phosphates. Phosphorous acid, phosphoric acid[1442, 1444] and mono- and di-alkyl phosphates[1445] react with excess of epoxides giving tertiary phosphates derived from polyalkylene glycol. These are formed by acid-catalyzed addition of alkylene oxide to the hydroxy-groups of the initially formed 2-hydroxyalkyl phosphates. Alkylene imines react similarly with phosphoric acid[1442]:



$$H_3PO_4 + CH_2{-}CH_2(\text{excess}) \rightarrow OP[O(CH_2CH_2O)_nH]_3$$

Good yields of disodium mono-$\beta$-hydroxyalkyl phosphates are obtained by reaction of disodium phosphate with epoxides such as glycidal,[1435] ethylene oxide,[1352] propylene oxide[1352] and glycidaldehyde diethyl acetal (with dipotassium phosphate) [1437]:



(R = H, Me, $CH_2OH$, $CH(OEt)_2$)

Epichlorohydrin gives glycerol-1,3-phosphate.[1193] Acid salts of monoalkyl phosphates react in a manner similar to disodium orthophosphate; thus *cyclo*hexyl ammonium 2-hydroxy*cyclo*hexyl hydrogen phosphate reacts with glycidal in boiling aqueous solution to form *cyclo*hexyl ammonium 2-hydroxy*cyclo*hexyl glyceryl phosphate.[1397] Dialkyl phosphates yield tertiary esters[1372, 1575]: thus dibenzyl phosphate and *cyclo*hexene oxide form dibenzyl *trans*-2-hydroxy*cyclo*hexyl phosphate.[1372]

The reaction of monoammonium or monosodium phosphate with glycerol at 175°–180°, a step in the preparation of calcium glycerophosphate, was examined by Bailly, who showed the initial product to consist of a mixture of $\alpha$- and $\beta$-glycerophosphate plus some diglycerophosphate.[1435–6]

Diazoalkanes readily alkylate the acidic hydroxyl groups of phosphoric acids but the scope of the reaction is limited by the availability of the required diazoalkane. Reichstein and Schindler obtained desoxycorticosterone phosphate from 21-diazoprogesterone and phosphoric acid.[1443] Generally all the acidic hydroxy-groups are alkylated; thus primary[1413] or secondary[620] phosphates yield tertiary esters. Acid salts of monoalkyl phosphates are selectively monoalkylated[1397, 1560]:

$$(PhCH_2O)_2PO_2H + R'_2CN_2 \rightarrow (PhCH_2O)_2PO.OCHR'_2 + N_2$$
$$ROPO_3H^- + R'_2CN_2 \rightarrow ROPO(OCHR'_2)O^-$$

Equilibration between orthophosphoric acid and the esters $(RO)_3PO$ (R = alkyl or aryl) proceeds readily under the influence of heat.[1527] Equimolar quantities of the acid and $(PhO)_3PO$ give an initial product containing up to 70% equimolar quantities of $(PhO)_2PO_2H$ and $PhOPO_3H_2$; the 4-component system then undergoes further equilibration.[1527]

$^{32}P$-labelled $BuOPO_3H_2$ and $(BuO)_2PO_2H$ have been prepared by equilibration of $H_3{}^{32}PO_4$ with $(BuO)_3PO$ at 176°.[1448]

## Tertiary Phosphate Esters

As a class, tertiary phosphates possess a fairly high degree of thermal stability. Decomposition to olefins, which is catalyzed by phosphoric acid and decomposition products,[1527] occurs on pyrolysis at temperatures above about 300°C.[1180, 1527, 1660]; extensive rearrangement of the double bond in the olefin occurs.[1660]

The following physico-chemical properties of the simpler tertiary phosphates are recorded: vapour pressures,[1323, 1353, 1371, 1378, 1396] dipole moments,[196, 876, 1654–6] enthalpies of formation of triethyl and tripropyl phosphates,[1530] surface tension and parachors,[771–3] specific molecular rotativities and magnetic susceptibilities,[1659] molecular and bond refractions,[1657] polarographic half-wave potentials[1658] and $^{31}P$

nuclear magnetic resonance shifts. Corresponding values relating to phosphorothionates, phosphonates, phosphites, etc., are given in many of the papers.

Compounds having a phosphoryl group have the ability to extract many cations, including those of the lanthanides, actinides, and zirconium, from aqueous acidic solution.[1404, 1516–24, 1644–53, 1728–32] Tributyl phosphate (TBP) is well established as an extraction solvent for uranium in the chemical processing of nuclear fuels,[1644, 1649] and for thorium and many other metals. Its extraction properties have been extensively studied. The following equilibrium is established for uranium extraction from aqueous nitric acid solution[1649–50, 1652]:

$$UO_2^{2+}{}_{(aq)} + 2NO_3^-{}_{(aq)} + 2TBP_{(org)} \rightleftharpoons UO_2(NO_3)_2,2TBP_{(org)}$$

The crystal structure of $UO_2(NO_3)_2,2(EtO)_3PO$ shows the uranium atom to be 8 co-ordinate with bidentate nitrate and unidentate phosphate ligands.[1648] Extraction studies indicate that many metal nitrates exist in simple molecular complexes, $M(NO_3)_n,mTBP$, in TBP solution; for example (Y, Ce, Eu, Tb, Tm, Lu, Am) $(NO_3)_3,3TBP$, (Zr, Th, Np, Pu) $(NO_3)_4,2TBP$, and (U, Np, Pu)$O_2(NO_3)_2,2TBP$.[1562] Uranyl salt–TBP complexes having the general formula $UO_2A_2,2TBP$ (where A = Cl, Br, $NO_3$, OAc, $ClO_4$) have been identified by partition coefficient and infra-red studies. [1646, 1650]

Phosphonates are strikingly superior to phosphates for the extraction of uranium and thorium.[1545] Distribution coefficient determinations for the extraction of uranyl nitrate from aqueous nitric acid solution into solvent solutions of a number of organophosphorus compounds give the following decreasing order of extraction power[1521, 1647, 1732]: $Bu_3PO > Bu_2PO.OBu > BuPO(OBu)_2 > [(BuO)_2PO.CH_2]_2 > [(BuO)_2PO]_2CH_2 > (sec\text{-}BuO)_3PO > (n\text{-}BuO)_3PO \gg$ triallyl phosphate $\gg (BuO)_2PO.OPh \ggg (PhO)_3PO$. Thermodynamic data for the extraction of uranyl nitrate by a number of phosphates and phosphonates are given by Siddall.[1522]

Distribution studies of proton acids between TBP and aqueous phases show the formation of the following complexes in the TBP phase: $HNO_3.TBP$, $HNO_3.2TBP$, $HCl.2TBP$, $HCl.3TBP$ and $HClO_4.2TBP$.[1651]

Triethyl phosphate has been suggested as a non-aqueous solvent[1662]; spectroscopic and conductimetric studies of solutions containing anhydrous ferric chloride suggest an equilibrium containing $Fe[OP(OEt)_3]_6^{3+}$ and $FeCl_4^-$ ions. Phosphoryl compounds such as $(MeO)_3PO$, $(MeS)_3PO$, and $(Me_2N)_3PO$, have been suggested as solvents for bases in organic reactions.[1663] The boron trichloride complex of triphenyl phosphate, $(PhO)_3PO,BCl_3$, is stable at 100°[1661] but the triethyl phosphate complex decomposes at room temperature giving ethyl chloride; the triphenyl phosphite–boron trichloride complex readily undergoes rearrangement giving phosphorus trichloride and triphenyl borate (cf. ref. 1661).

The hydrolysis of phosphate esters and related compounds has recently been reviewed by Cox and Ramsay.[1171] Phosphates having a $\beta$-hydroxyl substituent readily undergo rearrangement in acid solution, the classical example being glycerol $\alpha$- and $\beta$-phosphates. The sodium salts of these acids are stable when heated in sodium hydroxide solution, but the two acids are mutually transformed into each other on heating in dilute sulphuric acid solution; at pH 0·9, $\alpha$- and $\beta$- forms are present in a ratio of 87:13.[1436, 1664, 1667] Sodium methyl $\alpha$- and $\beta$-glycerophosphates undergo reversible transformation in alkaline solution.[1665] Nitrogen to oxygen phosphoryl migrations during the acid hydrolysis of *N*-di-*iso*propyl phosphoryl derivatives of ethanolamine, serine, and threonine, are reported.[1666]

The ready availability of trialkyl phosphates has led to their use as alkylating agents. Primary arylamines are readily converted in high yield to aryl dialkylamines by heating with trialkyl phosphate[1468, 1668–70]; similarly tertiary aliphatic amines may be converted into quaternary ammonium salts,[1673] alcohols to alkyl ethers, sodium acetate to alkyl acetate,[1672] sodium hydrosulphide to mercaptans and thioethers, thiourea to *S*-alkyl isothiouronium salts,[1262] and sulphides to sulphonium salts (cf. ref. 1261). Rates of quaternization of several tertiary mines with $(MeO)_3PX$ (X = O, S, Se) and $(MeO)_2POH$ are recorded.[1673]

PREPARATION OF PHOSPHORIC ACID TRIESTERS

Commercial methods of preparing trialkyl, triaryl, and mixed alkyl aryl phosphates, and some of the uses of the compounds are reviewed by Chadwick and Watt.[1194] Many routes to unsymmetrical tertiary phosphates were indicated earlier.

Triaryl phosphates are generally prepared by the direct interaction of phosphoryl chloride and the required phenol:

$$ArOH + POCl_3 \xrightarrow{\sim 100^\circ} ArOPOCl_2 + (ArO)_2POCl \xrightarrow[\sim 200^\circ]{ArOH} (ArO)_3PO$$

Catalysts, including metal halides such as aluminium, magnesium or zinc chlorides,[1509] magnesium metal,[1126] tertiary amines[1510] and ultra-violet light[1511] have been used to speed up the reaction. Other routes to triaryl phosphates are the reaction of phenols with phosphorus pentachloride, the Schotten–Baumann type reaction between phosphorus oxychloride and solutions of metal phenoxide,[1] the reaction of diaryl sulphites with phosphorus pentachloride,[1491] and the oxidation of triaryl phosphites. The direct esterification of phosphoric acid or acid phenyl phosphates with phenols, reported by Prahl,[1456] is difficult to realize in practice. Traces of triphenyl phosphate are present amongst the products from the reaction of sodium phenoxide and elemental phosphorus.[1457] Resinous polyaryl phosphates are produced by condensing phosphoryl chloride with a monohydric phenol and then with a dihydric phenol[1130, 1458]:

$$PhOH + POCl_3 \xrightarrow{CaCl_2} PhOPOCl_2 \xrightarrow[Sn]{p\text{-}C_6H_4(OH)_2} [PhOPO.OC_6H_4O]_n$$

Trialkyl phosphates were first obtained by Vögeli in 1849[1452] by heating alcohols with phosphoric acid. Although trialkyl phosphates can be, and are, prepared by solvolysis of phosphoryl chloride in alcoholic solution, the reaction requires careful control of reaction temperature and conditions so as to avoid dealkylation of the product by hydrogen chloride[1, 599–600, 1133, 1146, 1186] and pyrophosphate formation.[1527] Solvolysis of phosphoryl chloride is assisted by the addition of a catalytic amount of phosphorus trichloride.[1142] Trimethyl phosphate can be prepared by solvolysis of phosphoryl chloride with methyl alcohol by heating in a low-boiling solvent under reflux to facilitate removal of hydrogen chloride.[1526] The most commonly used methods involve reaction of phosphoryl chloride with sodium[1] or aluminium[1508] alkoxide in an excess of alcohol as solvent or with an alcohol plus tertiary amine in a hydrocarbon solvent[1460]:

$$3RONa + POCl_3 \rightarrow (RO)_3PO + 3NaCl$$

Phosphoryl bromide reacts much more rapidly with alcohols than does the chloride but, owing to rapid dealkylation of the product by hydrogen bromide, tertiary phosphates can be prepared only when the reaction is carried out with careful temperature control in the presence of a base.[902, 1462]

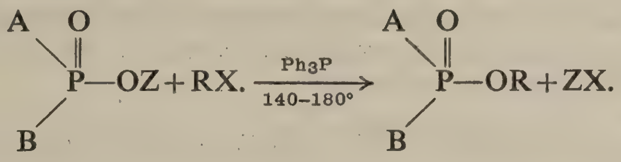
Other methods of preparing trialkyl phosphates are the pyrolysis *in vacuo* of acid salts of partial esters of phosphoric acid (for compounds up to $C_8$),[1463] oxidation of trialkyl phosphites, the reaction of trimethyl phosphate with an alkyl halide and tertiary amine catalyst,[1464] alkylation of tetra-alkyl ammonium salts of dialkyl phosphate[1495] and pyrolysis of alkyl metaphosphates or pyrophosphates,[1480] e.g.,

$$\left.\begin{array}{l}(RO)_2PO_2Na + ROPO_2Na_2\\ +(RO)_2PO_3H + ROPO_3H_2\end{array}\right\} \xrightarrow{\Delta} 2(RO)_3PO + Na_2HPO_4 + NaH_2PO_4$$

$$(MeO)_3PO + PhCH_2Cl \xrightarrow{R_3N + Na_2CO_3} (PhCH_2O)_3PO$$

$$Me_4N^+(MeO)_2PO_2^- + RX \rightarrow Me_4NX + (MeO)_2PO.OR$$

Methyl and ethyl phosphates, phosphonates and phosphinates readily undergo transesterification with alkyl halide in the presence of catalytic amounts of triphenylphosphine or tributylphosphine. The overall reaction, which is believed to proceed *via* the formation and decomposition of catalytic quantities of phosphonium salts, may be written[2285]:



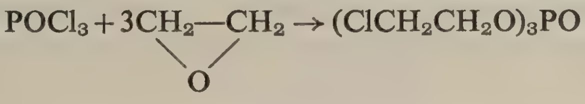
(Z = Me, Et; A = B = OR; A = alkyl, B = OR; A = B = alkyl)

The reaction of phosphorus pentoxide with ethers is complex.[1399–1401, 1498] With an excess of the ether and the olefin corresponding to R in $R_2O$, trialkyl phosphates can be made to predominate.[1493, 1496–7] Triethyl phosphate is produced commercially by heating phosphorus pentoxide with ether under an atmosphere of ethylene,[1194] the overall reaction being:

$$P_2O_5 + 3Et_2O \xrightarrow{180°} 2(EtO)_3PO$$

Ethyl orthoformate and phosphorus pentoxide react somewhat similarly; the products are triethyl phosphate, tetraethyl pyrophosphate, and ethyl formate.[1465] Tetraphosphorus decasulphide gives triethyl phosphorodithioate.[1465] Phosphorus pentoxide, or tetraphosphorus decasulphide, and olefin oxides react giving products which, depending on reaction conditions, can be water soluble 'monomers' or sparingly soluble 'polymers'.[1476]

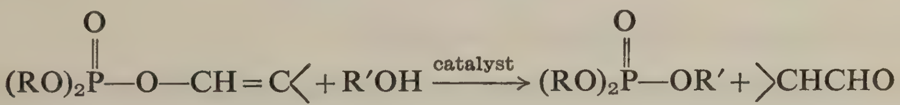
Tris-$\beta$-halogenoalkyl phosphates are readily formed from phosphorus oxychloride or bromide and olefin oxides[1500] in the presence of catalysts such as hydrogen chloride,[1492] phosphorus trichloride,[1142] aluminium chloride,[1499] zirconium or titanium chlorides[1501]:



Transesterification of phosphate esters does not, as a general rule, proceed satisfactorily. Exchange occurs readily in the presence of metal alkoxide catalyst but the catalyst is rapidly destroyed with formation of ether[1466–8]:

$$(RO)_3PO + R'OH \xrightarrow{R'O^-} (RO)_2PO.OR' + ROH$$
$$(RO)_3PO + OR'^- \rightarrow ROR' + (RO)_2PO_2^-$$

(where R, R′ = Ph, Et,[1466] and R, R′ = Et, Bu[1468]). In dialkyl vinyl phosphates transesterification of the enol linkage occurs readily in the presence of acid or base catalyst; the enol is liberated as the corresponding carbonyl compound[1007]:



$$(RO)_2\overset{\overset{\displaystyle O}{\|}}{P}—O—CH{=}C\!\!< + R'OH \xrightarrow{\text{catalyst}} (RO)_2\overset{\overset{\displaystyle O}{\|}}{P}—OR' + >\!CHCHO$$

Unsymmetrical alkyl phosphates may be obtained by equilibrating the appropriate trialkyl esters while hot, followed by fractionation[1469]:

$$(BuO)_3PO + (EtO)_3PO \xrightarrow{\Delta} (EtO)_2PO.OBu + (BuO)_2PO.OEt$$

$^{32}P$-labelled $(n\text{-}BuO)_3PO$ is conveniently prepared by heating $H_3{}^{32}PO_4$ with an excess of inactive $(n\text{-}BuO)_3PO$ at 200° for 1 hr.[1448]

Dialkyl aryl phosphates can be obtained by solvolysis of aryl phosphorodichloridate in an excess of an alcohol[1146]; more generally the Schotten–Baumann reaction between a dialkyl phosphorochloridate and phenol[1453] is used; alkyl diaryl phosphates are obtained similarly from alkyl phosphorodichloridate[1126]:

$$ArOPOCl_2 \xrightarrow{MeOH} (MeO)_2PO.OAr$$
$$(RO)_nPOCl_{(3-n)} + (3-n)ArONa \rightarrow (RO)_nPO(OAr)_{3-n} \qquad (n = 1 \text{ or } 2)$$

Dialkyl aryl phosphates are conveniently prepared from dialkyl phosphite, carbon tetrachloride and a phenol in the presence of a base or by the action of sodium aryloxide on tetra-alkyl pyrophosphate[1089]:

$$(EtO)_4P_2O_3 + ArOH \xrightarrow{aq.\ NaOH} (EtO)_2PO.OAr + (EtO)_2PO_2Na$$

### *Fluorocarbon Phosphates*

Phosphates in which the hydrogen atoms of the substituent groups are partially or completely replaced by fluorine atoms are described.[1454-5, 1477-9] Their preparation follows the usual pattern of phosphate syntheses:

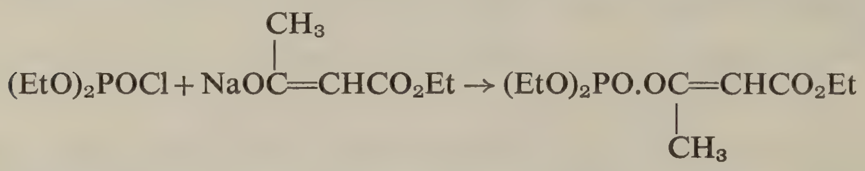
$$X(CF_2)_nCH_2OH + P_2O_5 + H_2O \rightarrow X(CF_2)_nCH_2OPO_3H_2 \qquad (X = H \text{ or } F)$$
$$(BuO)_nPOCl_{(3-n)} + (3-n)C_4F_9OH \xrightarrow{aq.\ NaOH} (BuO)_nPO(OC_4F_9)_{3-n} \qquad (n = 1, 2)$$
$$POCl_3 + 2PhOH + C_4F_9OH \xrightarrow{aq.\ NaOH} (PhO)_2PO.OC_4F_9 \text{ (main product)}$$
$$X(CF_2)_nCH_2OH + POCl_3 \xrightarrow{pyridine} [X(CF_2)_nCH_2O]_3PO \qquad (X = H, F)$$

### *Vinyl Phosphates*

The chemistry and preparation of these compounds, the enol phosphates, have been excellently reviewed by Lichtenthaler.[1007] Compounds having one vinyl ester group are normally obtained by the Perkow reaction (p. 1011) between trialky phosphite and, e.g., an $\alpha$-halogenocarbonyl compound, or by basic dehydrohalogenation and rearrangement of a dialkyl 2-halogeno-1-hydroxyalkyl phosphonate.

Other methods are the dehydrohalogenation of 2-halogenoalkyl phosphates, the reaction of enols with phosphoryl chloride[1506] or dialkyl phosphorochloridates,[1507] and the mercuric-ion catalyzed addition of dialkyl hydrogen phosphates to acetylenic compounds[1505]:

$$(RO)_2PO.OCH_2CH_2Cl \xrightarrow{NaH} (RO)_2PO.OCH{=}CH_2$$
$$POCl_3 + 3CH_3CHO + 3Et_3N \rightarrow (CH_2{=}CHO)_3PO + 3Et_3NHCl$$

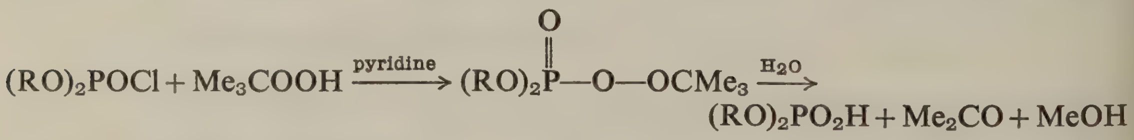


$$(EtO)_2POCl + NaO\overset{\displaystyle CH_3}{\overset{|}{C}}{=}CHCO_2Et \rightarrow (EtO)_2PO.O\underset{\displaystyle CH_3}{\underset{|}{C}}{=}CHCO_2Et$$

$$(RO)_2PO_2H + R'C{\equiv}CH \xrightarrow{Hg^{2+}} (RO)_2PO.OCH{=}CHR'$$

### *Phosphates containing* P–OX *bonds* (X = O, Si, Hg)

Dialkyl *tert*-butyl peroxyphosphates are readily obtained from chloridate and hydroperoxide in pyridine solution. They readily hydrolyze in water giving dialkyl phosphate, acetone and methanol[1470]:

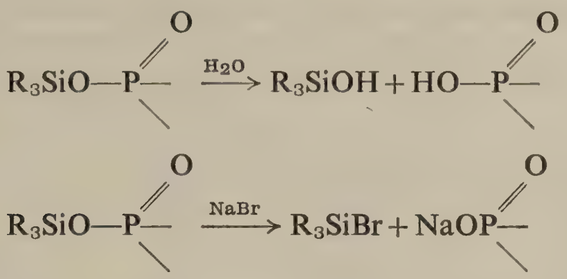


$$(RO)_2POCl + Me_3COOH \xrightarrow{pyridine} (RO)_2\overset{\displaystyle O}{\overset{\|}{P}}{-}O{-}OCMe_3 \xrightarrow{H_2O} (RO)_2PO_2H + Me_2CO + MeOH$$

Esters containing a P–O–Si group can be obtained by reaction of a hexa-alkyldisiloxane with phosphorus pentoxide, a trialkylsilyl ether with phosphoric acid, a trialkylsilyl chloride with phosphoric acid or a silicon halide with trialkyl phosphate[1471–2, 1490, 1607]:

$$P_2O_5 + 3(Me_3Si)_2O \rightarrow 3(Me_3SiO)_3PO$$

The lower alkyl compounds are distillable liquids which are readily hydrolyzed by acids or alkalis and are cleaved by heating with sodium bromide[1472]:



Tetra-alkoxysilanes yield solid hygroscopic polymers when heated with phosphorus pentoxide or phosphoryl chloride.[1473]

Ethyl mercury phosphates, $(EtHgO)_3PO$ and $(EtHgO)_2PO_2H$, can be obtained by interaction of tetraethyl lead, mercuric oxide, and phosphoric acid.[1474]

## Ester Derivatives of Phosphorothioic (Thiophosphoric) and Phosphoroselenoic Acids

### DIESTERS

Salts of diesters of phosphorothioic or phosphoroselenoic acid are readily obtained by the addition of sulphur or selenium to salts of dialkyl phosphites or by reaction with the dialkyl phosphite in the presence of ammonia or an amine. Thioic acid ester salts can also be prepared by hydrolysis of *O,O,O*-trialkyl phosphorothionate or *O,O,S*-trialkyl phosphorodithionate[1123] or from phosphorochloridate by treatment with a metal hydrosulphide.[1206] The acids themselves are obtained by treating the salt with an inorganic acid:

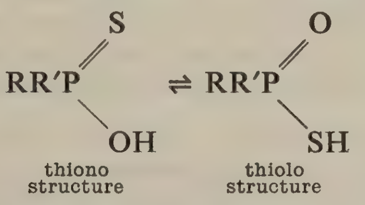
$$(RO)_2PO.H + R'_3N + S \rightarrow (RO)_2PO\bar{S}R'_3NH^+ \xrightarrow{H^+} (RO)_2PO.SH$$

$$(RO)_2PS + NaOH \rightarrow (RO)_2PO\bar{S}Na^+$$

$$(RO)_2PS.SR + NaOR' \rightarrow (RO)_2PO\bar{S}Na^+ + RSR'$$

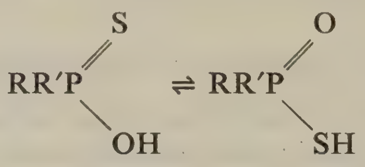
$$(RO)_2POCl + KSH \rightarrow (RO)_2PO\bar{S}K^+$$

Acids of the type RR′PO.SH (R, R′ = alkyl, aryl, alkoxy, aryloxy) exhibit a tautomeric equilibrium:



This equilibrium has been studied extensively by Kabachnik and co-workers[486, 1266–7, 1269, 1274] who have derived the equilibrium isomer concentrations from the $pK_a$ values of the monothio-acids and acids with similar substituents of the type $RR'PO_2H$ and $RR'PS_2H$, determined in 7% ethanol–water and 80% ethanol–water solvents.[1267] They find that the equilibrium is shifted to the thiono, RR′PS.OH, form and that the thiolo form appears only in noticeable amounts when the sum of the Hammett substituent constants of R and R′ ($\Sigma\sigma$) approaches zero. This effect is stronger in 7% than in 80% $EtOH–H_2O$. Results for some representative compounds are shown in Table VII.[1269]

*Table VII.—Effect of Structure on the Equilibrium*

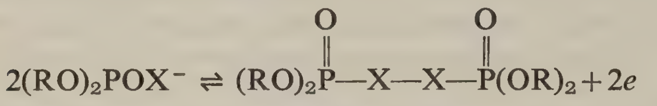


| R | R′ | $\Sigma\sigma$ | % thiolo form | |
|---|---|---|---|---|
| | | | 7% EtOH–$H_2O$ | 80% EtOH–$H_2O$ |
| EtO | EtO | −0·122 | 80 | 79 |
| MeO | MeO | −0·248 | 74 | 68 |
| PrO | PrO | −0·630 | 50 | 24 |
| Me | EtO | −1·179 | 19 | 2 |
| Ph | Ph | −1·184 | 18 | 2 |
| Et | EtO | −1·315 | 14 | 1 |
| Et | Et | −2·202 | 1 | 0·1 |
| *n*-$C_4H_9$ | *n*-$C_4H_9$ | −2·438 | 0·8 | 0 |
| *tert*-$C_4H_9$ | *tert*-$C_4H_9$ | −3·094 | 0 | 0 |

In benzene and chlorobenzene solvents p*K* measurements indicate a nearly complete shift to the thiono form.[1273]

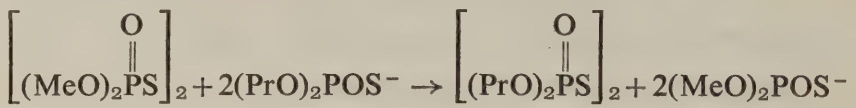
*Reactions of Dialkyl Esters and Their Salts*

Salts of dialkyl phosphorothioic or selenoic acids are oxidized by halogens to the corresponding bisdialkoxyphosphinyl disulphides (or diselenides). Foss[692] demonstrated a reversible equilibrium for oxidation with iodine and measured redox potentials in the systems:



$$2(RO)_2POX^- \rightleftharpoons (RO)_2\overset{\overset{\displaystyle O}{\|}}{P}—X—X—\overset{\overset{\displaystyle O}{\|}}{P}(OR)_2+2e \qquad (R = \text{alkyl; } X = S, Se)$$

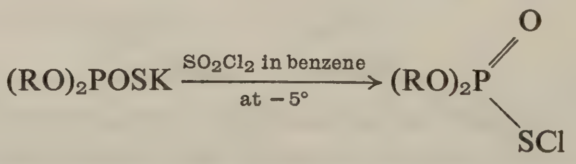
This equilibrium is progressively displaced to the right-hand side with increased electron donation of the R groups, so affording a simple route to the higher disulphides or diselenides:



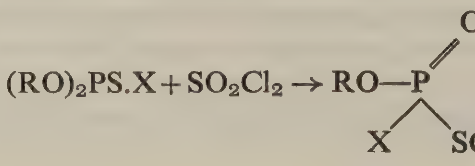
$$\left[(MeO)_2\overset{\overset{\displaystyle O}{\|}}{P}S\right]_2+2(PrO)_2POS^- \rightarrow \left[(PrO)_2\overset{\overset{\displaystyle O}{\|}}{P}S\right]_2+2(MeO)_2POS^-$$

The action of bromine on the acids or their salts yields bisdialkoxyphosphinyl disulphides (or diselenides).[692]

Chlorination of a dialkyl phosphorothioate with chlorine under controlled conditions at low temperature yields a dialkoxyoxophosphorane sulphenyl chloride.[1207] Better yields are obtained by chlorinating a salt of the acid or the corresponding bisdialkoxyphosphinyl disulphide with sulphuryl chloride[404, 1207–9]:

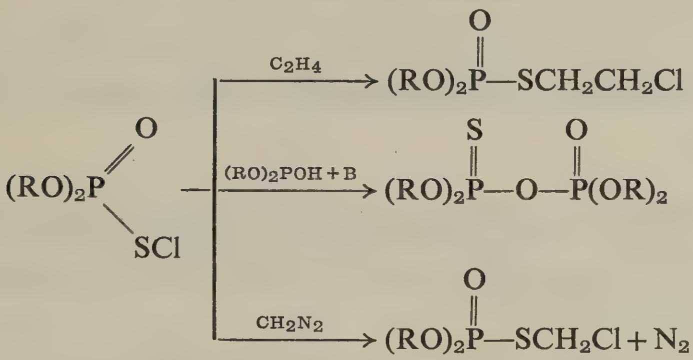


Similar compounds are obtained by chlorinating trialkyl phosphorothionates or dialkyl *N*,*N*-dialkyl phosphoramidothionates[1199]:

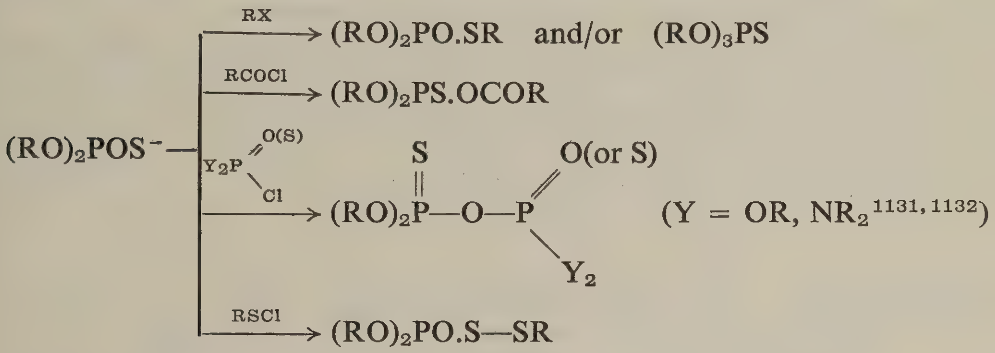


(X = OR, NEt₂)

These sulphenyl chlorides are extremely reactive. The lower alkyl compounds can be purified by distillation under good vacuum but are unstable and gradually lose active chlorine on storage, giving unidentified decomposition products.[1211] They liberate iodine from potassium iodide solution, react with alcohols, water, and amines, add spontaneously and exothermically to olefins such as ethylene or *cyclo*hexene giving *O,O*-dialkyl-*S*-2-chloroalkyl phosphorothiolates,[1207, 1209, 1211] and react with dialkyl phosphites in the presence of base giving tetra-alkyl monothiopyrophosphates,[1211] and with diazomethane to form chloromethyl thioesters[1211]:



Alkylation of dialkyl phosphorothioic acid salts can occur either on the sulphur or the oxygen atom, giving trialkyl phosphorothionates[1205] or *O,O,S*-trialkyl phosphorothiolates[1204, 1266] respectively, or a mixture of both products. Kabachnik states that alkylation invariably gives the *S*-alkyl ester.[1204] Acetylation gives the *O*-acetyl derivative.[1275] These and other reactions are shown below:



$$(EtO)_2POSH + CH_2N_2 \rightarrow \underset{\text{4 parts}}{(EtO)_2PO.SMe} + \underset{\text{1 part}}{(EtO)_2PS.OMe}^{1266}$$

$$(EtO)_2POSH + COCl_2 \rightarrow (EtO)_2POCl + COS + (EtO)_4P_2O_2S^{1225}$$

### TERTIARY ESTERS OF MONOTHIOPHOSPHORIC ACID

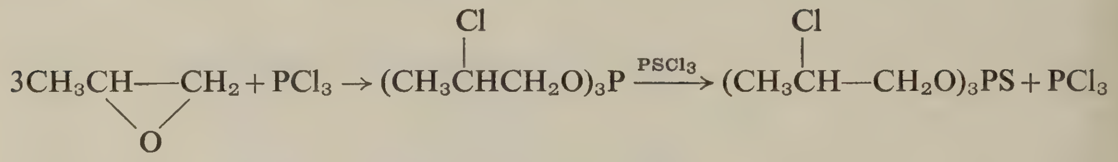
Symmetrical trialkyl phosphorothionates, $(RO)_3PS$, are conveniently obtained by reaction of thiophosphoryl chloride with alcoholic sodium alkoxide or with an alcohol in the presence of a base such as aqueous sodium hydroxide[1150, 1206]; or by adding sulphur to a trialkyl phosphite.[1289] Symmetrical compounds may be prepared by the addition of an alcohol to a mixture of sulphur and phosphorus trichloride in an inert solvent, a modification which avoids prior preparation and isolation of the phosphite.[1229]

$$3RONa + PSCl_3 \rightarrow (RO)_3PS + 3NaCl$$

Triaryl compounds can be prepared from thiophosphoryl chloride,[1148] but the reaction is sluggish.[1] A useful method which is based on the ready transfer of sulphur from thiophosphoryl chloride to triaryl phosphite involves reaction of thiophosphoryl chloride and a phenol in the presence of a catalytic amount of phosphorus trichloride[1184]:

$$\begin{gathered} PCl_3 + 3ArOH \rightarrow (ArO)_3P + 3HCl\uparrow \\ (ArO)_3P + PSCl_3 \rightarrow (ArO)_3PS + PCl_3 \end{gathered}$$

The direct reaction of thiophosphoryl chloride with alkylene oxides is unsatisfactory but proceeds readily in the presence of phosphorus trichloride. Thus propylene oxide forms tris(2-chloropropyl) phosphorothionate[1228]:

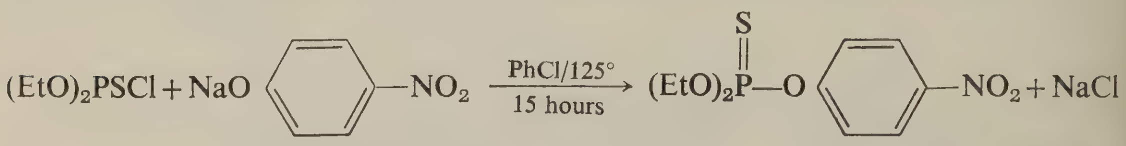


Trialkyl phosphites react exothermically with sulphur to form trialkyl phosphorothionates: $(RO)_3P + S \rightarrow (RO)_3PS$ (R = propyl, butyl, hexyl).[771] An example is the preparation of the insecticide 'Systox' by the addition of sulphur to diethyl 2-ethylthioethyl phosphite:[1289, 399]:

$$(EtO)_3P + EtSCH_2CH_2SH \xrightarrow{-EtOH} (EtO)_2POCH_2CH_2SEt \xrightarrow{S} (EtO)_2P(S)OCH_2CH_2SEt$$

Numerous compounds of the type $(RO)_2PS.OR'$ (R = alkyl; R′ = substituted alkyl, an aryl or heterocyclic residue) have been synthesized and tested as insecticides.[1151, 1230, 1247, 1264, 1282–3, 1289, 1291–8, 1449]

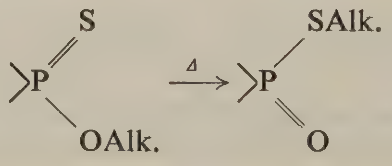
A few compounds, e.g., Parathion, *O*,*O*-diethyl-*p*-nitrophenyl phosphorothionate, and Systox, *O*,*O*-diethyl-*O*-(and *S*)-2(ethylthio)ethyl phosphorothioate, have been produced commercially for this purpose. A list of commercial phosphorothioate esters is given by Chadwick and Watt.[1194] The normal preparation involves condensation of dialkyl phosphorochloridothionate with an alcohol or phenol. Parathion was first produced in Germany by a method due to G. Schrader which involves condensing $(EtO)_2PSCl$ with dry sodium *p*-nitrophenoxide[1230]:



Catalytic amounts of tertiary amines or tertiary phosphines greatly accelerate this reaction and give high yields of Parathion.[1287] Various modifications of the basic process for manufacturing Parathion and its close analogues have been suggested. These involve the use of polar solvents such as alcohols or water to shorten reaction times,[1197] and reaction of dialkyl phosphorochloridothionate with the free phenol, sodium or potassium carbonate, and copper metal catalyst[1194, 1449] in a hydrocarbon,[1298] ketonic,[1288, 1295] chlorobenzene[1294] or aqueous solvent.[1296]

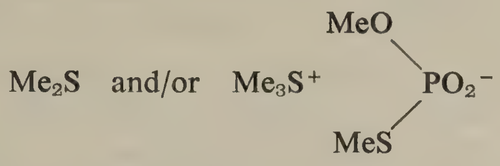
### *Isomerization*

Phosphorothionates which contain at least one *O*-alkyl substituent undergo fairly ready isomerization when heated to yield *S*-alkyl phosphorothiolate[1256, 1261, 1265]:

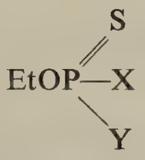


**Refs. p. 1082**

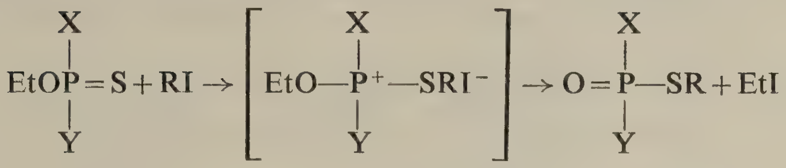
Trimethyl phosphorothionate isomerizes at 130° to *O,O,S*-trimethyl phosphorothiolate.[1256, 1261] The isomerization is catalyzed by traces of alkyl halide and by impurities in the thionate and by decomposition products



which result from alkylation of the thiolate at the sulphur atom.[1261] On heating a thionate with an alkyl halide, alkylation readily occurs on the sulphur atom yielding thiolate.[809, 1204] This has been shown to be a general reaction for compounds of the type:



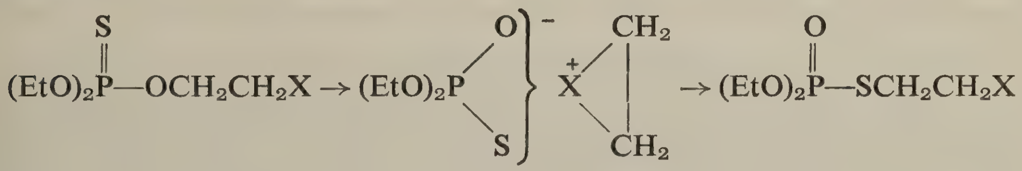
(X and Y can be R, RO, RS or $R_2N$)[1258]



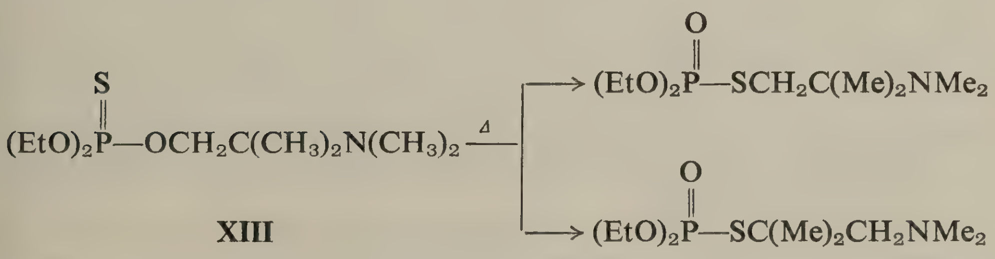
$$\mathrm{EtO}\overset{X}{\underset{Y}{P}}=S+RI \rightarrow \left[\mathrm{EtO}—\overset{X}{\underset{Y}{P^+}}—SR\,I^-\right] \rightarrow O=\overset{X}{\underset{Y}{P}}—SR+EtI$$

The alkylating properties of alkyl phosphates and thiophosphates have been reviewed.[2418]

Phosphorothionates having a $\beta$-aminoalkyl or $\beta$-thioalkyl substituent undergo facile rearrangement. Systox (**X**, where X = SEt) rearranges quantitatively at 130° to *O,O*-diethyl *S*-($\beta$-ethylmercapto)ethyl phosphorothiolate (**XII**, where X = SEt). The rearrangement is kinetically of first-order,[1263] has an activation energy of 25·4 kcal./mole[1265] and is facilitated by polar solvents.[1263, 1265] Amiton (**X**, where X = $NEt_2$) rearranges even more rapidly and can be obtained only when the temperature during its preparation is kept below 50°C.[1286] These rearrangements proceed *via* the cyclic immonium or cyclic sulphonium ion salt (**XI**, X = $NEt_2$ or SEt respectively). This has been demonstrated kinetically,[1263-4] by the lack of isomerization when formation of the cyclic ion salt **XI** is prevented as in the oxalate of Amiton or of **X** when X = SOEt,[1264] and by rearrangement of the thionate **XIII** to a mixture of isomers[1286]:



**X** **XI** **XII**



S
$(EtO)_2P—OCH_2C(CH_3)_2N(CH_3)_2$
Δ
O
$(EtO)_2P—SCH_2C(Me)_2NMe_2$
O
$(EtO)_2P—SC(Me)_2CH_2NMe_2$

**XIII**

Heavy-metal halides and silver nitrite react with trialkyl phosphorothionates at the sulphur atom, giving complexes which decompose, either at room temperature or on heating, to salts of *O*,*O*-dialkylphosphorothioic acid and alkyl halide or nitrite, respectively.[809,1299]

$$\mathrm{(MeO)_3PS + 2HgCl_2 \rightarrow (MeO)_3PS{,}2HgCl_2 \xrightarrow{102^\circ} (MeO)_2PO.S{,}HgCl{,}HgCl_2 + MeCl}$$
$$\mathrm{(RO)_3PS + AgNO_2 \rightarrow (RO)_2POS.Ag + RONO}$$

Phosphorothionates such as $\mathrm{(MeO)_2PS.SMe}$ and $\mathrm{(MeS)_2PS.OMe}$, having at least one OR group, behave similarly with mercuric chloride but trimethyl phosphorotetrathioate forms the complex $\mathrm{(MeS)_3PS{,}2HgCl_2}$, which decomposes in boiling ligroin into its constituents.[1299] Phosphoroselenoic acid esters with heavy metal halides behave similarly to the phosphorothioic acid esters.[809]

*O*,*O*,*S*-Trisubstituted phosphorothiolates are readily hydrolyzed by alkali with elimination of the –SR group; *O*,*O*,*O*-phosphorothionates are less readily hydrolyzed with loss of –OR group:

$$\mathrm{(RO)_2PO.SR \xrightarrow{NaOH} (RO)_2PO_2Na + RSH}$$
$$\mathrm{(RO)_3PS \xrightarrow{NaOH} (RO)_2POSNa + ROH}$$

The P–S–R group in thiolates is readily cleaved by chlorine or bromine; in anhydrous media dialkyl phosphorochloridate and sulphenyl chloride can be isolated,[1259] whilst in aqueous media dialkyl phosphate and sulphonyl chloride[1260] are the products:

$$\mathrm{(EtO)_2PO.SEt \xrightarrow{Cl_2} (EtO)_2POCl + EtSCl}$$
$$\mathrm{(EtO)_2PO.SEt \xrightarrow{Cl_2 + H_2O} (EtO)_2PO_2H + EtSO_2Cl}$$

### PHOSPHORODITHIOIC ACIDS

### O,O-*Dialkylphosphorodithioic and* O,O-*Diarylphosphorodithioic Acids*

Diesters of phosphorodithioic acids are very important intermediates in organophosphorus chemistry. Crude acids (80–90% pure) are produced in considerable quantity and form the starting materials for the production of a number of oil additives[1218,1243–5] and insecticides.[1246–7,1250,1279,1482] Alkali-metal and ammonium salts have been used as flotation agents,[1278] and heavy metal salts, e.g., those of barium and tin, are used as oil additives.[1216]

### *Preparation*

The crude acids are obtained by reaction of tetraphosphorus decasulphide with alcohols or phenols at temperatures generally in the range 20°–110°, depending on the reactivity of the hydroxy-compound and the stability of the dithiophosphate produced.[1129,1206,1216,1218,1223,1272,1277] The main reaction is:

$$\mathrm{P_2S_5 + 4ROH \rightarrow 2(RO)_2PS_2H + H_2S\uparrow}$$

Most primary and secondary alcohols and phenols may be converted in good yield to their corresponding dithiophosphate by suitable control of the reaction temperature and conditions. Even such reactive alcohols as *tert*-butyl alcohol and benzyl alcohol give good yields when the reaction is conducted below 45°; at higher temperatures (80°–100°) extensive decomposition occurs giving butylene and dibenzyl sulphide, respectively, as the main isolable products.[1256] Reaction of 2-methyl-2-nitro-1-propanol with tetraphosphorus decasulphide in pyridine gives the pyridine salt of *O*,*O*-bis(2-methyl-2-nitropropyl)phosphorodithionate and pyridine metaphosphorotrithioate, which by hydrolysis can be converted to phosphorothioic acid monohydrate.[1213]

Despite the importance of the dialkylphosphorodithioic acids there is little published information on the effects of the $\mathrm{ROH/P_2S_5}$ ratio, of the reaction conditions or of the history of the phosphorus sulphide on the amount and composition of the by-product neutral substances. In the reaction of ethanol with tetraphosphorus decasulphide, Bacon and LeSuer[1223] found the neutral compounds to consist of a mixture of *O,O,O*-triethyl phosphorothionate and tetra-(*O*-ethyl) trithiopyrophosphate together with small amounts of elemental sulphur and a lower sulphide of phosphorus suggested to be tetraphosphorus trisulphide. With the same reactants McIvor and co-workers[1079] report the isolation of *O,O,S*-triethyl phosphorothiolothionate and *S,S*-bis(diethyl phosphorothionyl)*O*-ethyl phosphorotrithioate $[(EtO)_2PS.S]_2PS.OEt$. Methyl and ethyl alcohols are reported to give rather poor yields of *O,O,S*-trialkyl phosphorothiolothionate.[1218]

The neutral fractions of crude methyl and ethyl phosphorodithioic acids have been examined by nuclear magnetic resonance analysis. The results, together with the approximate percentage range of composition formed in different samples, are indicated in Table VIII. Elemental sulphur was present in both the ethyl and methyl neutral fractions.[2074]

*Table VIII.—Analysis of the Neutral Fractions of Crude* O,O-*Dimethyl and Diethyl Phosphorodithionates*[2074]

| *O,O*-dimethyl | | *O,O*-diethyl | |
|---|---|---|---|
| Structure | % | Structure | % |
| $(MeO)_2PSSMe$ | 6–20 | $(EtO)_2PSSEt$ | $<2$ |
| $[(MeO)_2PS]S_2$<br>$(MeO)_2P\text{–}SH$ | 21–58 | $[EtO)_2PS]S_2$ | 19 |
| | | $(EtO)_2PSH$ | 2 |
| $[(MeO)_2PS]S$ | 27–38 | $[(EtO)_2PS]S$ | 63 |
| $(MeO)_3PS$ | 3–9 | $(EtO)_3PS$ | 6 |
| $(MeO)_2PSH$ | 7–16 | unassigned | 4 |
| unassigned | 0–11 | | |

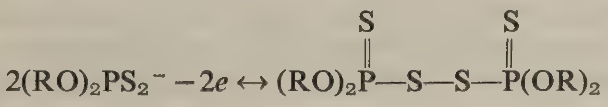
Separation of phosphorodithioic acids of lower molecular weight from the 10–20% of neutral impurities present in the crude products is readily achieved by extracting into aqueous alkali[1222] or by treating with ammonia in an inert solvent to precipitate the acid salt[1216]; these procedures are followed by careful acidification of the salt solution or the solid salt with an acid. *O,O*-Dimethyl phosphorodithioate may be ultimately purified by distillation after separation from the neutral impurities[1271] but, in general, higher alkyl compounds undergo decomposition at the temperatures required for distillation.

## *Properties and Reactions*

The phosphorodithioates are generally liquids, the lower alkyl members tending to undergo slow decomposition during storage. Salts of the acids, particularly with heavy metals, are often crystalline solids having characteristic melting points.[1254]

The lower alkyl compounds readily dissolve many metals, e.g., $(EtO)_2PS_2H$ rapidly dissolves lead, giving lead bisdiethyl phosphorodithioate and hydrogen.

Dissociation constants of a number of simple dialkyl- and diaryl-phosphorodithioic acids[1267, 1269, 1273] and 2-substituted ethyl compounds[1214] have been recorded. The atomic refraction of phosphorus and sulphur in compounds of the types $(RO)_2PS_2H$,[1212] $(RO)_2PS.SR$,[779] and $(RO)_2PS.S\text{–}SR$[779] are given by Kabachnik. Oxidation of salts of dialkylphosphorodithioic acids by iodine to bis(dialkoxythiophosphoryl) disulphides is reversible. Redox potentials for the system are given by Kakovskii *et al.*[1270]



$$2(RO)_2PS_2^- - 2e \leftrightarrow (RO)_2\overset{\overset{\displaystyle S}{\|}}{P}\text{—S—S—}\overset{\overset{\displaystyle S}{\|}}{P}(OR)_2$$

On being heated the acids decompose, giving a mixture of mercaptan, thio-ether, and olefin as volatile products. Yields of mercaptan are quite low (22·5% EtSH from $(EtO)_2PS_2H$[1256]). The reaction due to Kekulé, namely:

$$5EtOH + P_2S_5 \rightarrow 5EtSH + P_2O_5$$

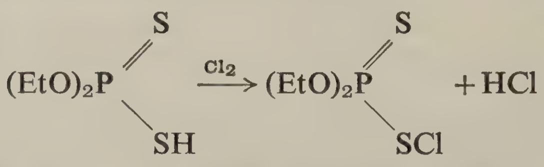
which is perpetuated in many textbooks of organic chemistry, cannot be realized under any conditions.[1273] Conversion of alcohols to mercaptans in high yield can be achieved by rearrangement of the sodium or potassium salt of the dialkyl phosphorodithioate in a polar solvent such as phenol at 180° followed by hydrolysis[1276]:

$$2ROH \rightarrow (RO)_2PS_2H \rightarrow (RO)_2PS_2K \xrightarrow[180°]{PhOH} (RS)_2PO_2K \xrightarrow[H^+]{H_2O} 2RSH$$

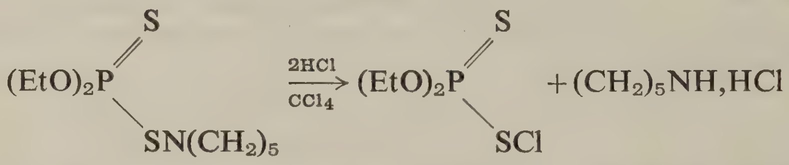
Chlorination of dialkyl- or diaryl-phosphorodithioic acids, which may be used without purification, or their metal salts or the corresponding disulphides, at 10°–40° with reagents such as chlorine,[1239, 1241–2] sulphuryl chloride,[1240] sulphur monochloride,[1238–9] sulphur dichloride[1238] or phosphorus pentachloride[1153, 1239] yields the corresponding dialkyl phosphorochloridothionates:

$$2(RO)_2PS_2H + 3Cl_2 \rightarrow (RO)_2PSCl + S_2Cl_2 + 2HCl$$
$$(RO)_2PS_2H + PCl_5 \xrightarrow{PSCl_3\ diluent} (RO)_2PSCl + HCl + PSCl_3$$

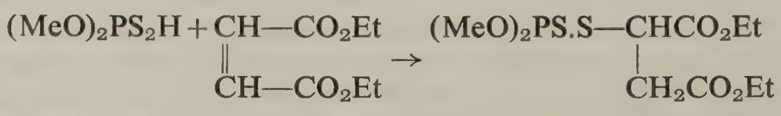
An extremely complicated set of reactions[1240] occurs and careful control of reaction temperature and of the molar proportion of chlorinating agent is necessary to obtain good yields. Controlled chlorination of $(EtO)_2PS_2H$ or $[(EtO)_2PS_2]_2$ with chlorine in carbon tetrachloride at −5° gives diethoxythionophosphorane sulphenyl chloride.[1227] Formation of sulphenyl chlorides during the chlorination:



was first proposed by Malatesta.[1242] *O,O*-Diethyl thionophosphorane sulphenyl chloride is readily obtained by the action of hydrogen chloride on *O,O*-diethyl *S*-piperidinophosphorothionothiolate[1099]:



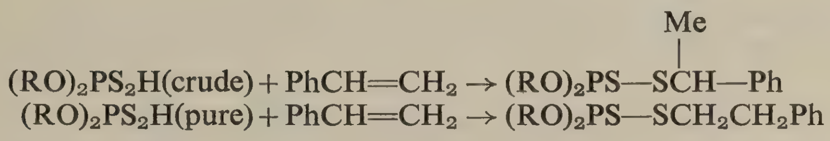
Addition of crude dialkyl phosphorodithioates to olefins has been extensively investigated because many of the adducts are commercially important as insecticides or oil additives. The insecticide Malathion is obtained by the addition of dimethyl phosphorodithioate to diethyl maleate using a small amount of a tertiary amine, such as triethylamine, as catalyst and a polymerization inhibitor such as hydroquinone[1246]:



$$(MeO)_2PS_2H + \begin{array}{l} CH{-}CO_2Et \\ \| \\ CH{-}CO_2Et \end{array} \rightarrow \begin{array}{l} (MeO)_2PS.S{-}CHCO_2Et \\ \qquad\qquad\quad | \\ \qquad\qquad CH_2CO_2Et \end{array}$$

Additions of dialkyl and diaryl phosphorodithioates to numerous unsaturated compounds are reported. Examples include ethylene[1221] and olefins of low[1218, 1223] and high[1243] molecular weight; dienes[1219, 1223, 1279]; acetylenic compounds[1513]; styrene[1223, 1249]; terpenes[1244–5]; esters of maleic and fumaric acids[1246, 1248]; chloromaleic, citraconic, itaconic esters,[1223] and related compounds[1512]; esters of methacrylic acid[1249]; acrylonitrile[1249]; vinyl alkyl sulphides,[1075] and vinyl sulphones.[1220]

The addition of crude dialkyldithiophosphoric acid to an unsymmetrical olefin gives the normal product, whereas with mercaptans addition occurs contrary to Markownikoff's rule and the addition is catalyzed by traces of peroxide in the olefin.[1222] After purification the dialkyl phosphorodithionates behave like mercaptans, giving anti-Markownikoff addition.[1219, 1222–3] It was concluded[1223] that the crude acids contain either a specific catalyst for the normal addition or a reducing agent which can destroy peroxides normally present in the olefin, thus allowing normal addition:



$$(RO)_2PS_2H(\text{crude}) + PhCH{=}CH_2 \rightarrow (RO)_2PS{-}S\overset{\overset{\displaystyle Me}{|}}{C}H{-}Ph$$

$$(RO)_2PS_2H(\text{pure}) + PhCH{=}CH_2 \rightarrow (RO)_2PS{-}SCH_2CH_2Ph$$

In the complete absence of peroxides, addition proceeds readily, giving the normal product.[1223] If addition of the pure acids to olefins is catalyzed by peroxides or ultra-violet light, the products are the same as for uncatalyzed reactions.[1219]

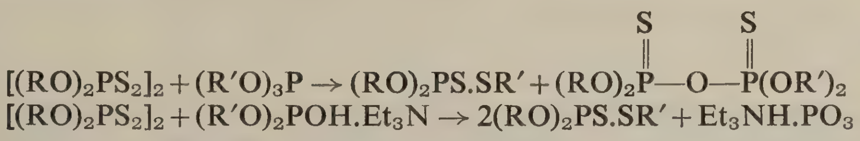
Some reactions of diesters of phosphorodithioic acids and their salts are shown on Chart XVIII.

### *Tertiary Esters of Phosphorodithioic Acids*

Most routes to the preparation of these esters have been indicated. Bis(*O*,*O*-dialkyl-thiophosphoryl) disulphides react readily with Grignard or organolithium reagents according to the equation[1514, 1674]:

$$[(RO)_2PS_2]_2 + R'M \rightarrow (RO)_2PS.SR' + (RO)_2PS_2M$$
$$(R = \text{alkyl};\ R' = \text{alkyl, vinyl, alkynyl, aryl})$$

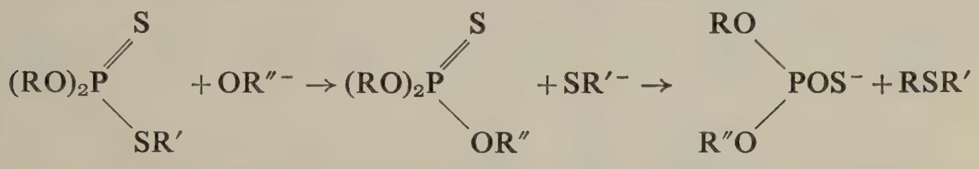
Trialkyl phosphites react giving *O*,*O*-dialkyl-*S*-alkyl phosphorodithioate and an unsymmetrical tetra-alkyl dithiopyrophosphate; salts of dialkyl phosphites also act as alkylating agents[1605]:



$$[(RO)_2PS_2]_2 + (R'O)_3P \rightarrow (RO)_2PS.SR' + (RO)_2\overset{\overset{\displaystyle S}{\|}}{P}{-}O{-}\overset{\overset{\displaystyle S}{\|}}{P}(OR')_2$$

$$[(RO)_2PS_2]_2 + (R'O)_2POH.Et_3N \rightarrow 2(RO)_2PS.SR' + Et_3NH.PO_3$$

*O*,*O*,*S*-Trialkyl phosphorothiolothionates and metal alkoxides in alcoholic solution readily form dialkyl sulphides and dialkyl phosphorothionate salts.[1223] The reaction represents an interesting example of the relative nucleophilic characters of $OR^-$ and $SR^-$ towards phosphoryl and carbon centres respectively:



The group most susceptible to nucleophilic attack is eliminated from the intermediate phosphorothionate, to appear in the dialkyl sulphide.

### ESTERS OF PHOSPHOROTRITHIOIC ($H_3PS_3O$), PHOSPHOROTETRATHIOIC ($H_3PS_4$), AND METAPHOSPHOROTRITHIOIC ACIDS ($HPS_3$)

Mercaptans react with tetraphosphorus decasulphide, giving initially alkyl metaphosphorotrithioates, which with more mercaptan yield dialkyl phosphorotetrathioates and eventually trialkyl phosphorotetrathioates[1201–3, 1255]:

$$2RSH + P_2S_5 \rightarrow RSPS_2 + H_2S$$
$$RSPS_2 + RSH \rightarrow (RS)_2PS_2H$$
$$(RS)_2PS_2H + RSH \rightarrow (RS)_3PS + H_2S$$

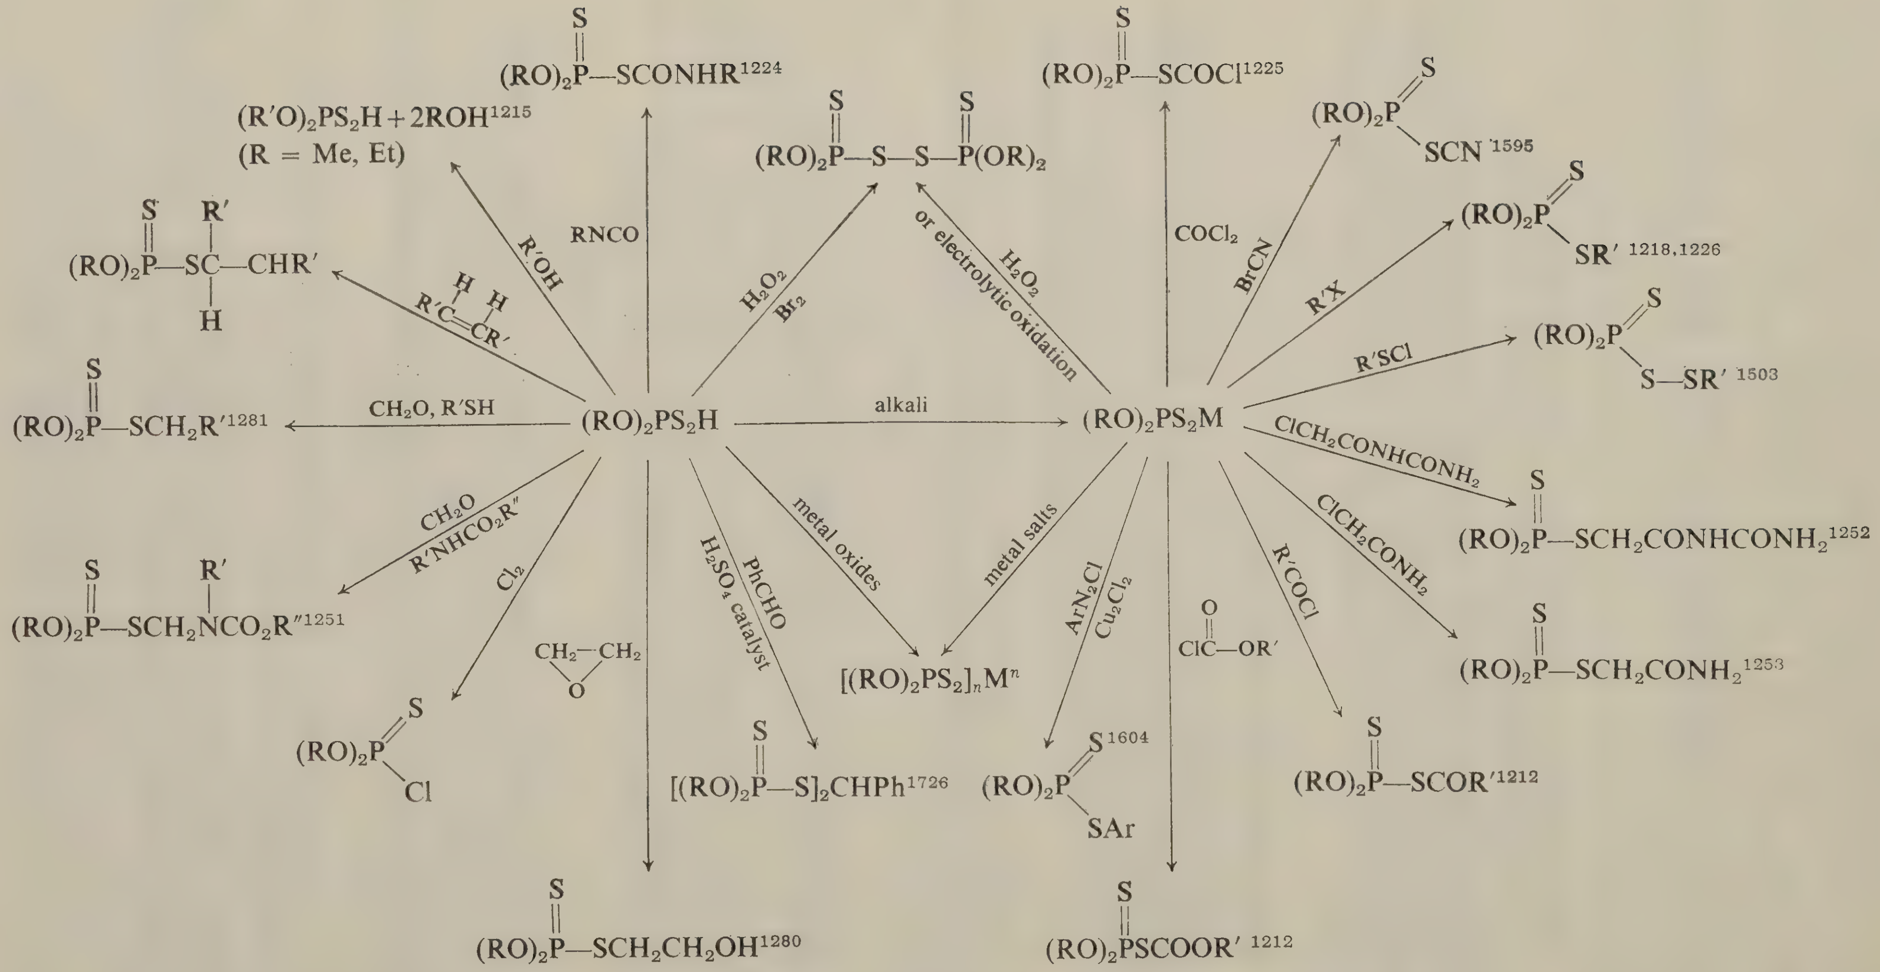


CHART XVIII.—Some reactions of diesters of phosphorodithioic acid and their salts

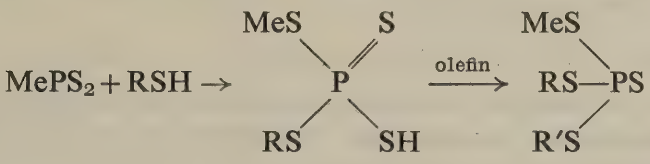
Methyl metaphosphorotrithioate, an insoluble crystalline solid, may be used to prepare unsymmetrical tertiary esters of phosphorotetrathioic acid[1203]:



$$\mathrm{MePS_2+RSH \rightarrow \underset{RS\qquad SH}{\overset{MeS\qquad S}{P}} \xrightarrow{olefin} \underset{R'S}{\overset{MeS}{RS{-}PS}}}$$

Dialkyl phosphorotetrathioates may be characterized as their mercuric salts.[1255] Triethyl phosphorotetrathioate is formed from tetraphosphorus decasulphide and triethyl trithio-orthoformate[1465]:

$$P_2S_5 + 3HC(SEt)_3 \rightarrow 2(EtS)_3PS + 3EtSCHS$$

Symmetrical trialkyl and triaryl phosphorotetrathioates are readily obtained by the action of sodium mercaptide on thiophosphoryl chloride.[1079, 1148, 1299, 2061]

*S,S,S*-Phosphorotrithioates, $(RS)_3PO$, may be prepared by oxidation of phosphorotrithioites first with air at 230°F. to about 80% completion and then with hydrogen peroxide,[1124] or from sodium mercaptide and phosphoryl chloride.[2061] Comparative rates of hydrolysis of $(EtO)_3PO$ and $(EtS)_3PO$ are given by Thain.[1125] Molar magnetic rotations of the lower trialkyl tri- and tetra-thiophosphates are recorded.[2061]

The reaction of lower sulphides of phosphorus with alcohols was studied by Kabachnik[635]; the isolated products testify to the complex nature of the reactions and are indicated below:

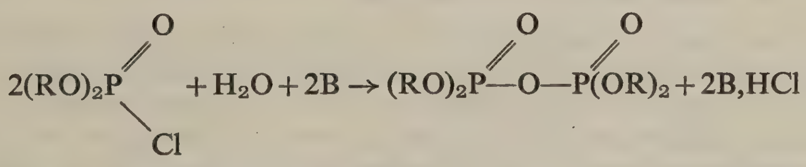
| Phosphorus sulphide | Reaction products with alcohol |
|---|---|
| $P_4S_7$ | $(RO_2PSH$, $(RO)_2PS_2H$, $(RO)_2PS.SR$, $H_2S$, P, $PH_3$ |
| '$P_4S_6$' | $(RO)_2PSH$, $(RO)_2PS.SR$, $H_2S$ |
| $P_4S_5$ | $(RO)_2PSH$, $(RO)_2PS.SR$ |
| '$P_4S_4$' | $(RO)_2PSH$, $(RO)_2PS.SR$, lower yields than from $P_4S_7$, $P_4S_6$ |

## DERIVATIVES OF PYROPHOSPHORIC ACID, THEIR SULPHUR AND SELENIUM ANALOGUES, AND HIGHER CONDENSED ACIDS

### Preparation of Pyrophosphates

#### CONDENSATION OF PHOSPHORYL HALIDATES

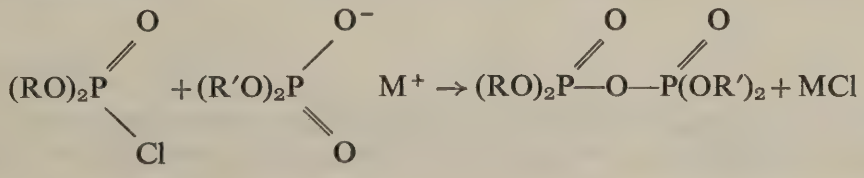
One of the simplest ways of obtaining symmetrical tetraesters of pyrophosphoric acid is the controlled hydrolysis of a dialkyl/aryl phosphorochloridate, generally in the presence of a base such as pyridine or sodium hydroxide[1482, 1532, 1549, 1551, 1554]:



$$\mathrm{2(RO)_2\underset{Cl}{\overset{O}{P}} + H_2O + 2B \rightarrow (RO)_2\overset{O}{P}{-}O{-}\overset{O}{P}(OR)_2 + 2B,HCl}$$

The reaction fails with dialkyl phosphorofluoridates.[1551]

A closely related reaction, which provides a route to unsymmetrical pyrophosphates[1534, 1589, 1599] is the reaction of a phosphorochloridate with the salt of a secondary phosphate[1230, 1415, 1548, 1550]:

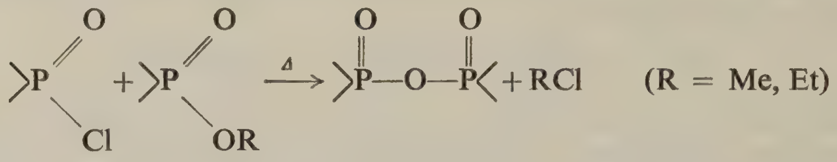


$$\mathrm{(RO)_2\underset{Cl}{\overset{O}{P}} + (R'O)_2\underset{O}{\overset{O^-}{P}}\ M^+ \rightarrow (RO)_2\overset{O}{P}{-}O{-}\overset{O}{P}(OR')_2 + MCl}$$

The formation of pyrophosphates by reaction of dialkyl phosphites with a polyhalogenated methane derivative and a base[673, 1089] probably proceeds via intermediate formation of halidate and acid salt:

$$2(RO)_2POH + 2CCl_4 + 2NaOH \rightarrow (RO)_4P_2O_3 + 2CHCl_3 + H_2O + 2NaCl$$

Pyrophosphates are formed by the thermal elimination of alkyl chloride between a molecule of a phosphorochloridate and a molecule of a tertiary phosphate ester. By using monofunctional reagents good yields of pyrophosphates may be obtained.[1533, 1536] The mechanisms and scope of the reaction are discussed by Stölzer and Simon [1487]:



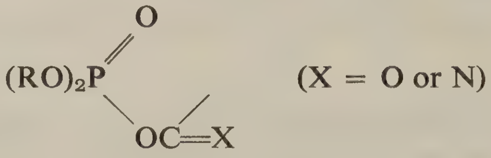
In its simplest form, the reaction of phosphoryl chloride with triethyl phosphate, the reaction was used by Schrader for the preparation of an insecticide formulated as hexaethyl tetraphosphate (Bladan):

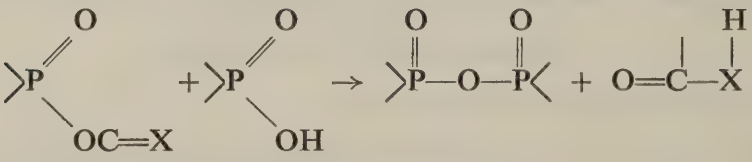
$$POCl_3 + 3(EtO)_3PO \rightarrow OP[OPO(OEt)_2]_3$$

More recent work on this reaction indicates the product to be a mixture of condensed phosphates of which the component with greatest physiological activity, tetraethyl pyrophosphate (TEPP), constitutes some 10–15%.[1531] Products which contain higher proportions of TEPP (up to about 40%) may be obtained using a higher ratio of phosphate to phosphoryl chloride.[1536, 1552]

### CONDENSATIONS INVOLVING REACTIVE PHOSPHATE ESTER INTERMEDIATES

Many elegant pyrophosphate syntheses involve condensation of phosphoric acid or its esters with reactive intermediates, or in some cases isolable compounds of the type:

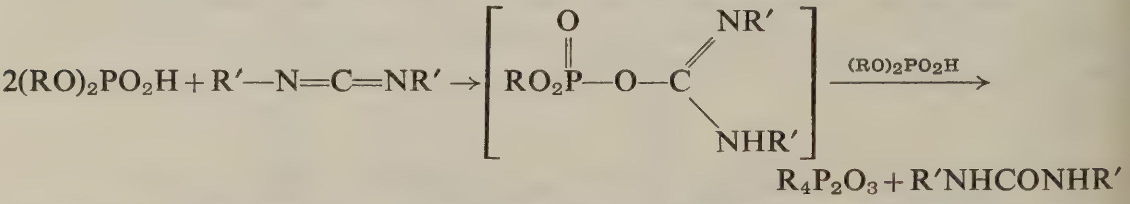




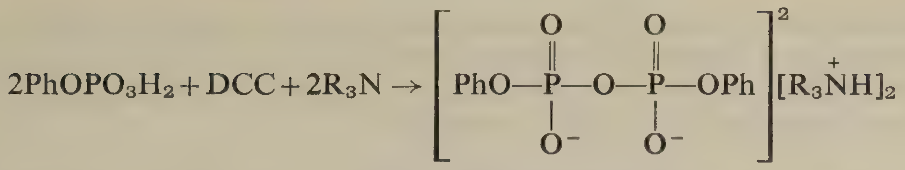
The principal examples are discussed below:

#### *Use of Carbodi-imides and Related Compounds*

Dialkyl and diaryl phosphates react readily with carbodi-imides (generally, di*cyclo*hexyl carbodi-imide (DCC) has been used) at room temperature to form a symmetrical tetraester of pyrophosphoric acid and a urea derivative.[1123, 1382, 1384] Salts of dialkyl phosphates and weak bases such as pyridine behave similarly, but salts of strong bases such as triethylamine do not react.[1383, 1429] The reaction is thought to proceed via the formation of an intermediate isourea phosphate[1382]:

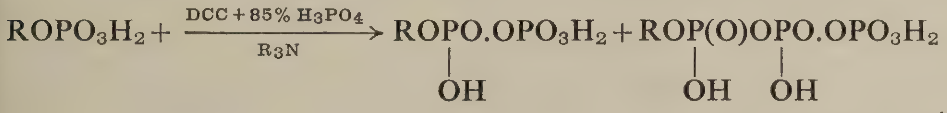


Monoalkyl phosphates[1382] or their monobasic salts with strong tertiary organic bases such as tributylamine[1383] yield *P*,*P*′-disubstituted pyrophosphates, e.g.,



$$2PhOPO_3H_2 + DCC + 2R_3N \rightarrow \left[ PhO-\overset{\overset{O}{\|}}{\underset{\underset{O^-}{|}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{O^-}{|}}{P}}-OPh \right]^{2}[R_3\overset{+}{N}H]_2$$

In the nucleotide field Khorana and co-workers have prepared mixtures of nucleotide di- and tri-phosphates by the reaction of nucleotide-5′-phosphates with an excess of phosphoric acid and DCC[1561-2]:

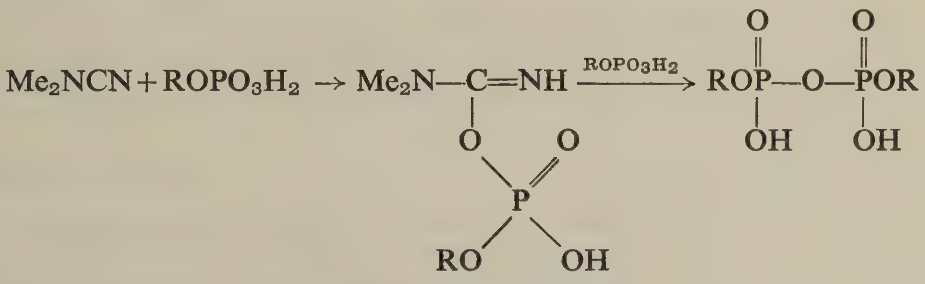


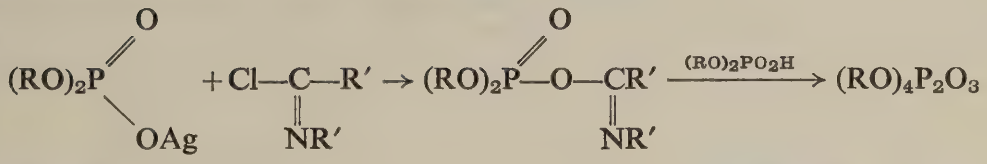
$$ROPO_3H_2 + \xrightarrow[R_3N]{DCC + 85\%\ H_3PO_4} RO\underset{\underset{OH}{|}}{P}O.OPO_3H_2 + RO\underset{\underset{OH}{|}}{P}(O)O\underset{\underset{OH}{|}}{P}O.OPO_3H_2$$

(as $R_3N$ salts)

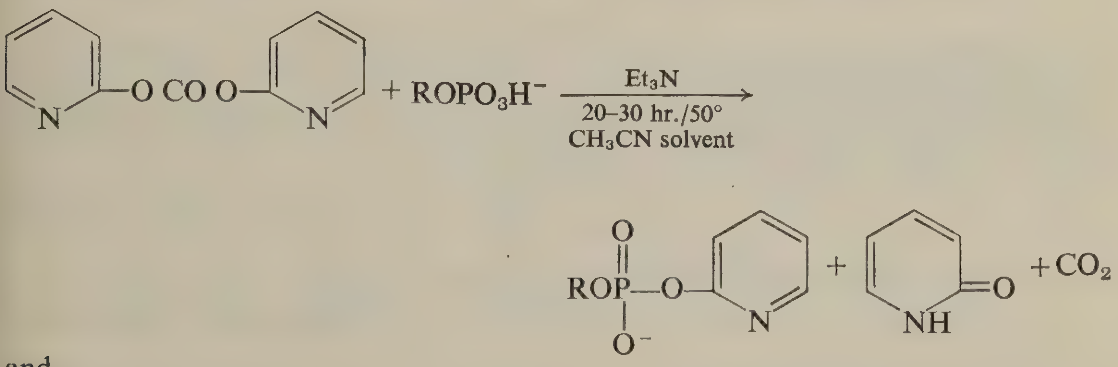
### *Imidoyl Phosphates and α-Pyridyl Phosphates*

Analogous to the hypothetical intermediates formed in carbodi-imide condensations are the imidoyl phosphates.[1123] Such compounds may be prepared by the Beckmann rearrangement of oximes in the presence of a phosphate or by the action of silver or tertiary amine salts of dialkyl phosphates with an imidoyl chloride.[1123, 1563] They can be prepared as reactive intermediates by the action of dimethyl cyanamide ($Me_2NCN$),[1535] or keten imides ($R{-}CH{=}C{=}NR_2$)[1377] with a dialkyl phosphate and by reaction of trichloroacetonitrile with an acid phosphate.[1438-9] They react with acid phosphates to form pyrophosphate derivatives:

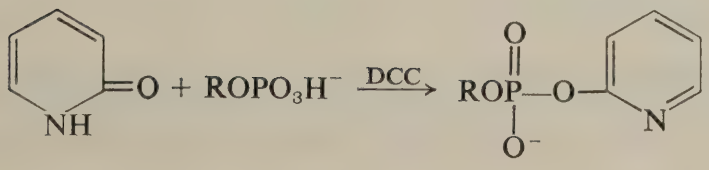




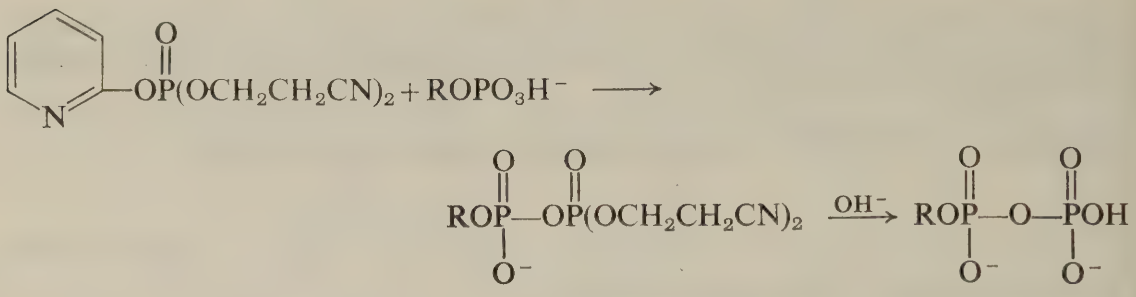
Closely related to imidoyl phosphates are the α-pyridyl phosphates, which may be obtained by reaction of a monoalkyl or aryl acid phosphate salt with di-α-pyridyl carbonate or the corresponding acid with α-hydroxypyridine and DCC[1623]:



and

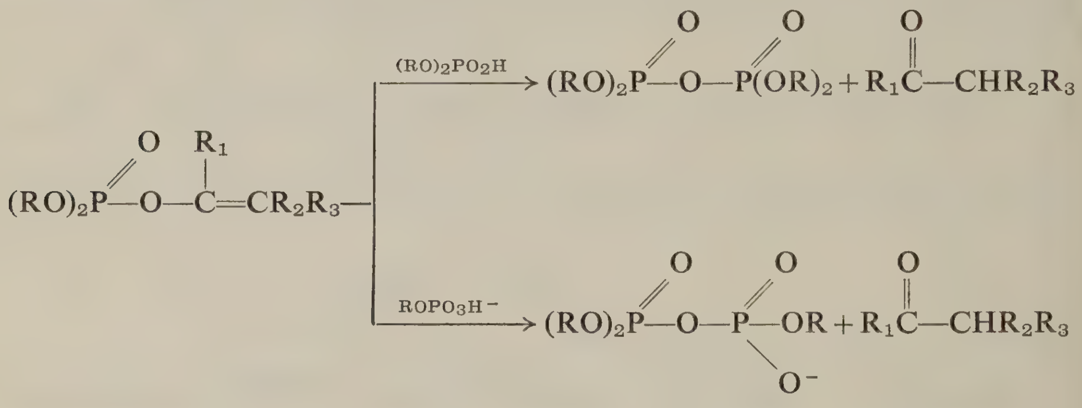


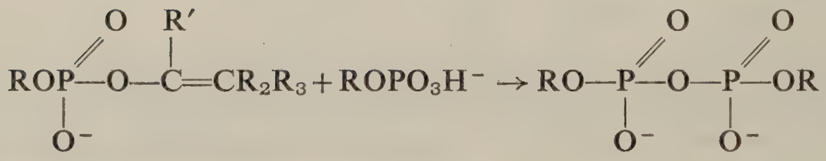
They react with phosphoric acid monoesters, giving symmetrical diesters of pyrophosphates, with alcohols giving phosphoric acid diesters, and with amines to give phosphoric acid ester amides. Monoesters of pyrophosphoric acid can be prepared using bis(2-cyanoethyl)-α-pyridyl phosphate[1544]:



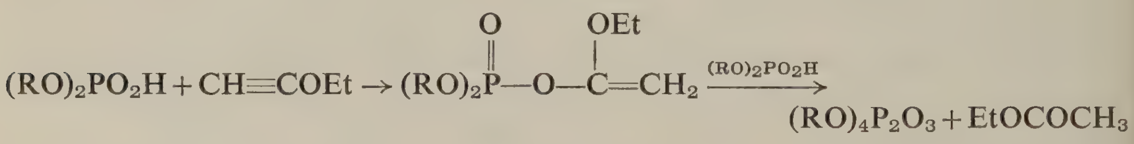
### *Vinyl Phosphates*

Vinyl esters of phosphoric acid react with di- and mono-substituted esters of phosphoric acid, when a carbonyl compound corresponding to the vinyl ester is eliminated and a pyrophosphate is formed. Tetra-,[1020] tri-,[1440, 1539] and symmetrical di-pyrophosphate esters[1547] may be prepared in this way:





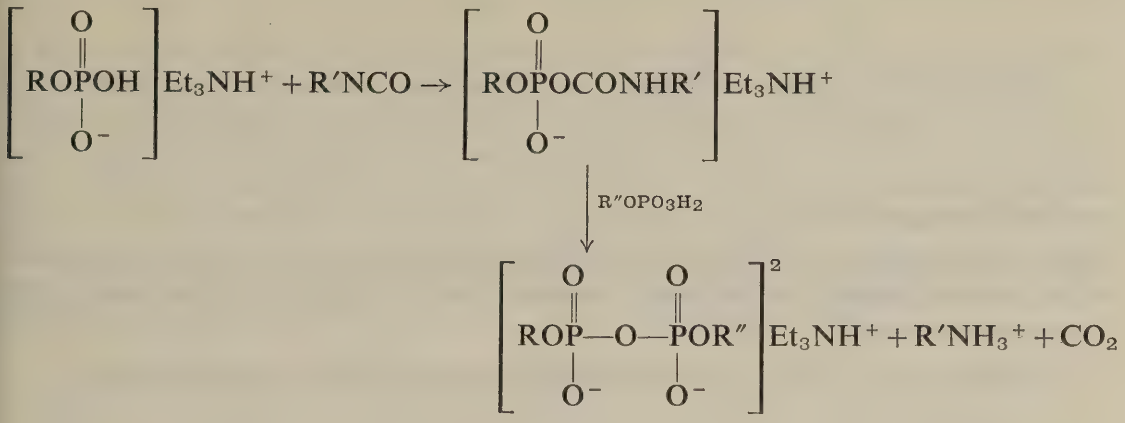
Symmetrical tetra-alkyl pyrophosphates may be prepared by the condensation of secondary phosphates in the presence of ethoxyacetylene[1546]; the intermediate 1-ethoxyvinyl phosphates can be obtained by reaction of dialkyl phosphates and ethoxyacetylene in the presence of a mercuric salt[1505]:

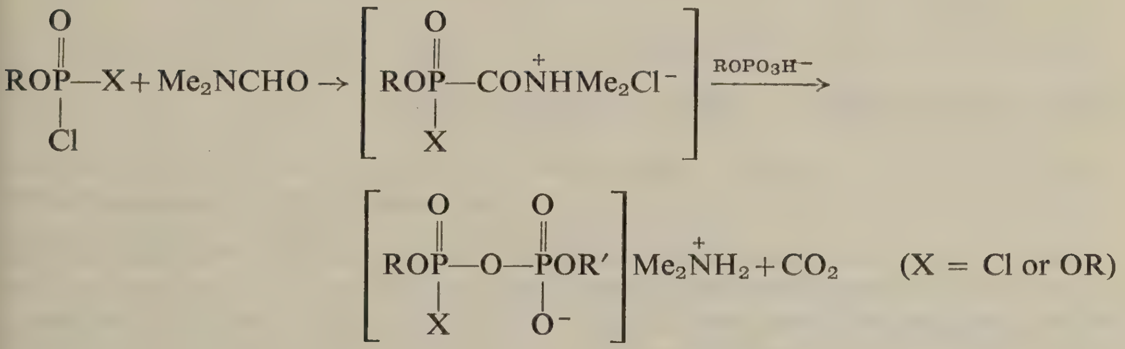


$$(RO)_2PO_2H + CH{\equiv}COEt \rightarrow (RO)_2\overset{\overset{\displaystyle O}{\|}}{P}{-}O{-}\overset{\overset{\displaystyle OEt}{|}}{C}{=}CH_2 \xrightarrow{(RO)_2PO_2H} (RO)_4P_2O_3 + EtOCOCH_3$$

### *Carbamoyl Phosphates*

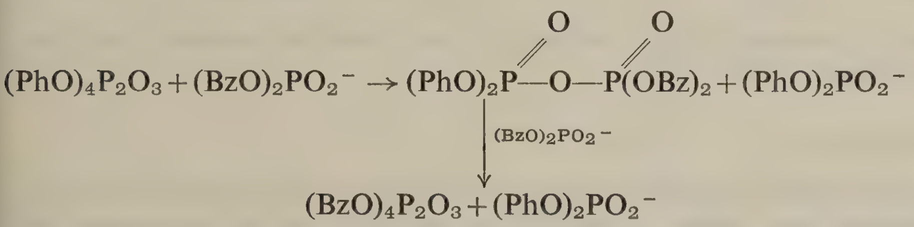
Monobasic anions of phosphoric acid or its monoesters react with organic isocyanates, giving anhydrides of phosphoric acid and carbamic acid which react with more phosphoric acid or ester to form phosphoric acid anhydrides.[1447] Similar compounds are formed by reaction of phosphorohalidate with dimethylformamide[1538]:





### BY EXCHANGE REACTIONS

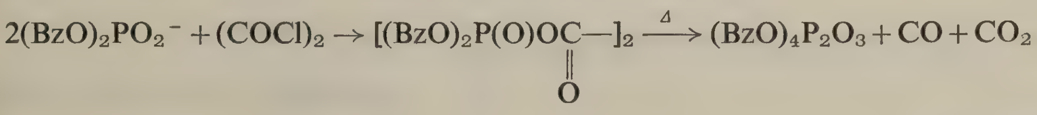
The formation of pyrophosphates by exchange reactions has been studied largely by Todd and his co-workers. Highly reactive pyrophosphates such as tetraphenyl pyrophosphate readily undergo exchange with dialkyl phosphates in the presence of a base to form tetra-alkyl pyrophosphate and diphenyl phosphate[1415, 1548]; thus tetrabenzyl pyrophosphate may be prepared by reaction with dibenzyl phosphate:



Such exchange reactions always occur so as to produce the less reactive pyrophosphate, i.e., the salt of the stronger phosphoric acid. Similar exchange reactions take place between secondary phosphates and anhydrides, such as trifluoroacetic acid anhydride[1429, 1548] or tetraethyl pyrophosphite,[1545] and acid chlorides such as aromatic sulphonyl chlorides,[1386, 1393, 1548, 1574] thionyl chloride,[1415] and diethyl phosphorochloridite,[1542] to yield the symmetrical pyrophosphate ester:

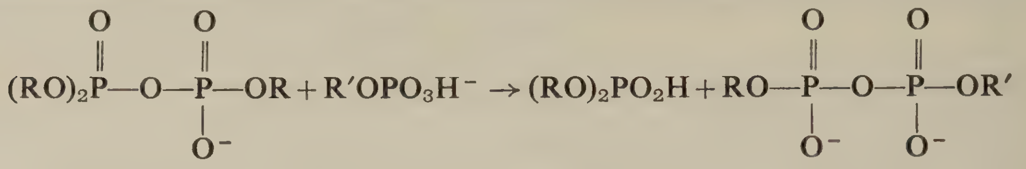
$$2(RO)_2PO_2^- + ArSO_2Cl \rightarrow (RO)_4P_2O_3 + Cl^- + ArSO_3^-$$
$$2(EtO)_2PO_2H + (EtO)_2P{-}O{-}P(OEt)_2 \rightarrow (EtO)_4P_2O_3 + 2(EtO)_2POH$$

Oxalyl chloride and dibenzyl phosphate react to form a crystalline mixed anhydride which decomposes on heating to tetrabenzyl pyrophosphate[1415]:



$$2(BzO)_2PO_2^- + (COCl)_2 \rightarrow [(BzO)_2P(O)O\underset{\underset{O}{\|}}{C}{-}]_2 \xrightarrow{\Delta} (BzO)_4P_2O_3 + CO + CO_2$$

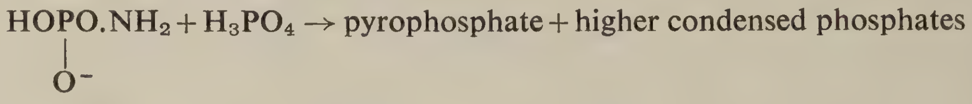
*P,P′-unsym*-Pyrophosphate diesters can be prepared by exchange reactions between salts of triesters of pyrophosphoric acid and monobasic primary phosphate[1440]:



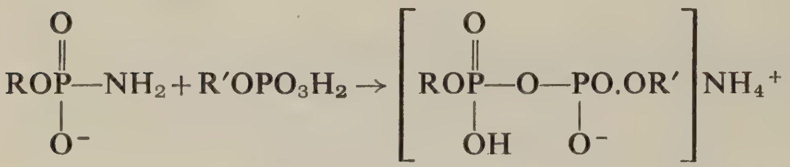
$$\mathrm{(RO)_2\overset{\overset{O}{\|}}{P}{-}O{-}\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}{-}OR + R'OPO_3H^- \rightarrow (RO)_2PO_2H + RO{-}\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}{-}O{-}\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}{-}OR'}$$

FROM PHOSPHORAMIDATES

Salts of phosphoramidic acid and alkyl phosphoramidic acids, but not phosphoramidic diesters themselves, are weak phosphorylating agents for phosphoric acid in aqueous solution[1568-71, 2066, 2068]:



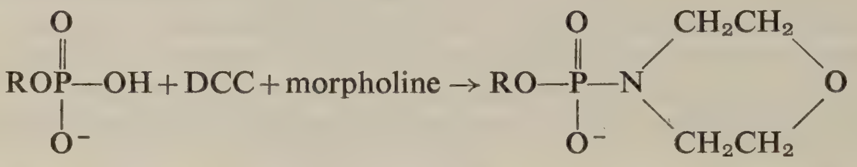
$$\mathrm{HO\underset{\underset{O^-}{|}}{P}O.NH_2 + H_3PO_4 \rightarrow}\text{ pyrophosphate + higher condensed phosphates}$$



$$\mathrm{RO\underset{\underset{O^-}{|}}{\overset{\overset{O}{\|}}{P}}{-}NH_2 + R'OPO_3H_2 \rightarrow \left[RO\underset{\underset{OH}{|}}{\overset{\overset{O}{\|}}{P}}{-}O{-}\underset{\underset{O^-}{|}}{P}O.OR'\right]NH_4^+}$$

(R = benzyl, R′ = adenosine-5-)[1570]

The early work using phosphoramidates has been considerably developed by the use of *O*-alkyl *N*-substituted phosphoramidic acids derived from amines such as aniline, benzylamine, and morpholine[1557-8, 1567, 1572] and of *O*-alkyl phosphoroimidazolides.[1200, 1595] A useful introduction has been the direct formation of *O*-alkyl phosphoramidic acids, particularly nucleotide phosphoramidates, by reaction of a monoester of phosphoric acid with an excess of di*cyclo*hexyl carbodi-imide and an amine such as morpholine[1557-8, 1567, 1573]:



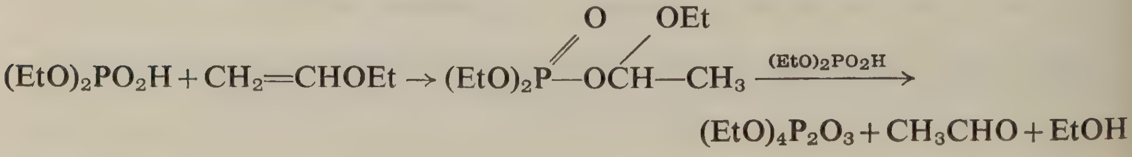
The mechanism of pyrophosphate formation from phosphoramidates has been investigated by Hamer.[2420, 2421]

MISCELLANEOUS METHODS

Tetraethyl pyrophosphate has been obtained by the following methods: action of phosphorus pentoxide on diethyl ether[1498]; action of salts of carboxylic and carbonic acids on diethyl phosphorochloridate[1578, 1608]; action of silver nitrate,[1541] silver carbonate[1608] or lead carbonate[1603] on diethyl phosphorochloridite; oxidation of diethyl phosphite with nitrosyl chloride in the presence of pyridine[1077, 1542]; oxidation of tetraethyl pyrophosphite or $(EtO)_2PO.OP(OEt)_2$ with dinitrogen tetroxide[862]; heating a mixture of diethyl phosphate and triethyl phosphate with copper bronze[1531]; action of ethyl vinyl ether on diethyl phosphate[1545]; and the reaction of phosphoryl chloride with less than the calculated amount of ethanol[1592]:

$$\mathrm{2(EtO)_2PCl + 2AgNO_2 \rightarrow (EtO)_4P_2O_3 + 2AgCl + N_2 + N_2O}$$

$$\mathrm{2(EtO)_2PO.H + 2NOCl \xrightarrow{pyridine} (EtO)_4P_2O_3 + 2HCl + N_2O}$$



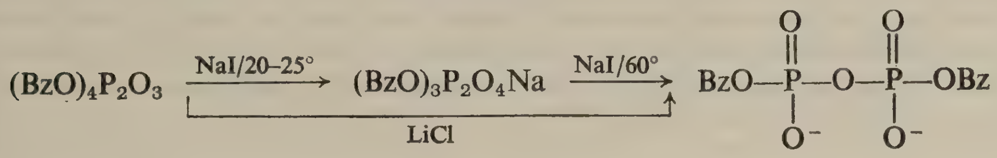
Silver salts of pyrophosphoric acid[1,1531] or its partial esters react readily with alkyl iodides giving the tetrasubstituted pyrophosphate[1537,1576]:

$$Ag_4P_2O_7 + 4EtI \rightarrow (EtO)_4P_2O_3 + 4AgI$$

A mixture of *P,P*-diethyl and *P,P′*-diethyl pyrophosphates is reported to be formed by the action of an excess of ethanol on phosphorus pentoxide.[1577]

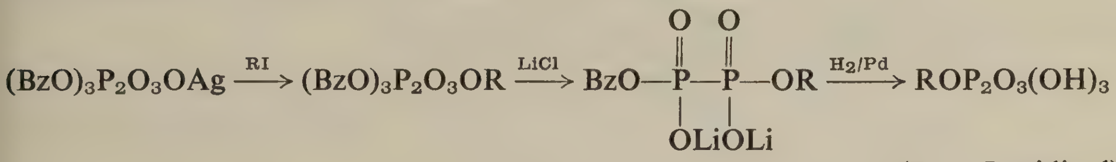
Dealkylation, usually debenzylation, reactions have been fairly widely used in the pyrophosphate field to prepare esters of mono-,[1576,1589] tri- and *P,P*-disubstituted pyrophosphates. Benzyl groups can be removed from benzyl-substituted pyrophosphate esters by metal salts such as lithium chloride,[1576] sodium iodide[1537] or lithium thiocyanate, by tertiary amines and by phenolysis[1589,1599] to give the *P,P′*-diester from which any residual benzyl groups can be removed by hydrogenation over palladium catalyst[1589,1599]:

$$(Bu_3NH)_2{}^+HPO_4{}^- \xrightarrow{DCC} (Bu_3NH)_3P_3O_9$$



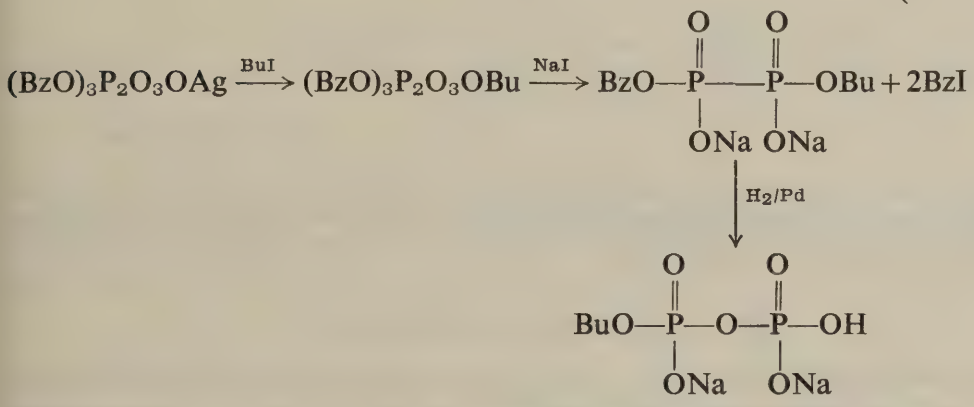
$$(BzO)_4P_2O_3 \xrightarrow{NaI/20\text{–}25^\circ} (BzO)_3P_2O_4Na \xrightarrow{NaI/60^\circ} BzO\text{—}\overset{O}{\underset{O^-}{P}}\text{—}O\text{—}\overset{O}{\underset{O^-}{P}}\text{—}OBz \qquad (BzO)_4P_2O_3 \xrightarrow{LiCl} BzO\text{—}\overset{O}{\underset{O^-}{P}}\text{—}O\text{—}\overset{O}{\underset{O^-}{P}}\text{—}OBz$$

The general procedures applicable in this field are illustrated by the formation of uridine diphosphate,[1576] *P*-butyl-*P′*-benzyl pyrophosphate[1537] and monobutyl pyrophosphate[1537] from silver tribenzyl pyrophosphate:



$$(BzO)_3P_2O_3OAg \xrightarrow{RI} (BzO)_3P_2O_3OR \xrightarrow{LiCl} BzO\text{—}\overset{O}{\underset{OLi}{P}}\text{—}\overset{O}{\underset{OLi}{P}}\text{—}OR \xrightarrow{H_2/Pd} ROP_2O_3(OH)_3$$

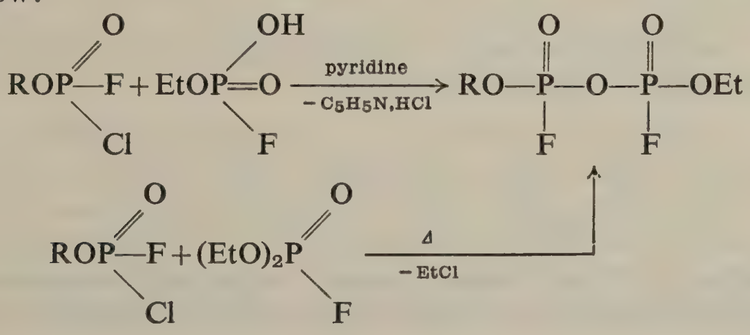
(R = 5-uridinyl)



$$(BzO)_3P_2O_3OAg \xrightarrow{BuI} (BzO)_3P_2O_3OBu \xrightarrow{NaI} BzO\text{—}\overset{O}{\underset{ONa}{P}}\text{——}\overset{O}{\underset{ONa}{P}}\text{—}OBu + 2BzI \xrightarrow{H_2/Pd} BuO\text{—}\overset{O}{\underset{ONa}{P}}\text{—}O\text{—}\overset{O}{\underset{ONa}{P}}\text{—}OH$$

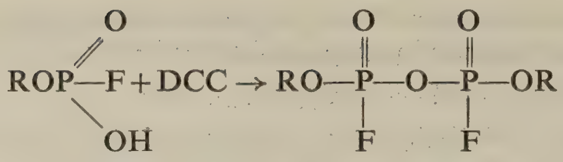
## Esters of Fluorodiphosphoric Acids

As a consequence of the high stability of the P–F bond, esters of *P,P′*-difluorodiphosphoric acid may be obtained by conventional synthesis from suitable fluoro-substituted phosphoric acid derivatives.[1136,1483,1487–8] Typical reactions are indicated below:

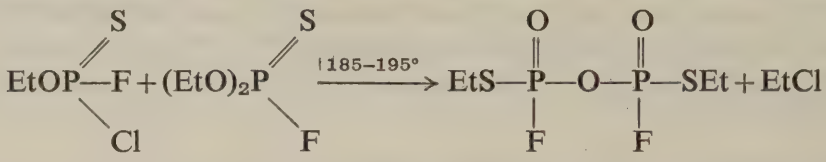


$$ROP\overset{O}{\underset{Cl}{\text{—}}}F + EtOP\overset{OH}{\underset{F}{=}}O \xrightarrow[-C_5H_5N,HCl]{pyridine} RO\text{—}\overset{O}{\underset{F}{P}}\text{—}O\text{—}\overset{O}{\underset{F}{P}}\text{—}OEt$$

$$ROP\overset{O}{\underset{Cl}{\text{—}}}F + (EtO)_2P\overset{O}{\underset{F}{}} \xrightarrow[-EtCl]{\Delta} RO\text{—}\overset{O}{\underset{F}{P}}\text{—}O\text{—}\overset{O}{\underset{F}{P}}\text{—}OEt$$

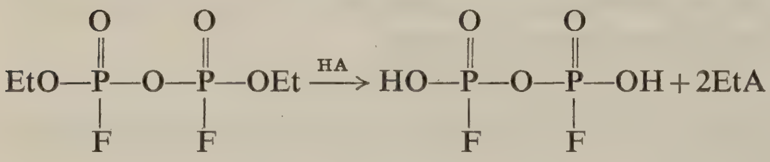


The thermal reaction of *O*-ethyl phosphorochloridofluoridothionate with *O*,*O*-diethyl phosphorofluoridate occurs with rearrangement of ethyl groups from oxygen to sulphur to form *sym*-*S*,*S*-diethyl difluorodithiopyrophosphate[1487]:



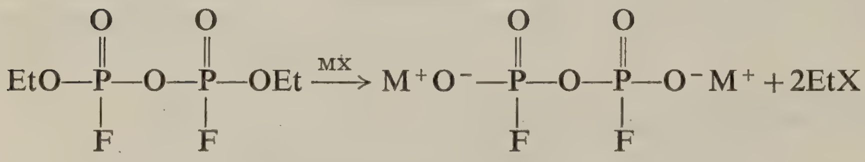
Compounds having a fluorine atom and an alkoxyl group attached to the same phosphorus atom undergo facile dealkylation with organic acids giving the acid ester and a fluorophosphoric acid. Dealkylation by metal salts, tertiary amines or thiourea yields the metal, quaternary ammonium or alkyl isothiouronium salt of the fluorophosphoric acid respectively[1485–7]:

$$\mathrm{EtOPOF_2 + R_3N \rightarrow [R_3\overset{+}{N}H][PO_2F_2]^-}$$



$$\mathrm{EtO{-}\overset{O}{\underset{F}{P}}{-}O{-}\overset{O}{\underset{F}{P}}{-}OEt \xrightarrow{HA} HO{-}\overset{O}{\underset{F}{P}}{-}O{-}\overset{O}{\underset{F}{P}}{-}OH + 2EtA}$$

(HA = phenol or $\mathrm{RCO_2H}$)



$$\mathrm{EtO{-}\overset{O}{\underset{F}{P}}{-}O{-}\overset{O}{\underset{F}{P}}{-}OEt \xrightarrow{MX} M^+O^-{-}\overset{O}{\underset{F}{P}}{-}O{-}\overset{O}{\underset{F}{P}}{-}O^-M^+ + 2EtX}$$

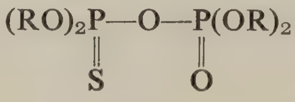
(X = I, Cl, OAc, $\mathrm{NO_3}$)

Fluorophosphoric acid and *sym*-difluoropyrophosphoric acid can also be formed by hydrogenolysis of diphenyl phosphorofluoridate and *P*,*P*′-diphenyl-*P*,*P*′-difluoropyrophosphoric acid, respectively.[1136]

### Thio- and Seleno-pyrophosphates

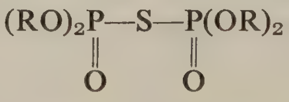
Known characterized derivatives of thiopyrophosphoric acids are limited almost entirely to fully esterified lower *O*-alkyl esters of mono-, di-, and tri-thiopyrophosphoric acid and to various ester amides and amides which are of considerable interest as potential insecticides. Generally the compounds exhibit a moderately high anticholinesterase action[1078–9, 1132, 1594, 1612]; they are less toxic and more stable to hydrolysis than the corresponding pyrophosphate esters. Preparation of thio- and seleno-pyrophosphates has been reviewed by Schrader *et al.*[1078] and by McIvor *et al.*[1079]

Tetra-alkyl monothiopyrophosphates could conceivably exist in two isomeric forms, a thiono form **I**, and a thiolo form **II**.



$$\mathrm{(RO)_2\underset{S}{P}{-}O{-}\underset{O}{P}(OR)_2}$$

**I**



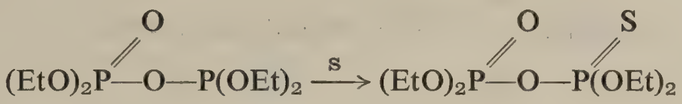
$$\mathrm{(RO)_2\underset{O}{P}{-}S{-}\underset{O}{P}(OR)_2}$$

**II**

Raman,[1585] infra-red,[1079] and nuclear magnetic resonance[1579] spectra show that the compounds always exist in the thiono form (I) even when the method of preparation, e.g., oxidation of tetraethyl thiopyrophosphite, $(EtO)_2P{-}S{-}P(OEt)_2$,[634] might reasonably be expected to yield the thiolo form. Tetraethyl selenopyrophosphate,[1581] like the sulphur compound, exists in the selenono rather than a selenolo form.[354,1579]

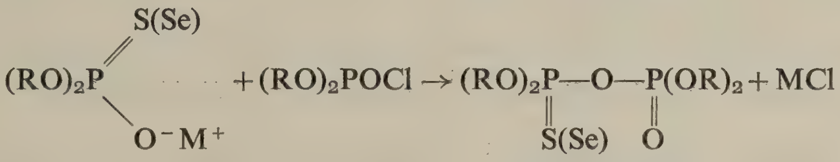
PREPARATION

Tetraethyl thionopyrophosphate was first prepared by Arbuzov in 1931 by the addition of sulphur to tetraethyl phosphorous phosphoric anhydride[1584]:

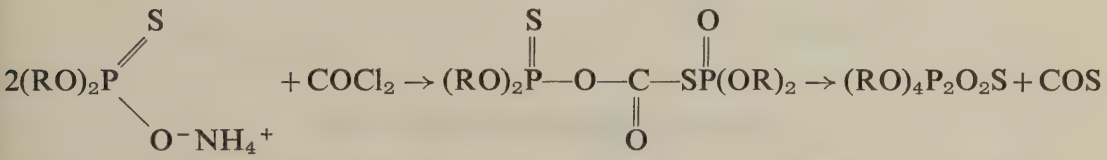


$$(EtO)_2\overset{O}{P}—O—P(OEt)_2 \xrightarrow{S} (EtO)_2\overset{O}{P}—O—\overset{S}{P}(OEt)_2$$

Tetraesters of monothio- and monoseleno-pyrophosphoric acids may be obtained from a dialkyl phosphorothioic acid or dialkyl phosphoroselenoic acid, respectively, by reaction with a dialkyl phosphorochloridate and tertiary base,[1132,1594] from a salt of the acid and phosphorochloridate,[1132,1582–3,1602] or by the action of hydrogen sulphide on a phosphorochloridate.[1582] Salts of dialkyl phosphorothioic acids react with carbonyl chloride,[1592] thiocarbonyl chloride[1592] or oxalyl chloride,[1602] giving monothiopyrophosphates:

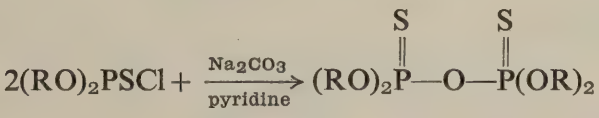


$$(RO)_2\overset{S(Se)}{\underset{O^-M^+}{P}} + (RO)_2POCl \rightarrow (RO)_2\underset{S(Se)}{P}—O—\underset{O}{P}(OR)_2 + MCl$$



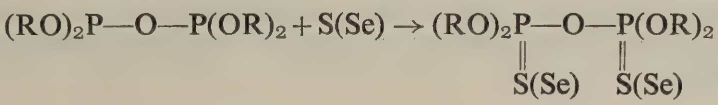
$$2(RO)_2\overset{S}{\underset{O^-NH_4^+}{P}} + COCl_2 \rightarrow (RO)_2\overset{S}{P}—O—\underset{O}{C}—S\overset{O}{P}(OR)_2 \rightarrow (RO)_4P_2O_2S + COS$$

Dithio-compounds are readily prepared by careful hydrolysis of *O,O*-dialkyl phosphorochloridothionates by water and tertiary base or better by the action of an alkali metal carbonate with pyridine catalyst[1593–4]:



$$2(RO)_2PSCl + \xrightarrow[\text{pyridine}]{Na_2CO_3} (RO)_2\overset{S}{P}—O—\overset{S}{P}(OR)_2$$

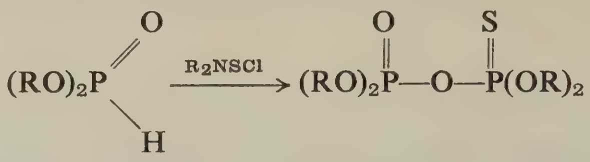
Tetra-alkyl dithiopyrophosphates or tetra-alkyl diselenopyrophosphates can be formed by the addition of sulphur or selenium to tetra-alkyl pyrophosphite[1602]:

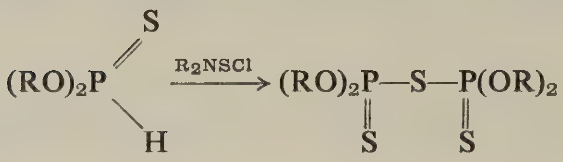


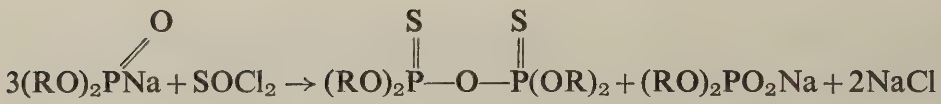
$$(RO)_2P—O—P(OR)_2 + S(Se) \rightarrow (RO)_2\underset{S(Se)}{P}—O—\underset{S(Se)}{P}(OR)_2$$

A number of reactions of dialkyl phosphites result in the formation of thiopyrophosphate, e.g., reaction of $(RO)_2POH$ with sulphur dichloride[709,710,1078] and pyridine or with $Me_2NSCl$.[710,1078] Dithiopyrophosphates result from the reaction of a sodium dialkyl phosphite with thionyl chloride.[1078] Trithiopyrophosphates are formed from *O,O*-dialkyl thiophosphites and amine sulphenyl chloride[1078,1099,1100];

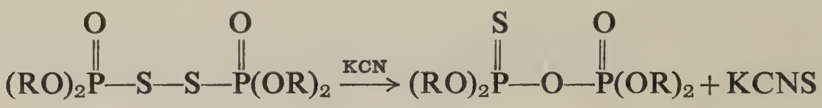
physical properties of a number of these compounds are listed by Almasi and Hantz[1099]:



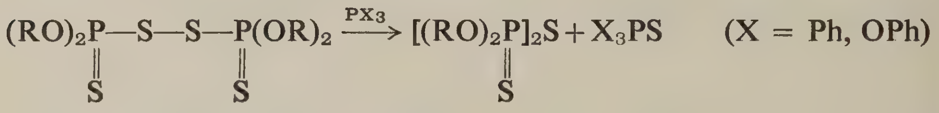




Bis-dialkoxyphosphoryl disulphides and bis-dialkoxythiophosphoryl disulphides may be reduced by potassium cyanide,[1078] triphenylphosphine or triphenyl phosphite[1603] (contrast the action of trialkyl phosphites with $(RO)_2P_2S_4$[1605] and $[(RO)_2PO]Se_2$,[1002] p. 1010) giving mono and trithiopyrophosphates, respectively:



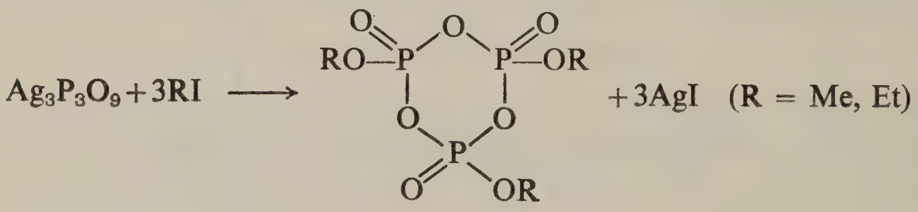
$$(RO)_2\overset{O}{\overset{\|}{P}}-S-S-\overset{O}{\overset{\|}{P}}(OR)_2 \xrightarrow{KCN} (RO)_2\overset{S}{\overset{\|}{P}}-O-\overset{O}{\overset{\|}{P}}(OR)_2+KCNS$$



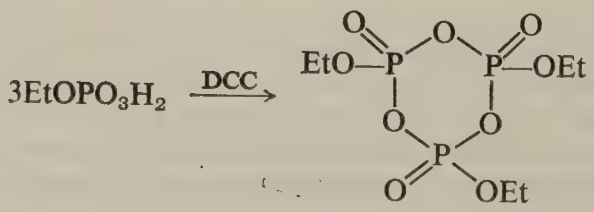
$$(RO)_2\underset{S}{\underset{\|}{P}}-S-S-\underset{S}{\underset{\|}{P}}(OR)_2 \xrightarrow{PX_3} [(RO)_2\underset{S}{\underset{\|}{P}}]_2S+X_3PS \qquad (X = Ph, OPh)$$

## Esters of Trimetaphosphoric Acid

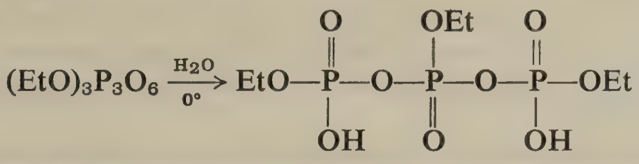
Silver trimetaphosphate and methyl or ethyl iodide react in acetonitrile solution giving the corresponding trialkyl trimetaphosphates[1409]:



A novel reaction used to prepare triethyl trimetaphosphate and less pure samples of the tris(2-cyanoethyl) and tribenzyl esters is the condensation of a monoalkyl phosphate with an excess of di*cyclo*hexyl carbodi-imide in dry dioxan[1386]; in a similar reaction bis(tributylammonium) phosphate condenses to tributyl ammonium trimetaphosphate:



Triethyl trimetaphosphate is hydrolyzed almost instantly at 0° in water to form the linear triethyl tripolyphosphate (cf. ref. 1386)

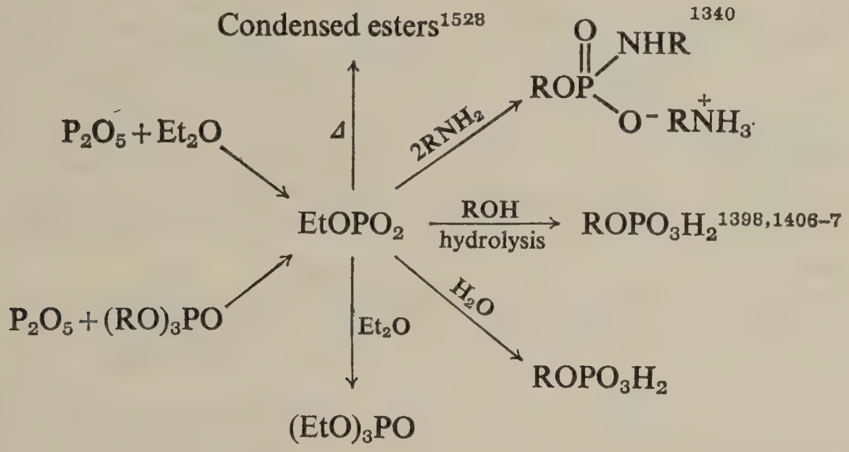


$$(EtO)_3P_3O_6 \xrightarrow[0^\circ]{H_2O} EtO-\underset{OH}{\overset{O}{\overset{\|}{P}}}-O-\underset{O}{\underset{\|}{\overset{OEt}{P}}}-O-\underset{OH}{\overset{O}{\overset{\|}{P}}}-OEt$$

Methanolysis of the trimethyl ester (prepared by the silver salt method) is stated to yield 50% tetramethyl pyrophosphate and 35% monomethyl phosphate[1409]; in contrast, methanolysis of the triethyl ester (prepared by the DCC method) gives 89–90% ethyl methyl phosphoric acid.[1386] Aniline and the triethyl ester form anilinium *O*-ethyl-*N*-phenyl phosphoramidate.[1386]

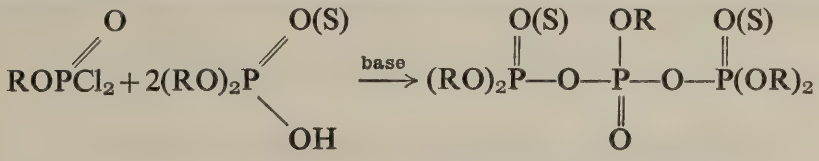
### 'ETHYL METAPHOSPHATE'

The chloroform-soluble ethyl metaphosphate $(EtOPO_2)_n$ which may be prepared, following Langheld,[1398, 1405] by reaction of phosphorus pentoxide with diethyl ether in chloroform solution, has been investigated by several groups of workers. The infra-red spectrum bears some resemblance to that of triethyl trimetaphosphate,[1409] and the nuclear magnetic resonance spectrum[1399–1400] and chromatographic analysis[1401] indicate the substance to consist of a number of ethylated condensed acids of phosphorus. Thilo *et al.* conclude from their chromatographic analysis[1401] that the Langheld ester does not consist of a mixture of tetraethyl tetrametaphosphate and tetraethyl *iso*tetrametaphosphate, as was assumed previously by Rätz and Thilo,[1587] on the basis of hydrolysis and ammonolysis. Formation and reactions of 'ethyl metaphosphate' are indicated below:

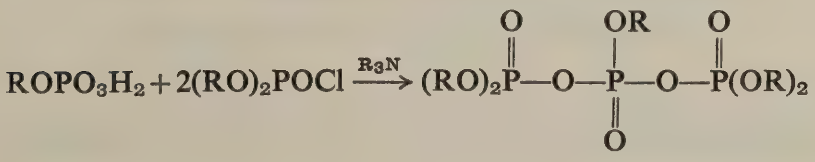


## Esters of Triphosphoric Acid

Pentaesters of triphosphoric acid and dithiotriphosphoric acids have generally been obtained by interaction of the appropriate phosphorodichloridate with the salt of a dialkyl-phosphoric or phosphorothioic acid,[1132, 1550, 1553, 1588] or from a phosphoric acid monoester and dialkyl phosphorochloridate generally in the presence of a tertiary base.[1550, 1553] Few compounds other than lower alkyl esters are known:



$$ROPCl_2{=}O + 2(RO)_2P({=}O(S))OH \xrightarrow{base} (RO)_2\overset{O(S)}{\overset{\|}{P}}-O-\underset{O}{\underset{\|}{\overset{OR}{P}}}-O-\overset{O(S)}{\overset{\|}{P}}(OR)_2$$

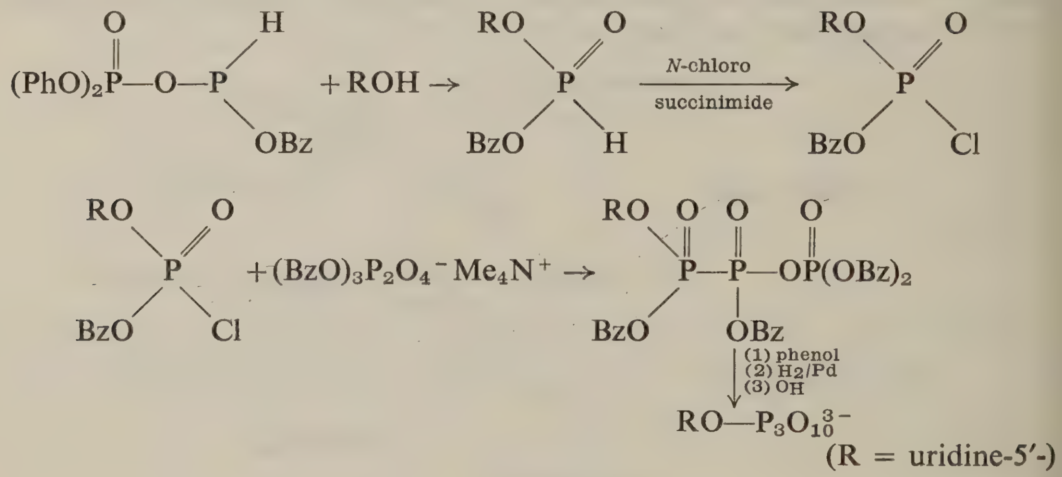


$$ROPO_3H_2 + 2(RO)_2POCl \xrightarrow{R_3N} (RO)_2\overset{O}{\overset{\|}{P}}-O-\underset{O}{\underset{\|}{\overset{OR}{P}}}-O-\overset{O}{\overset{\|}{P}}(OR)_2$$

Pentaethyl triphosphate prepared by the classical technique from pentasilver triphosphate and ethyl iodide[1179,1601] consists of a mixture of compounds.[1408] Hydrolysis gives $(EtO)_2PO_2H$ and $EtOPO_3H_2$ in close to the theoretical 2:1 ratio; ammonolysis gives a 2:1 mixture of ammonium phosphoramidate and ammonium diethyl phosphate.[1601] Hydrolysis data for pentaethyl triphosphate are given by Simon and Stölzer.[1550]

The patent literature contains a number of claims for the formation of penta-alkyl triphosphates and hexa-alkyl tetraphosphates which, in view of the ready reorganization of polyphosphate esters[1408] and the techniques of preparation given are almost certainly mixtures of several condensed esters (cf. ref. 1590). Such methods are the thermal reaction of phosphoryl chloride with triethyl phosphate,[1536] the reaction of phosphorus pentoxide with diethyl ether[1528] or with phenol,[1179] the direct reaction of alcohols with phosphoryl chloride[1591] and the reaction of phosphorus pentoxide with triethyl phosphate.[1339] The 'pentaethyl triphosphate' prepared by the last method yields mainly diethyl and monoethyl phosphates on hydrolysis, but not in the calculated 2:1 ratio.[1601]

Adinosine-5′-triphosphate[1596] and uridine-5′-triphosphate,[1589] identical with the naturally occurring compounds, have been prepared by Todd and his co-workers. The uridine compound was obtained by condensing a protected uridine-5′-benzyl phosphorochloridate with tetramethylammonium tribenzyl pyrophosphate to form the protected uridine-5′-tetrabenzyl triphosphate, which on debenzylation by hot phenol and then hydrogenolysis to remove the benzyl groups, followed by hydrolysis, gave the triphosphate (isolated as the sodium salt):



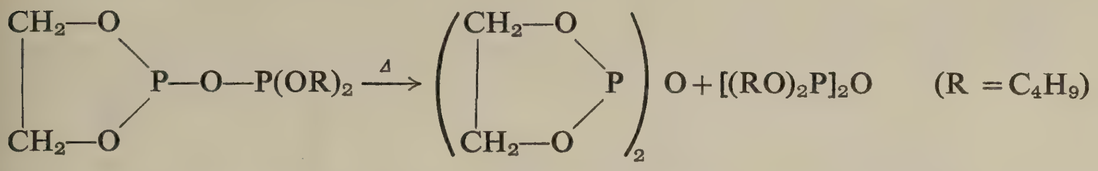
## ESTERS OF PYROPHOSPHOROUS ACID, $(RO)_2P–O–P(OR)_2$

The action of bromine[1584,1616] or chlorine[1617] or 1,2-dibromoethane,[1714] on sodium dialkyl phosphites gives a complex mixture of products. For example, sodium diethyl phosphite and bromine form a mixture of diethyl phosphite, triethyl phosphate, tetraethyl pyrophosphite, tetraethyl pyrophosphate and tetraethyl hypophosphite.[1584] Tetraesters of pyrophosphorous acid have generally been made by the reaction between a salt of a dialkyl phosphite and a dialkyl phosphorochloridite,[1602,1614,1616,1618,1621] or by the controlled action of water on dialkyl phosphorochloridite, usually in the presence of a tertiary organic base[1615,1619]:

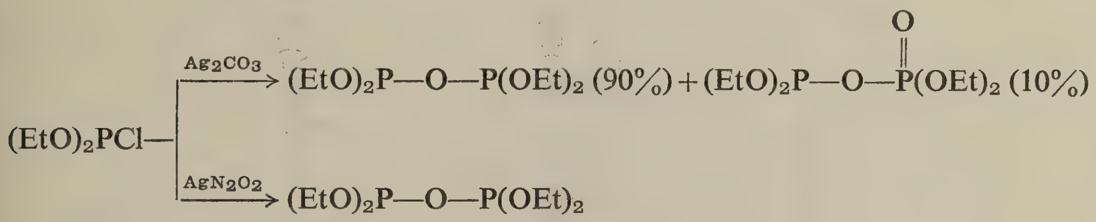
$$(R'O)_2PONa + (RO)_2PCl \rightarrow (R'O)_2P—O—P(OR)_2$$
$$2(RO)_2PCl \xrightarrow[-2R_3N,HCl]{H_2O+2R_3N} (RO)_2P—O—P(OR)_2$$

In addition to simple tetra-alkyl pyrophosphites a number of derivatives are known in which the phosphorus atom forms part of a 1,3-dioxa-2-phospha-ring system.

[1614–5,1618–9] Yields of the higher unsymmetrical esters are reduced by symmetrization during distillation[1615,1619]:



Tetraethyl pyrophosphite has been prepared, together with some 10% tetraethyl isohypophosphate, by the action of silver carbonate on diethyl phosphorochloridite,[1543] or by reaction of the chloridite with silver hyponitrite[638]:



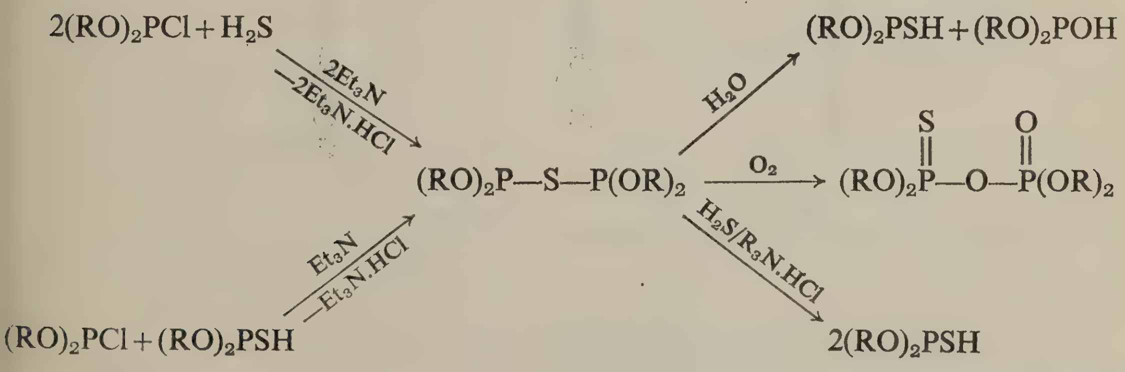
The lower tetra-alkyl pyrophosphites are liquids which can be distilled under vacuum without decomposition. In many of their properties they resemble tertiary phosphites. They react with 2 moles of iodine[1584,1616] and form adducts with 2 moles of cuprous halide.[1584,1614–5] They are readily oxidized, particularly by dinitrogen tetroxide,[862] to form tetraesters of pyrophosphoric acid; addition of sulphur[1602,1614–5] or selenium[1602] gives dithio- or diseleno-pyrophosphate, respectively. Hydrolysis is exothermic, giving 2 moles of dialkyl phosphite.[1584,1615] Carboxylic acids and amines readily cause P–O–P group fission to form acyl phosphite[1613,1621] and *N*-substituted dialkyl phosphoramidite[1621,1624] respectively.

Amides, particularly peptides, are conveniently prepared under mild conditions by adding tetraethyl pyrophosphite to a mixture of amine and acid in diethyl phosphite solvent[1621–2]; higher yields are claimed for bis-*o*-phenylene pyrophosphite,[1620] a reagent which is prepared by the action of water vapour *in vacuo* on *o*-phenylene phosphorochloridite[1619]:

$$(RO)_2P{-}O{-}P(OR)_2 + R'CO_2H \rightarrow (RO)_2POCOR' + (RO)_2POH$$
$$(RO)_2POCOR' + R''NH_2 \rightarrow R'CONHR'' + (RO)_2POH$$

Some reactions of pyrophosphites are shown in Chart XIX.

Tetra-alkyl thiopyrophosphites are prepared by the action of hydrogen sulphide on dialkyl phosphorochloridites in the presence of a strong organic base such as triethylamine, or from the chloridite and a dialkyl thiophosphite.[634] The compounds are highly susceptible to atmospheric oxidation, yielding tetra-alkyl monothionopyrophosphate. They are readily hydrolyzed and react with hydrogen sulphide in the presence of an amine hydrochloride giving dialkyl thiophosphite[634]:



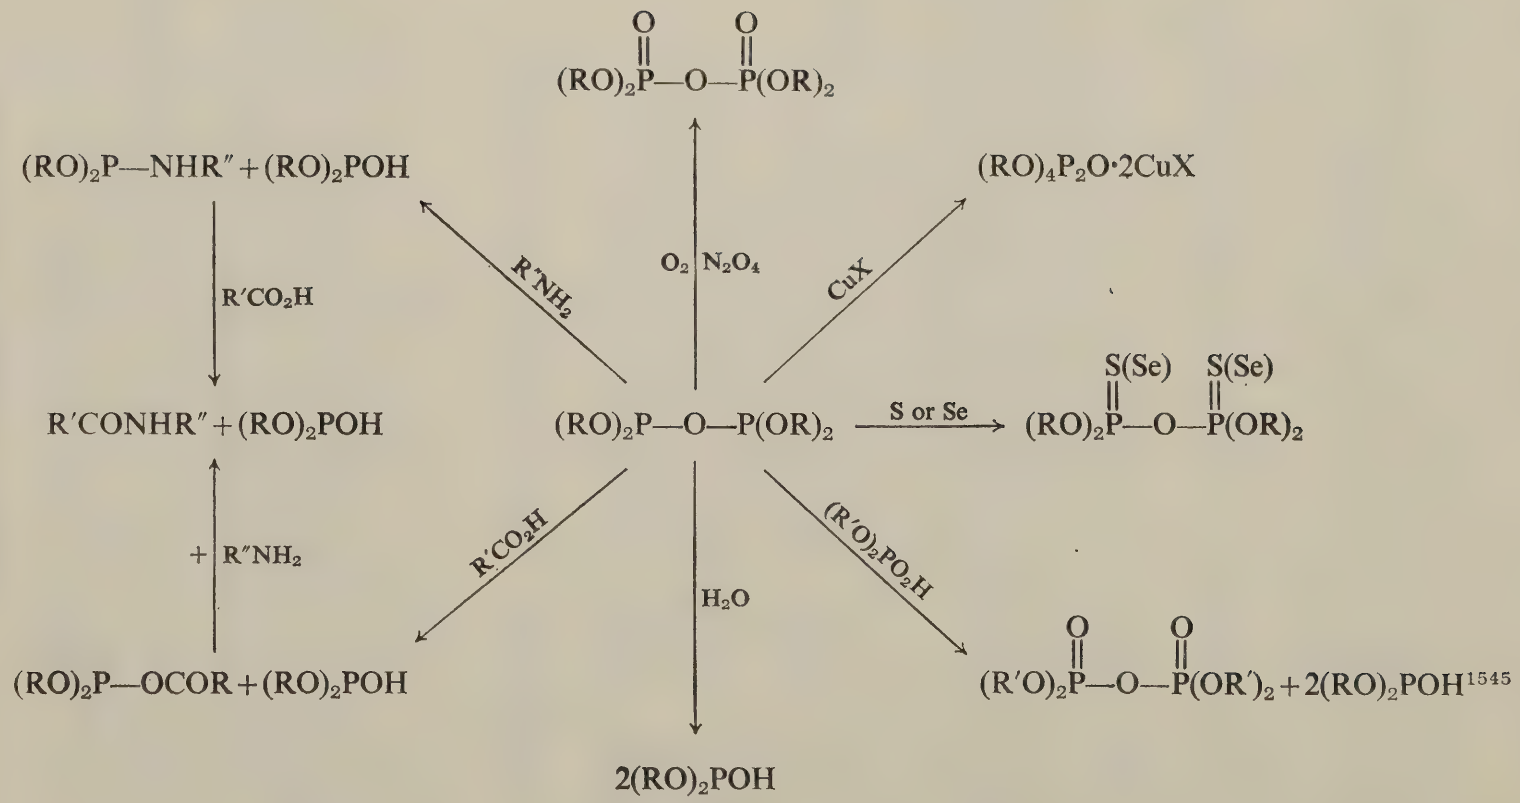


CHART XIX.—Some reactions of pyrophosphites

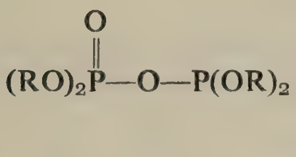
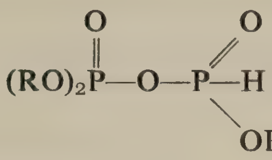
## Esters of Phosphorous Phosphoric Anhydride (isoHypophosphates)

Tetra-alkyl isohypophosphates $R_4P_2O_6$ (I) which are isomeric with tetra-alkyl hypophosphate (III) and with trialkyl esters of alkyl phosphonic-phosphoric anhydride (IV) may be readily obtained by reaction of a phosphorochloridite with a dialkyl phosphate[1638]:

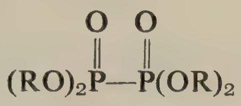


$(RO)_2\overset{O}{\overset{\|}{P}}-O-P(OR)_2$

I

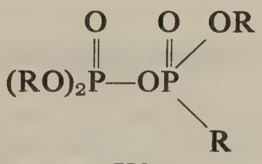


II

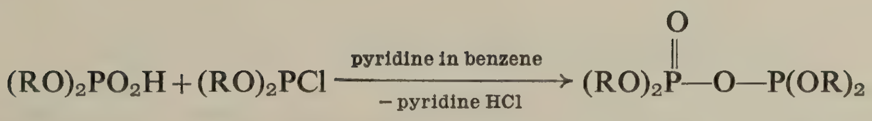


$(RO)_2\overset{O}{\overset{\|}{P}}-\overset{O}{\overset{\|}{P}}(OR)_2$

III

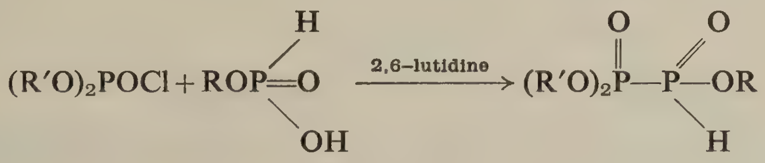


IV

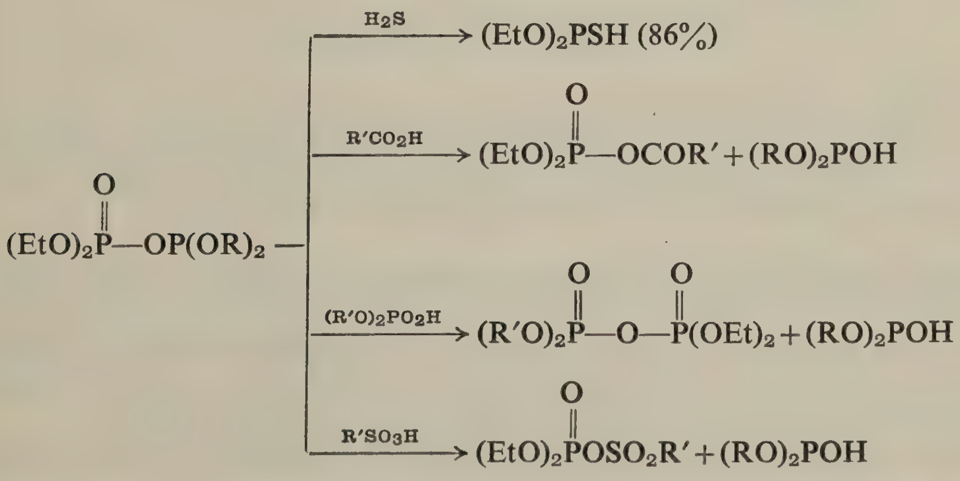


$$(RO)_2PO_2H + (RO)_2PCl \xrightarrow[-\text{ pyridine HCl}]{\text{pyridine in benzene}} (RO)_2\overset{O}{\overset{\|}{P}}-O-P(OR)_2$$

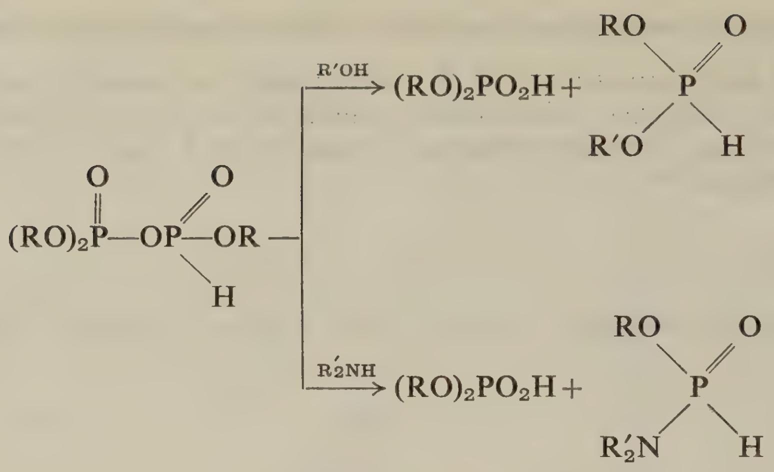
Trialkyl isohypophosphates (II) are formed from dialkyl phosphorochloridate and monoalkyl phosphite:



The tetra-alkyl esters react with hydrogen sulphide, giving dialkyl phosphorothioite,[1640] and with acids to form mixed anhydrides of phosphoric acid.[1639] The triesters have been used by Todd and co-workers to prepare complex unsymmetrical dialkyl phosphites as intermediates for nucleotide synthesis.[1598] They react with amines giving *O*,*N*,*N*-trialkyl phosphoramidites.[1641]



**Refs. p. 1082**



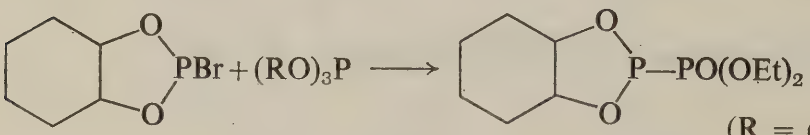
## Esters of Hypodiphosphorous Acid

Tetra-alkyl or aryl esters of hypodiphosphorous acid are claimed to be prepared by the reduction of phosphorochloridites with metallic sodium. Similar reactions with phosphorodichloridites are said to form compounds of the type RO—P=P—OR[1633]:

$$(RX)_2PCl \xrightarrow{Na} (RX)_2P\text{—}P(XR)_2 \qquad (X = O, S)$$

The reaction of diphosphorus tetraiodide with phenol gives a reasonable yield of tetraphenyl hypodiphosphite, but Grignard reagents, alcohols and amines cause fission of the P–P bond.[1635]

Low yields of hypodiphosphorous phosphoric esters are obtained by the reaction of catechol phosphorobromidite with trialkyl phosphites[877]:



(R = ethyl and higher alkyls)

## Esters of Hypophosphorous Acid

Methyl and ethyl hypophosphites were first prepared in 1960 by Kabachnik and co-workers[1636] by alkylating hypophosphorous acid with the appropriate diazoalkane: only one equivalent of diazoalkane reacts, regardless of the amount used:

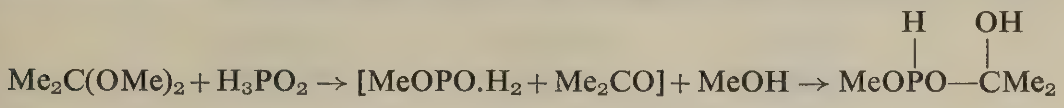
$$CH_2N_2 + H_3PO_2 \xrightarrow{\text{ether}} MeOPO.H_2 + N_2$$

The distilled esters decompose rapidly at room temperature but can be stored at $-60°C$. More recently it has been shown that compounds having an ortho-carbonyl function, such as orthocarbonates, orthocarboxylates, ketals and acetals, react with anhydrous hypophosphorous acid giving alkyl hypophosphites[1637]:

$$H_3PO_2 + R_nC(OR')_{4-n} \rightarrow ROPO.H_2 + R'OH + RCO(OR)_{2-n} \qquad (n = 0, 1, 2)$$

Methyl and ethyl hypophosphites, obtained by mixing methyl or ethyl orthoformate with hypophosphorous acid at room temperature followed by vacuum distillation, have been characterized by nuclear magnetic resonance spectroscopy.

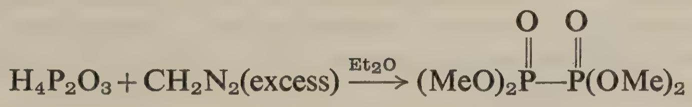
Acetone dimethyl ketal and hypophosphorous acid react giving methyl(1-hydroxy-1, 1-dimethyl)methyl phosphinate, which is believed to result from addition of by-product acetone to the initially formed methyl hypophosphite:



$$Me_2C(OMe)_2 + H_3PO_2 \rightarrow [MeOPO.H_2 + Me_2CO] + MeOH \rightarrow MeO\overset{H}{\overset{|}{P}}O\text{—}\overset{OH}{\overset{|}{C}}Me_2$$

## Esters of Hypophosphoric Acid

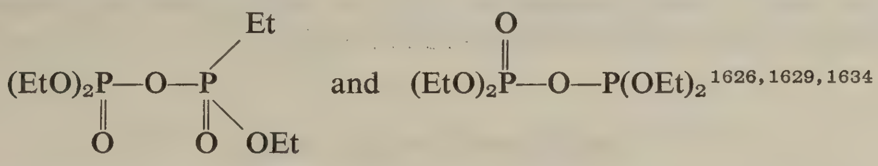
Tetramethyl and tetraethyl esters of hypophosphoric acid are best prepared by the action of an ethereal solution of diazomethane or diazoethane on the anhydrous acid[1625-6]:



$$H_4P_2O_3 + CH_2N_2(\text{excess}) \xrightarrow{Et_2O} (MeO)_2\overset{O}{\overset{\|}{P}}\text{—}\overset{O}{\overset{\|}{P}}(OMe)_2$$

The presence of the P–P bond in the compounds is shown by lack of reactivity with cuprous halides, iodine and other mild oxidizing agents. The Raman spectrum shows a strong band at 260 cm.$^{-1}$ in the methyl compound. This is comparable with that at 274 cm.$^{-1}$ in the acid and is assigned to the P–P skeletal vibration.[1625-6] The action of methyl iodide on tetrasilver hypophosphate gives a mixture of tetramethyl hypophosphate and tetramethyl pyrophosphate.[1628]

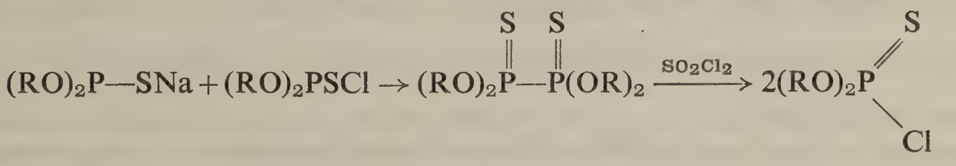
Attempts to build hypophosphate esters from two monophosphorus-containing components have so far been only partially successful, owing to concurrent formation of esters having P–O–P bonds. Diethyl phosphorochloridate is reduced by sodium in toluene to form some 65% tetraethyl hypophosphate together with tetraethyl pyrophosphate.[1626-7] Condensation of the chloridite with sodium diethyl phosphite gives up to a 53% yield[1629] but thermal condensation with triethyl phosphite gives largely a mixture of:



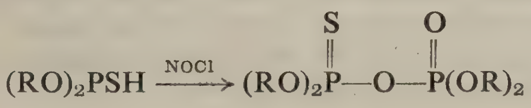
Hypophosphates are also formed by the action of sulphuryl chloride on sodium dialkyl phosphites[1629, 1714] (whereas the action of bromine gives a mixture of products[1584, 1714]) and by thermal decomposition of bis-dialkoxyphosphinyl mercury compounds.[686]

Tetraethyl hypophosphate can be hydrolyzed almost quantitatively to diethyl phosphite and diethyl phosphate[1626, 1630]; chlorination with sulphuryl chloride gives 2 moles of diethyl phosphorochloridate.[1630]

Tetra-alkyl dithiohypophosphates have been prepared in good yield by the condensation of a sodium dialkyl thiophosphite with a dialkyl phosphorochloridothionate.[1632] They react with sulphuryl chloride in carbon tetrachloride to form 2 moles of dialkyl phosphorochloridothionate:



An earlier reported preparation of these compounds by the action of nitrosyl chloride on dialkyl thiophosphite[1631] is stated to yield a tetra-alkyl monothiopyrophosphate and not a dithiohypophosphate[1632]:



$$(RO)_2PSH \xrightarrow{NOCl} (RO)_2\overset{S}{\overset{\|}{P}}\text{—}O\text{—}\overset{O}{\overset{\|}{P}}(OR)_2$$

## AMINO PHOSPHINES

The 'amino phosphines' comprise derivatives of the following:

| $P(NH_2)_3$ | $RP(NH_2)_2$ | $R_2P(NH_2)$ |
|---|---|---|
| phosphorous triamide | phosphonous diamide | phosphinous amide |

### Derivatives of Ammonia

The halogen atom attached to phosphorus in phosphorus trihalides, phosphonous dihalides and phosphinous halides is readily replaced on ammonolysis. However, the primary products of these reactions, phosphorous triamide, phosphonous diamide and phosphinous amide, have been isolated in only a few special cases, owing to such factors as instability of the compounds and the difficulty of separation from by-product ammonium halide.

Attempts to make aminodimethylphosphine by ammonolysis of dimethyl chlorophosphine or *N*,*N*-dimethyl dimethylphosphinous amide give only a mixture of the poly(dimethylphosphino) amines, $(Me_2P)_2NH$ and $(Me_2P)_3N$.[334] In contrast the aminophosphine $(CF_3)_2PNH_2$, a colourless liquid, is thermally stable up to 250°C. *in vacuo* and shows no direct conversion into poly(bis-trifluoromethyl phosphinyl) amines[249] which are prepared by the reactions indicated below[2147]:

$$(CF_3)_2PNH_2 + (CF_3)_2PCl \xrightarrow{Me_3N} [(CF_3)_2P]_2NH \qquad \text{(decomposes slowly at 300°C.)}$$

$$[(CF_3)_2P]_2NH \xrightarrow{Na/NH_3} [(CF_3)_2P]_2N^-Na^+ \xrightarrow{(CF_3)_2PCl} [(CF_3)_2P]_3N \qquad \text{(decomposes at 150°C.)}$$

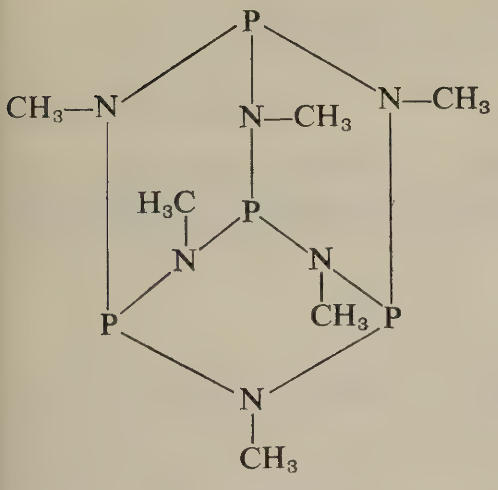
A few ester derivatives of phosphoramidous acid $[(HO)_2PNH_2]$ and phosphorodiamidous acid $[HOP(NH_2)_2]$ are reported; diphenyl phosphoramidite, $(PhO)_2PNH_2$, decomposes even at room temperature giving off white phosphorus; phenyl phosphorodiamidite is reported to be an amorphous solid, m.p. 110°–112° (decomp.).[386]

### Derivatives of Primary Amines

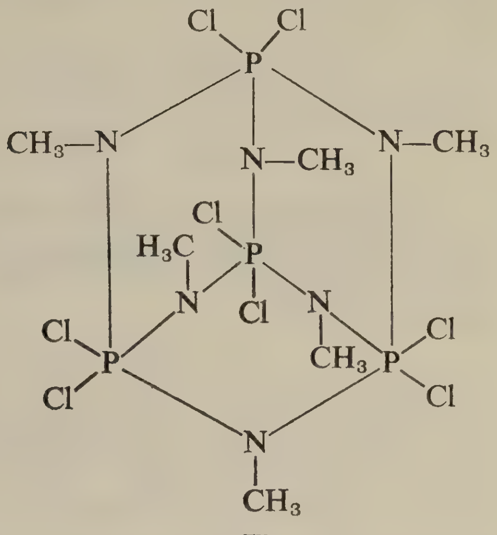
Michaelis[943] showed that the initial reaction of a primary amine with phosphorus trichloride affords an *N*-alkyl phosphoramidous dichloride, $RNHPCl_2$. The lower alkyl members of this class of compounds may be distilled *in vacuo* without decomposition. But, in general, compounds of this type, characterized by a group –NH–PX–, are unstable to heat and readily undergo condensation and transformation to other substances. The nature of the products becomes increasingly ill-defined with further replacement of chlorine on the phosphorus atom by primary amine. Until recently the literature showed no successful characterization of a P–N compound derived from phosphorus trichloride and a primary amine. By working with an excess of methylamine over phosphorus trichloride, and in the absence of a solvent, Holmes and Forstner isolated a compound $P_4N_6(CH_3)_6$, **I**, a member of a new class of P–N compounds, having a cage-like structure analogous to tetraphosphorus hexa-oxide in which the oxygen atoms are replaced by $>$N–Me groups.[711] A related compound $P_4N_6(CH_3)_6Cl_8$, **II**, having two chlorine atoms attached to each phosphorus atom, has been made by interaction of phosphorus pentachloride and methylamine hydrochloride.[1540]

Aryl phosphonous and phosphinous halides react with primary *tert*-alkyl aliphatic amines and aromatic amines to give well-defined products having sharp melting-points. Typical of such products are *N*-substituted diphenyl phosphinamidites, $Ph_2PNHR$[2151] and *N*,*N'*-di*tert*-butyl phenyl phosphonous diamide,[539] and bis-(diphenylphosphino) methylamine.[588] With aryl hydrazines, phosphonous halides give compounds of the type PhP═NNHAr.[388]

Aromatic amines react with phosphorus trichloride to give not *N*-aryl phosphoramidous dichloride but a compound named by Michaelis[2168] as a phosphazochloride



I



II

as the initial product. Phenyl phosphazochloride was shown by Michaelis to be dimeric in solution. It is best prepared by the reaction of phosphorus trichloride and aniline hydrochloride:

$$2PhNH_3^+Cl^- + 2PCl_3 \rightarrow (PhN{=}PCl)_2 + 2HCl\uparrow$$

Further reaction of these compounds with aromatic amines,[2168] or the reaction of phosphorus trichloride with five equivalents of aromatic amine, yields compounds of the phosphorazo class RN=PNHR:

$$5PhNH_2 + PCl_3 \rightarrow (PhN{=}P{-}NHPh) + 3PhNH_3Cl$$

A few compounds of this class have been characterized by Grimmel[1580] and exhibit dimeric behaviour in solution, as well as one compound, *p*-methoxyphenyl-*N*-bis(*p*-methoxyiminophosphine), which is monomeric in benzene solution.[2164] Phosphazo-compounds are of interest for the preparation of amides, particularly peptides. When phosphorus trichloride is added to a mixture of an amine and a carboxylic acid in an inert solvent the phosphazo-compound is formed and reacts with the carboxylic acid, giving the amide[1580, 2165-6]:

$$R{-}N{=}P{-}NHR + 2R'CO_2H \rightarrow 2R'CONHR + HPO_3$$

Related reactions are those which employ 'phosphite amides' *O,O*-dialkyl *N*-substituted phosphoramidites, formed *in situ* by reaction of amino compounds and dialkyl phosphorochloridites, for the synthesis of peptides.[2167]

### Derivatives of Secondary Amines

Secondary amines and phosphorus trichloride react exothermically to produce by successive substitution *N,N*-disubstituted phosphoramidous dichlorides, bis-(*N,N*-disubstituted) phosphorodiamidous chlorides and tris-(*N,N*-disubstituted) phosphorous triamides[943]:

$$PCl_3 \xrightarrow[-\ NH,HCl]{+2R_2NH} R_2NPCl_2 \rightarrow (R_2N)_2PCl \rightarrow (R_2N)_3P$$

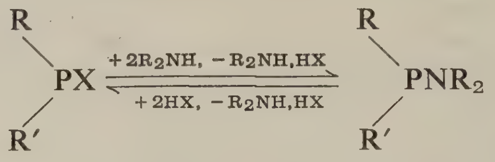
**Refs. p. 1082**

In like manner, phosphonous dichlorides form the *N*,*N*-disubstituted phosphonamidous chloride and then bis-(*N*,*N*-disubstituted) phosphonous diamide. Phosphinous halides form *N*,*N*-disubstituted phosphinous amide[384,388,446,539,588,703,943,2094,2431]:

$$R'PCl_2 \xrightarrow[-R_2NH,HCl]{+2R_2NH} R'P(NR_2)Cl \rightarrow R'P(NR_2)_2$$

$$R'_2PCl \xrightarrow[-R_2NH,HCl]{+2R_2NH} R'_2PNR_2$$

Aminohalogenophosphines, $R'P(NR_2)X$ (where $X = Cl$, Br, I; $R' = R_2N$, alkyl, aryl or halogen), can be prepared by treating aminophosphines with anhydrous hydrogen halide,[68,334,336,477,767] and by aminolysis of the corresponding halophosphine[384,2151]:



by coproportionation of halogenophosphine and aminophosphine,[647,756]

$$(R_3N)_3P + 2PCl_3 \rightarrow 3PCl_2NR_2$$

and by the action of Grignard reagents (or, better, organolithium compounds) on $R_2NPX.R$.[68,334,336,767] The chlorine atoms of *N*,*N*-dimethyl phosphoramidous dichloride are readily replaced by cyano-groups through the agency of silver cyanide[767]:

$$Me_2NPCl_2 \xrightarrow{AgCN} Me_2NP(CN)_2$$

Ligand exchange between the following pairs of compounds, $PCl_3:P(NEt_2)_3$, $PCl_3:ClP(NEt_2)_2$, $MePCl_2:MeP(NMe_2)_2$, $MePCl_2:MeP(NEt_2)_2$, $MePBr_2:MeP(NMe_2)_2$ and $MePBr_2:MeP(NEt_2)_2$ was investigated by Van Wazer and Maier.[756] In all cases the equilibrium constant for disproportionation of the intermediate products, obtained by exchanging halogen for dialkyl amino-groups, was found to be so small that it could not be determined within experimental error from the stoicheiometry of the products.

In contrast with phosphonous chlorides and phosphinous chlorides, which undergo both oxidation and fluorination with arsenic or antimony trifluoride giving derivatives of phosphorus pentafluoride,[556,891,991] *N*,*N*-dialkyl phosphoramidous chlorides and alkyl phosphorodichloridites undergo normal exchange to form *N*,*N*-dialkyl phosphoramidous difluorides and alkyl phosphorofluoridites, respectively[981]:

$$YPCl_2 \xrightarrow{SbF_3} YPF_2 \qquad (Y = R_2N\text{—}, RO\text{—})$$

The dialkylaminofluorophosphines are interesting ligands; they will displace carbon monoxide from nickel and molybdenum carbonyls, giving compounds of the type $Ni(CO)_2L_2$, $NiL_4$ and $Mo(CO)_3L_3$ (where $L = Me_2NPF_2$, $Et_2NPF_2$).

Alkyl/aryl dialkylaminochlorophosphines react like the halogenophosphines with $As/SbF_3$ giving alkyl/aryl dialkylaminofluorophosphoranes[2431]:

$$3RPCl.NR'_2 + 3MF_3 \rightarrow 3RPF_3NR'_2 + 2M + MCl_3 \qquad (M = As, Sb)$$

They may be converted to the corresponding fluorophosphines by reaction with sodium fluoride in tetramethylene sulphone[2431]:

$$RPCl.NR'_2 + NaF \rightarrow RPF.NR'_2 \qquad (R = Me, Ph, R'_2N)$$

Diethylamino tri- and tetra-fluorophosphoranes are obtained from $PF_5$ or $PhPF_4$ respectively by reaction with diethylaminotrimethyl silane[2142]:

$$RPF_4 + Me_3SiNEt_2 \rightarrow RP(NEt_2)F_3 + Me_3SiF \qquad (R = Ph, Et_2N)$$

Aminolysis of difluorotrifluoromethyl phosphine with dimethylamine proceeds abnormally to give a mixture of the expected product, *N,N*-dimethyl trifluoromethyl phosphonamidous fluoride, and dimethylammonium hydrotetrafluorotrifluoromethyl phosphate:

$$3CF_3PF_2 + 3Me_2NH \rightarrow 2CF_3PF(NMe_2) + Me_2NH_2^+ + CF_3PF_4H^-$$

The structure of the anion was confirmed by infra-red and n.m.r. spectroscopy.[455]

## Reactions of Dialkylaminophosphines

The aminophosphines form a class of highly reactive compounds. Many of their reactions resemble those of tertiary phosphines. They are readily oxidized by atmospheric oxygen and react exothermically with sulphur at room temperature. Such reactions are best conducted at a controlled temperature in an inert solvent if product isolation is desired[2]:

$$A_2PNR_2 \rightarrow A_2PX.NR_2 \qquad (X = O, S; A = \text{alkyl, aryl}, R_2N)$$

The compounds readily undergo a quaternization reaction with compounds such as alkyl halides, *N*-halogenoamines, sulphenyl chlorides and halogens to form quasiphosphonium salts (see page 941):

$$A_2PNR_2 + R'X \rightarrow A_2\overset{+}{P}(NR_2)R'X^- \qquad (R' = \text{alkyl, RS—}, R_2N, \text{halogen})$$

Aminophosphines are good ligands. Complexes with mercury(II), cadmium(II), copper(I), nickel(II) and cobalt(II) are reported.[384, 633] Cadmium and mercury iodides form complexes of the type $A_2PNR_2,MI_2$ and $[A_2PNR_2]_2,MI_2$ (where $M = Cd$, $Hg$; $R =$ lower alkyl; $A = R_2N$, $R_2'N$, phenyl). The cuprous iodide complex of *N,N*-diethyl diphenyl phosphinamidite is a tetramer in benzene solution, $[Ph_2PNEt_2,CuI]_4$, in keeping with the behaviour of cuprous iodide complexes of simple phosphines.[384] Hexa-*N*-methyl phosphorous triamide will displace one or two carbon monoxide ligands from nickel carbonyl to form complexes $(Me_2N)_3P,Ni(CO)_3$ and $[(Me_2N)_3P]_2,Ni(CO)_2$. Tetra-*N*-methyl phosphorodiamidous chloride and tetra-*N*-methyl cyanophosphorous diamide form the complexes $[(Me_2N)_2PX]_2,Ni(CO)_2$ (where $X = Cl$ or $CN$).[633]

The borine complex $(Me_2N)_3P,BH_3$ is particularly stable; it decomposes only above 250°C. In contrast, the borine complex of bis-(dimethylamino)phosphine, $(Me_2N)_2PH,BH_3$, made by reduction of bis-(dimethylamino)chlorophosphine with lithium borohydride, decomposes slowly at room temperature; the borine complex of dimethylaminophosphine, $Me_2NPH_2,BH_2$, could not be made by a similar method.[860]

The P–N bond in phosphorous amides is readily broken by acid hydrolysis and by protic reagents such as alcohols, mercaptans, anhydrous halogen acids and by other amines, with elimination of amine and formation of a phosphorous *O*-ester, *S*-ester, halide or another amino-compound, respectively:

$$A_2PNMe_2 + BXH \rightarrow A_2PXB + Me_2NH$$
$$(X = O, S; A = \text{alkoxy, dialkylamino})^{388, 2149}$$
$$A_2PNMe_2 + PhNH_2 \rightarrow A_2PNHPh + Me_2NH^{2170}$$

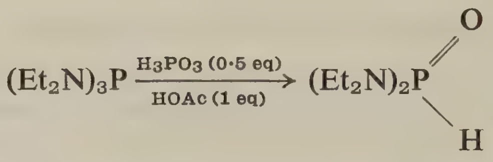
In compounds having more than one P–N bond, use of an excess of protic reagent leads to the complete elimination of the nitrogen component from the phosphorus atom. By careful control of reagent quantities intermediate amino-esters can be obtained:

$$(Me_2N)_3P + EtOH \rightarrow (Me_2N)_2POEt \text{ (82\% yield)} + Me_2NH^{2149}$$
$$(Me_2N)_3P + 3EtOH \rightarrow (EtO)_3P \text{ (91·2\% yield)} + 3Me_2NH^{2170}$$

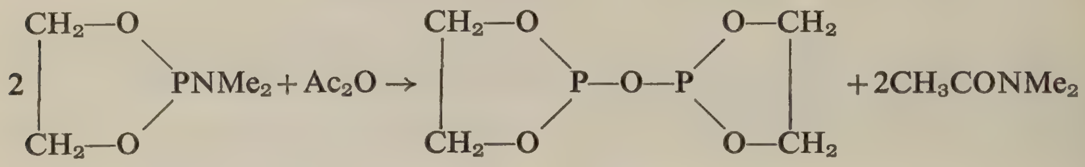
Carboxylic acids react to form carboxylic acid amide and a phosphorous acid derivative, e.g.,

$$(Me_2N)_3P + 3CH_3CO_2H \rightarrow 3CH_3CONMe_2 + H_3PO_3{}^{2170}$$

Bis-*N*,*N*-diethylaminophosphine oxide can be made from tris-(diethylamino) phosphine by treatment with one equivalent of acetic acid[2149] or with phosphorous acid[2169]:



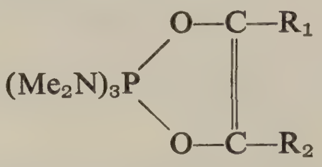
Diethylene pyrophosphite is formed by the action of acetic anhydride on *N*,*N*-dimethyl ethylene phosphoramidite[2149]; acetyl ethylene phosphite is a possible intermediate:



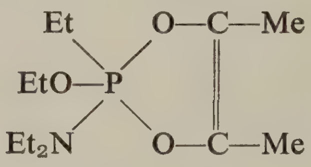
Like the amides of other Groups IV and V elements, phosphorous amides combine readily with compounds having multiple unsaturation such as carbon dioxide and disulphide, organic isocyanates and organic isothiocyanates to form phosphorylated carbamates and ureas[698, 2170]:

$$R_nP(NMe_2)_{3-n} + (3-n)CS_2 \rightarrow R_nP(SCS.NMe_2)_{3-n}$$
$$R_nP(NMe_2)_{3-n} + (3-n)PhNCS \rightarrow R_nP(PhNCS.NMe_2)_{3-n}$$
$$(R = \text{alkyl, aryl}; n = 0, 1, 2)$$

Phosphorous triamides are reported to react like trialkyl phosphites with $\alpha$-$\beta$ dicarbonyl compounds to form phosphorane derivatives. Tris-(dimethylamino) phosphine and benzil or diethyl mesoxalate react exothermically to form the compound **I** in high yield[96]; *N*,*N*,*O*-triethyl ethyl phosphonamidite and diacetyl form the related compound **II**.[2141]

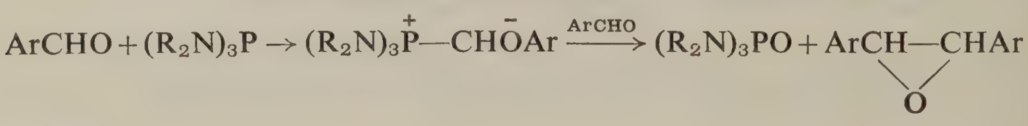


($R_1$ = OEt, $R_2$ = $CO_2Et$
or $R_1$ = $R_2$ = phenyl)
**I**



**II**

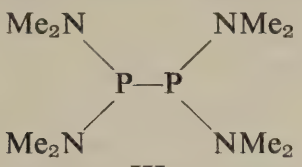
Molar quantities of aromatic aldehydes and tris-(dialkylamino)phosphines react to form solid salt-like quasiphosphonium betaines which interact with more aldehyde to form a mixture of *cis*- and *trans*-stilbene and tris-(dialkylamino)phosphine oxide[739]:



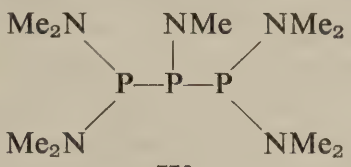
$$ArCHO + (R_2N)_3P \rightarrow (R_2N)_3\overset{+}{P}—CH\overset{-}{O}Ar \xrightarrow{ArCHO} (R_2N)_3PO + ArCH—CHAr$$

### Amino-derivatives of Di- and Poly-phosphines

Reduction of bis(dimethylamino)chlorophosphine with sodium in hexane solution affords rather poor yields of tetrakis-(dimethylamino)diphosphine **III** and pentakis-(dimethylamino)triphosphine, m.p. 18°–20°C., **IV**, together with products of side reactions which correspond to the disproportionation of the starting material.[647]



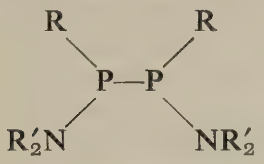
**III**



**IV**

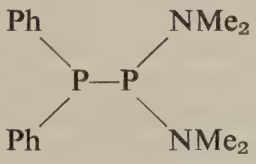
The diphosphine derivative is a solid, m.p. 48°. It forms adducts with oxygen, sulphur and diborane in which the P–P bond remains intact, but with hydrogen chloride, methyl iodide, phosphorus trichloride and on heating, partial P–P bond fission occurs giving a mixture of products.

Symmetrical and unsymmetrical di-substituted bis(dialkylamino)diphosphines **V** and **VI** have been described.

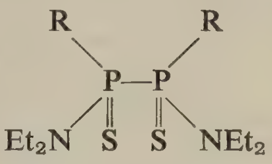


R = phenyl, *cyclo*hexyl, ethyl

**V**



**VI**



R = *cyclo*hexyl

**VII**

The symmetrical compounds may be obtained in reasonably good yield by reduction of *N*,*N*-dialkyl alkyl (or phenyl) phosphonamidous chloride with sodium–potassium alloy in ether[703] or from *sym*-diphenyl diiododiphosphine and dimethylamine.[733] Compound **VI** was obtained by condensing sodium diphenyl phosphine with bis-(dimethylamino)chlorophosphine.[733] Compound **V** (R = *cyclo*hexyl) reacts with sulphur giving two crystalline products suggested to be the racemic and meso forms of *P*,*P′*-di*cyclo*hexyl-*P*,*P′*-diethylamino-diphosphine disulphide **VII**.[703] Compound **VI** forms a diborine adduct; it also decomposes readily on heating to tetraphenyl diphosphine and $(C_6H_5)_2P.PNMe_2.P(C_6H_5)_2$.[733]

## IMINO DERIVATIVES OF ORGANOPHOSPHORUS COMPOUNDS

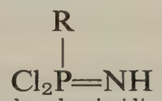
Compounds described in this section are pentavalent compounds of phosphorus which contain a real or potential phosphorus–nitrogen double bond. Parent structures and nomenclature of such compounds are indicated below. One book[2278] and several reviews[2195] are concerned with compounds in these classes.

$R_3P{=}NR'$
phosphine imide

$Cl_3P{=}NH$
phosphorimidic trichloride

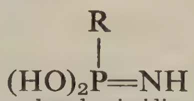
$(HO)_3P{=}NH$
phosphorimidic acid

$R_3P{=}N{-}N{=}CR_2$
phosphazines



$Cl_2\overset{R}{\overset{|}{P}}{=}NH$

phosphonimidic dichloride

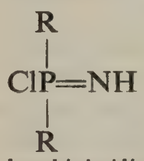


$(HO)_2\overset{R}{\overset{|}{P}}{=}NH$

phosphonimidic acid

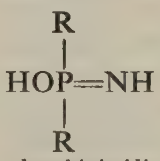
$R_3P{=}N{-}N{=}N{-}R$

phosphazides



$Cl\overset{R}{\overset{|}{\underset{R}{\underset{|}{P}}}}{=}NH$

phosphinimidic chloride



$HO\overset{R}{\overset{|}{\underset{R}{\underset{|}{P}}}}{=}NH$

phosphinimidic acid

### Phosphine Imines (Iminophosphoranes, Phosphine Imides)

The preparation and properties of phosphine imines, $R_3P{=}NR'$ ($R$ = alkyl, aryl; $R'$ = alkyl, aryl, benzoyl), were first investigated by Staudinger and Hauser.[110] Although there are few reports of phosphine imines in which all the substituents on phosphorus are aliphatic,[110, 2185, 2225, 2263] numerous triaryl, generally triphenyl, phosphine imines are known and may be represented by the formula $R_3P{=}NY$ (where Y = alkyl,[2101, 2185] aryl,[2089, 2185, 2189] hydrogen,[2159] acyl,[2107, 2183, 2189] $RSO_2$–,[2183] $>SO_2$,[2246] $-PO(OR)_2$,[198] $-PO(R)_2$,[2273] $-CO_2R$,[2190] halogen (X),[2184] $-CONPh_2$,[2189] $-SiMe_3$,[2159, 2205] $-S^+Me_2X^-$, $-PPh_3{}^+X^-$,[2108] $PhC{=}CCl$–[2252] and amino.[2414] Compounds in which R = alkyl and Y is alkyl, phenyl or trimethylsilyl are liquids which can be purified by distillation under reduced pressure without decomposition.[110, 2159] When R is phenyl the compounds are frequently crystalline solids, which are often stable up to 150°C. and can be purified by sublimation or crystallization from inert solvents.

Relatively few unsubstituted phosphine imines have been made. The alkyl compounds, $R_3P{=}NH$ (R = ethyl, propyl, butyl),[2159] are colourless liquids which can be distilled under reduced pressure. Triphenylphosphine imine, m.p. 128°, is rapidly hydrolyzed to triphenylphosphine oxide in moist air but can be stored under a dry nitrogen atmosphere. It is soluble in inert organic media and is monomeric in benzene solution.[2106, 2182–3, 2205] Various other aryl compounds, $Ar_3P{=}NH$ (Ar = *o*-, *m*-, *p*-tolyl), and mixed ethyl phenylphosphine imines have been described.[2106] The aryl compounds are solids with well-defined melting points and are monomeric in solution. Reactions of triphenylphosphine imines are shown in Chart XX.

#### PROPERTIES

Phosphine imines may be regarded as members of the isoelectronic series $R_3PO$–$R_3PNH$ – $R_3PCH_2$, in which the nucleophilicity and basicity increase from left to right.[2260] They are the conjugate bases of *N*-quasiphosphonium salts, and the relationship is formally similar to that between phosphonium salts and methylene phosphoranes (see page 945):

$$R_3P=NR' \underset{-HX}{\overset{+HX}{\rightleftharpoons}} R_3P^+.NHR'X^-$$

They are basic in character and readily add hydrogen halides and react with alkyl halides to form *N*-quasiphosphonium salts.[11, 110, 2100, 2101, 2108] $pK_a$ values for two series of phosphine imines, *N*-(substituted phenyl) triphenylphosphine imines and *N*-phenyl tri-(*p*-substituted phenyl) phosphine imines in 95% ethanol solution are reported.[2293]

Staudinger noted that the properties of phosphine imines such as basicity, reactivity and stability to hydrolysis are determined to a large extent by the substituents attached to nitrogen and to phosphorus; for example, reactivity of compounds $R_3P{=}NPh$ decreases in the series R = alkyl > phenyl > benzyl.[110]

#### *Hydrolysis*

Phosphine imines undergo hydrolysis to tertiary phosphine oxides and amines:

$$R_3P{=}NR + H_2O \rightarrow [R_3P^+NHROH^-] \rightarrow R_3PO + RNH_2$$

The hydrolytic stability is greater when the phosphorus atom carries aromatic substituents and increases as the nitrogen atom carries more electropositive substituents, as in the series –*N*-alkyl < –*N*-aryl < –*N*-acyl < –*N*-$SO_2Ar$, or when the nitrogen carries a bulky substituent such as *tert*-butyl (cf. Table IX). The heats of hydrolysis of *N*-ethyl trimethylphosphine imine to $Me_3PO$ and of *N*-ethyl triphenylphosphine imine to $Ph_3PO$ in dilute hydrochloric acid have been determined, and bond dissociation energies $D(Me_3P{=}NEt) \simeq 97$ kcal./mole, $D(Ph_3P{=}NEt) \simeq 125$ kcal./mole have been calculated.[2185]

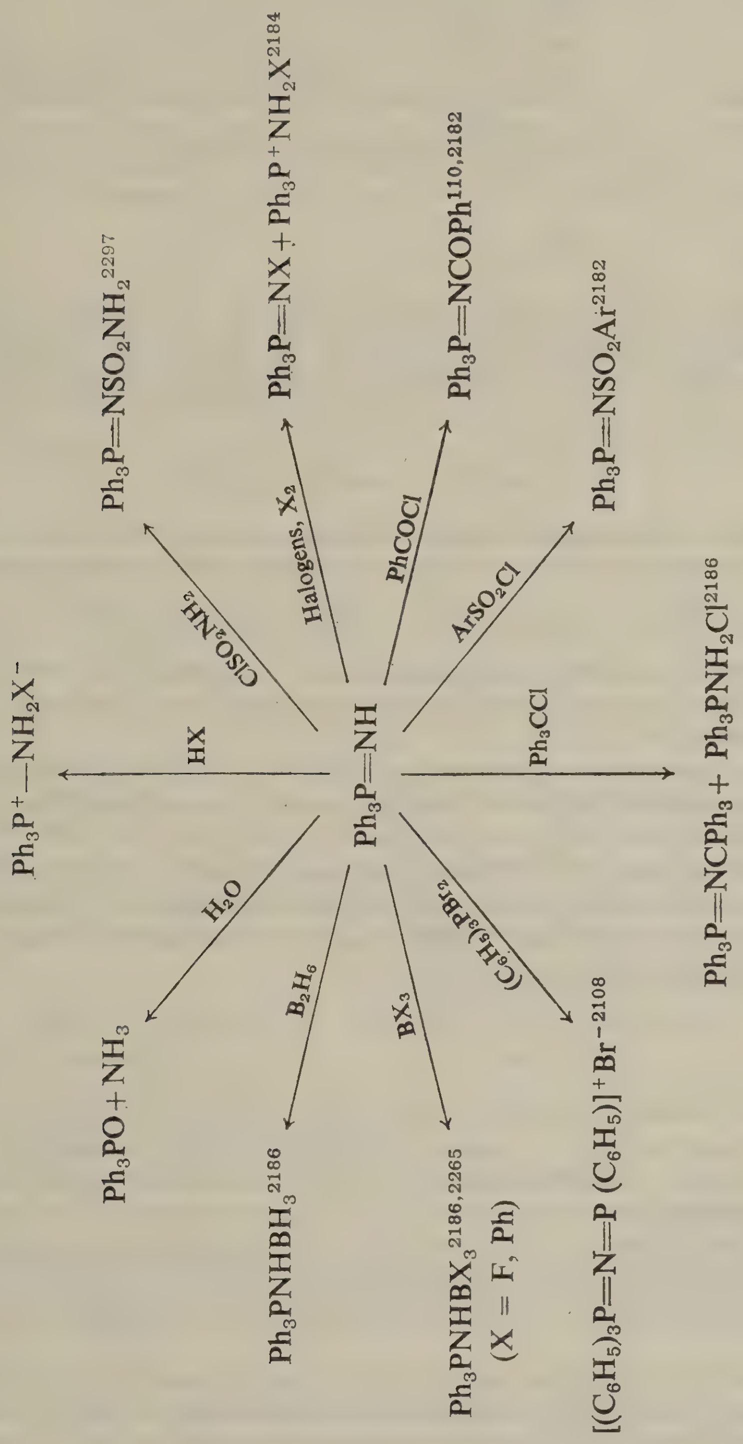


CHART XX.—Some reactions of triphenylphosphine imines

*Table IX.—Effect of Structure on Hydrolysis of Phosphine Imines*

| Phosphine imine | Conditions for hydrolysis | Ref. |
|---|---|---|
| $Et_3P{=}NEt$ | Hydrolyzed instantly with cold water | 2185 |
| $Ph_3P{=}NEt$ | Hydrolyzed by moist air | 2101 |
| $Ph_3P{=}N\text{-}t\text{-}Bu$ | Stable to moist air | 2101 |
| $Ph_3P{=}NAr$ | Dilute acid | 198 |
| $Ph_3P{=}NCO_2R$ | Boiling acid | 198 |
| $Ph_3P{=}NCOPh$ | Unaffected by boiling for 6 hr. with dilute acid | 2235 |
| $Ph_3P{=}NPOPh_2$ | Stable to boiling $H_2O$, dilute $H_2SO_4$, alcoholic NaOH | 2273 |
| $(Ph_3P{=}N)_2SO_2$ | Stable to boiling aqueous NaOH | 2246 |

### *Thermal Stability*

Phosphine imines having hydrogen atoms, alkyl or aryl groups attached to nitrogen are thermally stable and can frequently be purified by distillation under vacuum or by vacuum sublimation. Compounds with *N*-acyl substituents decompose at 150°–200°C. to form phosphine oxide and nitrile[110, 2235, 1987]:

$$RCON{=}PR_3 \xrightarrow{\Delta} RCN + R_3PO$$

Attempts to make *N*-thioacylphosphine imine by reaction of thioacyl azides and tertiary phosphines give a mixture of tertiary phosphine sulphide and nitrile[198]:

$$RCS.N_3 + R_3P \rightarrow [R_3P{=}NCS.R] \rightarrow R_3PS + RCN$$

*N*-Diphenylphosphinyl triphenylphosphine imines, e.g., $Ph_2PO.N{=}PPh_3$, are very stable thermally but the corresponding tributylphosphine imine decomposes at ambient temperature.[2273]

A number of workers have examined the ultra-violet and/or infra-red spectra of phosphine imines, and comparison of the spectra with those of phosphine oxides and methylene phosphoranes has aroused much interest.[198, 2100, 2246, 2257, 2264, 2284] Recently the infra-red spectra of *N*-phenyl triphenylphosphine imine, *N*-(toluene-*p*-sulphonyl) triphenylphosphine imine and *N*-(toluene-*p*-sulphonyl) phosphorimidic trichloride and the corresponding $^{15}N$-substituted compounds have been measured.[2257] The P=N absorption frequencies are:—

| $Ph_3P{=}NPh$ | $Ph_3P{=}NSO_2(p\text{-}CH_3{-}C_6H_4)$ | $Cl_3P{=}NSO_2(p{-}CH_3{-}C_6H_4)$ |
|---|---|---|
| 1344 cm.$^{-1}$ | 1147 cm.$^{-1}$ | 1199 cm.$^{-1}$ |

Like phosphine oxides, phosphine imines form adducts with many metal salts. The stability of these adducts is largely dependent on the *N*-substituent.[2260] Triphenylphosphine imine adducts with Co(II), Ni(II) and Cu(II) halides are reported.[2262] *N*-Phenyl triphenylphosphine imine forms highly stable solids, $Ph_3P{=}NPh.MI_2$ (M = Cd, Hg), when mixed with the metal iodide in benzene–acrylonitrile solvent, but complexes with transition metal salts such as $NiCl_2$, $CoCl_2$, e.g., $(Ph_3P{=}NPh)_2$, $MCl_2$, are unstable in solution and can be prepared only by fusing the components together.[2260]

Adducts of triphenylphosphine imine with boron compounds, $Ph_3P{=}NH,BX_3$ (X = H, F, Ph) are high-melting solids which are non-electrolytes in nitrobenzene solution.[2186] In the absence of water boron trifluoride and *N*-alkyl triphenylphosphine imines form complexes $Ph_3P{=}N^+R{-}BF_3^-$; if water is present the product is an alkylaminotriphenylphosphonium tetrafluoroborate. The stability of these complexes is very dependent on the nature of the alkyl group, R. When R = methyl or ethyl the complexes are stable to atmosphere, with R = *iso*propyl the complex decomposes slowly in air, and when R = *ter*-butyl the complex decomposes to its constituents under low vacuum.[2265]

The following metal alkyl–phosphine imine complexes are reported: $Ph_3P{=}NH,(CH_3)_3Al$ (dimeric in benzene),[2264] $R_3P{=}NSiMe_3,M(CH_3)_3$ (R = methyl, ethyl, phenyl; M = Al, Ga, In).[2263, 2298–300]

### PREPARATION OF PHOSPHINE IMINES

1. Reaction of tertiary phosphines with covalent azides (see p. 1072)
2. Reaction of *N*-chloro compounds with tertiary phosphines (see p. 1079)
3. From *N*-quasiphosphonium salts.

The elements of hydrogen halide are readily removed from amino- and mono-substituted amino-phosphonium salts by treatment with a suitable base such as liquid ammonia, triethylamine, sodamide or magnesium hydride[2101, 2105–6, 2108, 2182, 2261]:

$$R_3P^+NHR'X^- \xrightarrow{NaNH_2} R_3P{=}NR'$$

A convenient route to *N*-aryl triphenylphosphine imines is from dihalogenotriphenylphosphorane and an aromatic primary amine in the presence of triethylamine. The intermediate *N*-arylaminotriphenylphosphonium salts may be isolated when pyridine is used as base[177, 2100]:

$$Ph_3PBr_2 + ArNH_2 + 2Et_3N \rightarrow Ph_3P{=}NAr + 2Et_3N,HBr$$
$$Ph_3PBr_2 + ArNH_2 + C_5H_5N \rightarrow Ph_3P^+NHArBr^- + C_5H_5N,HBr$$

Similar reactions using aromatic diamines yield diphosphine imines. Amines such as 2,4,6-trichloro-, 2,4,6-tribromo- and 2,4,6-trimethyl-aniline do not react. Ammonia, primary aliphatic amines, hydrazine and phenyl hydrazine react with dibromotriphenylphosphorane, even in the presence of triethylamine, to form the phosphonium salt.[2100] Sodamide in liquid ammonia has been widely used to prepare strongly basic phosphine imines such as trialkyl- and triaryl-phosphine imines, alkyl arylphosphine imines and *N*-alkyl triphenylphosphine imines from the corresponding phosphonium salts.[2101, 2105–6, 2108, 2182]

A lithium chloride complex of dodecyl dimethylphosphine imine, $C_{12}H_{25}P(Me)_2{=}NH,LiCl$, is reported to be formed on reduction of dodecyl dimethylaminophosphonium chloride with butyl lithium; the free imine is obtained by distillation to break down the complex.[2255]

Triphenylphosphine imine has been obtained by the reaction[2106]:

$$[Ph_3P.NH_2]^+N_3^- + Ph_3P \xrightarrow[180-200°]{\Delta} 2Ph_3P{=}NH + N_2$$

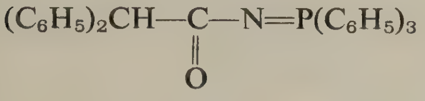
*Miscellaneous Methods*

*N*-Benzoyl triphenylphosphine imine can be made by heating $\alpha,\beta$-dibenzoyl hydroxylamine with triphenylphosphine[2121]:

$$PhCONHOCOPh + Ph_3P \rightarrow [PhCO_2^-Ph_3P^+NHCOPh] \rightarrow Ph_3P{=}NCOPh + PhCO_2H$$

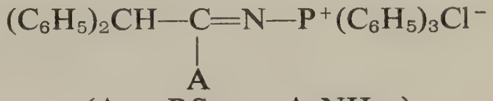
The chlorovinylphosphine imine **I** results from reaction of triphenylphosphine with chlorodiphenyl acetonitrile in an inert solvent.[2252] It reacts with methyl alcohol to form the acyl phosphine **II**[2252] and with mercaptans and amines to form the phosphonium salts **III**[2253]:

$$(C_6H_5)_2CCl.CN + (C_6H_5)_3P \rightarrow [(C_6H_5)_2CCN^-.(C_6H_5)_3P^+Cl] \rightarrow \underset{\textbf{I}}{(C_6H_5)_2C{=}CCl{-}N{=}P(C_6H_5)_3}$$



$$(C_6H_5)_2CH{-}\underset{\underset{O}{\|}}{C}{-}N{=}P(C_6H_5)_3$$

**II**



$$(C_6H_5)_2CH{-}\underset{\underset{A}{|}}{C}{=}N{-}P^+(C_6H_5)_3Cl^-$$

(A = RS— or ArNH—)

**III**

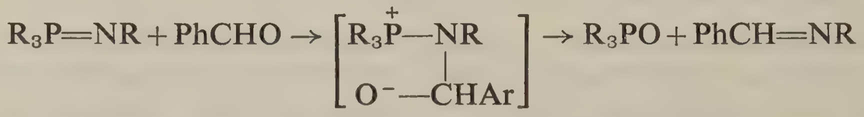
Aminophosphines, having the general structure $R_2PNHR'$ ($R = Ph$ or $OEt$; $R' = Ph$ or $Pr$), react with carbon tetrachloride or trichlorobromomethane to form phosphine imines $R_2PX{=}NR'$ ($X = Cl$ or $Br$) and chloroform.[2413]

Triphenylphosphine oxide, sulphide and *N*-phenylimide, and *O*,*O*,*O*-triethyl thiophosphate undergo trans-sulphonylimination by reaction with *N*-sulphinyl sulphonamides to form the corresponding *N*-sulphonyliminophosphorus derivatives[2352]:

$$RSO_2NSO + Ph_3PA \rightarrow Ph_3P{=}NSO_2R + ASO \qquad (A = O, S, NPh)$$
$$(EtO)_3PS + RSO_2NSO \rightarrow (EtO)_3P{=}NSO_2R + \text{‘}S_2O\text{’}$$

REACTIONS OF PHOSPHINE IMINES

Phosphine imines, like methylene phosphoranes, react with compounds containing an $A{=}O$ or $A{=}S$ group to form tertiary phosphine oxide or sulphide and a carbon compound having an $A{=}NR$ grouping. Examples of reactions are the conversion of isocyanates to carbodiimides, ketens to ketimines, carbon dioxide to isocyanate and carbon disulphide to isothiocyanate.[110,198] Kinetics of the reaction of $PhN{=}P(C_6H_4X)_3$ and $AC_6H_4N{=}PPh_3$ with benzaldehyde indicate that a betaine intermediate is involved. The rate-limiting step of the reaction changes, owing to variations of substituent A's affecting a delicate balance between the nucleophilicity of the nitrogen atom and the electrophilicity of the phosphorus atom[2293]:



$$R_3P{=}NR + PhCHO \rightarrow \left[\begin{array}{l} R_3\overset{+}{P}{-}NR \\ \quad\;\; | \qquad | \\ O^-{-}CHAr \end{array}\right] \rightarrow R_3PO + PhCH{=}NR$$

Some reactions of phosphine imines are indicated in Chart XXI.

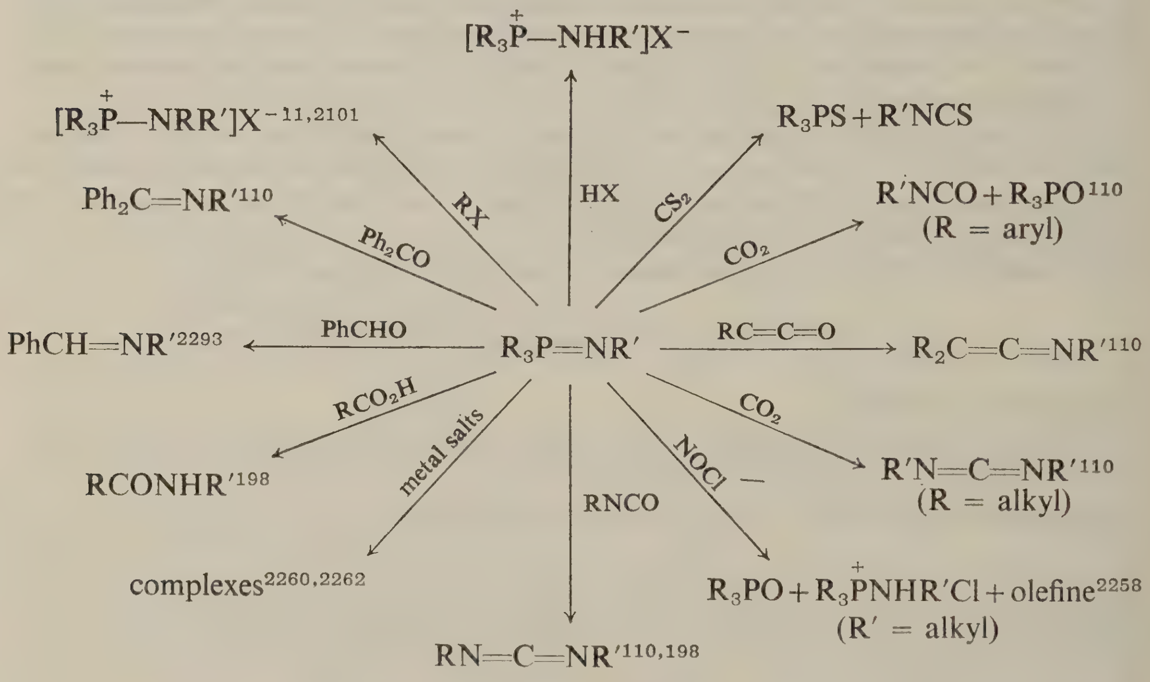


CHART XXI.—Reactions of phosphine imines

REACTION OF TRIVALENT PHOSPHORUS COMPOUNDS WITH AZIDES

Trivalent phosphorus compounds react with a wide variety of covalent azides to form complexes (phosphazides) which, in general, decompose at or below room temperature to nitrogen and an iminophosphorus compound:

$$A_1A_2A_3P + RN_3 \rightarrow [A_1A_2A_3P{=}N{-}N{=}N{-}R] \rightarrow A_1A_2A_3P{=}NR + N_2$$
$$(A_1A_2A_3 = \text{alkyl, aryl, alkoxy, halogen, hydrogen})$$

The rate of these reactions falls rapidly with diminishing nucleophilic character of the phosphorus atom, as for example along the series:

$$(R_2N)_3P > R_3P > Ar_3P > (MeO)_3P > (PhO)_3P > PCl_3(\text{zero at} \leqslant 35°)$$[110, 2266, 2270, 2273]

The effects of substituents on the phosphorus atom on the reaction of phenyl azide with $PA_3$ ($A = Cl$ or Ph) to form trichloro-*N*-phenylphosphine imine, dichlorophenyl-*N*-phenylphosphine imine, chlorodiphenyl-*N*-phenylphosphine imine and triphenyl-*N*-phenylphosphine imine are indicated below:

| *Reagents* | *Product* | *Reaction conditions* |
|---|---|---|
| $PCl_3 + PhN_3$ | $PhN{=}PCl_3$ | Reflux 3 days in benzene solution[2256] |
| $PhPCl_2 + PhN_3$ | $PhN{=}PCl_2Ph$ | Reflux 24 hr. in benzene solution[2256] |
| $Ph_2PCl + PhN_3$ | $PhN{=}PCl(Ph)_2$ | Reflux 2 hr. in benzene solution[2256] |
| $Ph_3P + PhN_3$ | $PhN{=}P(Ph)_3$ | Reacts violently at room temperature[110] |

Kinetic studies by Horner and Gross indicate a second-order reaction between triphenyl phosphine and *p*-substituted phenyl azides in xylene solution.[198] Electron-withdrawing groups like nitro increase the reaction rate and electron donating groups like dimethylamino decrease the reaction rate relative to phenyl azide. The kinetics indicate the rate of decomposition of the intermediate phosphazides to be greater than their rate of formation.

### *Phosphazides*

Phosphazides were reported by Staudinger to be very unstable compounds which can sometimes decompose explosively.[110, 177] In addition to the generally accepted structure **IV**, favoured by Staudinger, the existence of the isomeric form **V** has been considered by a number of authors. Evidence based largely on infra-red spectral analyses suggests that both forms can exist according to the nature of the R and R′ groups.[2189, 2256, 2266, 2271–2]

$$\underset{\textbf{IV}}{R_3P{=}N{-}N{=}N{-}R'} \qquad \underset{\textbf{V}}{R_3P{=}\overset{+}{N}(R')N{=}N^-}$$

Relatively few stable phosphazides have been isolated. They are yellow-coloured compounds which usually decompose at their melting point to the corresponding phosphine imine. Known compounds are of the type $R{-}N{=}N{-}N{=}PR'_3$: where R is strongly electron withdrawing as in *N*-(2,4,6-trinitrophenyl) triphenyl phosphazide,[2268] *N*-(*O*-carboxyphenyl) triphenyl phosphazide,[198] the *N*-(toluene-*p*-sulphonyl) phosphazides, $p\text{-}CH_3C_6H_4SO_2N{=}N{-}N{=}P(C_6H_5)_2X$ ($X = Ph, NHPh, N(C_3H_7)_2$) and the diphosphazide $PhN[P(Ph)_2{=}N{-}N{=}NSO_2C_6H_4CH_3\text{-}p]_2$[2269]; or where R′ is strongly electron releasing as in the amino-phosphazides, e.g., *N*-phenyl tris-(dipropylamino)phosphazide[2250] and *N*-phenyl tri-*iso*amyl phosphazide[110]; or where R is triphenylmethyl or 9-phenyl-9-fluorenyl and R′ is phenyl (very stable solids which undergo acid-catalyzed and iodine-catalyzed decomposition in polar solvents to the phosphine imine)[2189]; and the silicon compound $(C_6H_5)_3SiN{=}N{-}N{=}P(C_6H_5)_3$ which decomposes readily to *N*-(triphenylsilyl) triphenylphosphine imine.[2271]

### *Tertiary Phosphines*

There is a considerable volume of literature concerned with the reaction of tertiary phosphines (largely triphenyl phosphine) with organic azides to form *N*-substituted phosphine imines. Generally the reactants are mixed together in benzene solvent and the solution is heated until evolution of nitrogen ceases. Examples of the classes of azide which have been used are: alkyl[198, 2185] and aryl azides,[110, 177, 198] α-azido-carboxylic acids,[110, 198] benzoyl azide,[110] sulphonyl azides,[110, 2267, 2269] organosilicon azides,[2159, 2184, 2271] diarylphosphinyl and diarylthiophosphinyl azides,[2194, 2273] phenylphosphonyl and phenylthiophosphonyl diazides,[2274] diphenylcarbamyl azide,[2184] cyanogen azide,[2197] triphenylmethyl azide[2189] and alkyl and aryl diazides.[221] Although benzoyl azide and triphenylphosphine readily form the expected *N*-benzoyl triphenylphosphine imine,[110, 198, 2183] the analogous thio-compound from thiobenzoyl azide decomposes spontaneously to the phosphine sulphide and benzonitrile[198]:

$$\mathrm{PhCSN_3 + Ph_3P \rightarrow [Ph_3P{=}NCSPh] \rightarrow Ph_3PS + PhCN}$$

A useful route to *N*-hydrogen substituted phosphine imines is *via* the *N*-trimethylsilylphosphine imines. These readily lose the trimethylsilyl group on treatment with an alcohol containing a little sulphuric acid[2106, 2159, 2205]:

$$\mathrm{R_3P + Me_3SiN_3 \xrightarrow{-N_2} R_3P{=}NSiMe_3 \xrightarrow[ROH]{H^+} R_3P{=}NH}$$

This reaction fails when applied to *N*-trimethylsilyl dimethyldodecylphosphine imine; the product was found to be either dimethyl dodecylphosphine oxide or a bis-(phosphoranylidene) ammonium salt or a mixture of these two compounds[2255]:

$$\mathrm{RMe_2P{=}N{-}SiMe_3 \xrightarrow[H_2SO_4]{MeOH} RMe_2PO + [RMe_2P{=}N{=}PMe_2R]^+OMe^-}$$

Organotin, organogermanium and organosilicon nitrogen-substituted phosphine imines, iminophosphates and imidophosphoric amides (compounds $\mathrm{R_{4-n}M(N{=}PR'_3)_n}$; where R = alkyl, aryl; R′ = alkyl, aryl, alkoxyl, dialkylamino; M = Si, Ge, Sn) are made by reaction of the organometallic halide, sodium azide and appropriate trivalent phosphorus compound under anhydrous and anaerobic conditions[2160, 2194, 2273]:

$$\mathrm{PhSnCl_3 + 3NaN_3 + 3Ph_3P \rightarrow (Ph_3P{=}N)_3SnPh}$$
$$\mathrm{Ph_3SnCl + NaN_3 + (Me_2N)_3P \rightarrow Ph_3Sn{-}N{=}P(NMe_2)_3}$$
$$\mathrm{Bu_2GeCl_2 + 2NaN_3 + 2(MeO)_3P \rightarrow Bu_2Ge[N{=}P(OMe)_3]_2}$$

Diphenylphosphinyl chloride reacts similarly with triphenyl phosphine, but with diphenylthiophosphinyl chloride the reaction fails owing to formation of triphenylphosphine sulphide and diphenyl chlorophosphine which, in turn, reacts with sodium azide giving polymeric $\mathrm{Ph_2PN}$[2194, 2273]:

$$\mathrm{Ph_2POCl + NaN_3 + Ph_3P \rightarrow Ph_3P{=}NPOPh_2}$$
$$\mathrm{Ph_2PSCl + Ph_3P \rightarrow Ph_3PS + Ph_2PCl}$$
$$\mathrm{Ph_2PCl + NaN_3 \rightarrow (Ph_2PN)_n + N_2 + NaCl}$$

The reaction of triphenyl phosphine with diazidoquinones such as 2,3-diazido-1,4-naphthaquinone gives two products, the expected bisphosphine imine **VI** and the phosphorarylidine aminotriazole **VII**. The relative amounts of compounds of the type **VI** and **VII** formed are strongly influenced by the nature of the reaction solvent and the reacting phosphine. The triazole is the only compound isolated from $\mathrm{Bu_3P}$, $\mathrm{(C_5H_{10}N)_3P}$ and $\mathrm{PhP(C_5H_{10}N)_2}$.[2266]

Compound **VII**, in common with other negatively substituted phosphine imines, is highly resistant to hydrolysis.

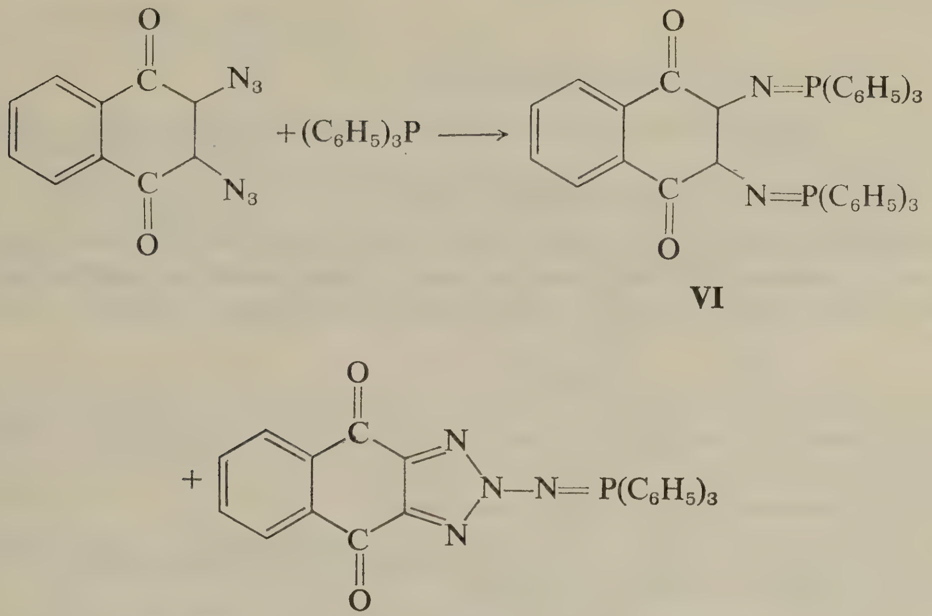
Phosphine led into an ether solution of phenyl azide does not react, on account of the low solubility of phosphine.[110] Phenyl phosphine and phenyl azide react violently with evolution of nitrogen.[110] The reaction of diphenylphosphine with triphenylsilyl azide involves addition and oxidation[2275]:

$$\mathrm{(C_6H_5)_3SiN_3 + (C_6H_5)_2PH \xrightarrow{-N_2} (C_6H_5)_3SiNH{-}P(C_6H_5)_2 \xrightarrow[-N_2]{(C_6H_5)_3SiN_3} (C_6H_5)_3SiNHP(C_6H_5)_2{=}NSi(C_6H_5)_3}$$

Tetraphenyl diphosphine forms the compound

$$\mathrm{(C_6H_5)_3SiN{=}P(C_6H_5)_2{-}P(C_6H_5)_2{=}NSi(C_6H_5)_3.}^{2275}$$

The reaction of hydrazoic acid with tertiary phosphines was studied by Staudinger[110] who formulated the products from $Ph_3P$ and $Et_3P$ as $Ph_3P{=}NH.HN_3$ and $Et_3P{=}NH.HN_3$ respectively. More recent work[2106, 2109] shows the triphenyl compound to be the phosphonium azide $Ph_3\overset{+}{P}NH_2N_3^-$.



**VI**

**VII**

*Halogenophosphines*

As indicated earlier, phosphorus trichloride and halogenophosphines react much more slowly with azide than the tertiary phosphines. Diphenyl chlorophosphine will react with phenyl azide,[2256, 2267] toluene-*p*-sulphonyl azide,[2267] and benzoyl azide[2198] to form *N*-substituted diphenyl phosphinimidic chlorides:

$$Ph_2PCl + RN_3 \rightarrow Ph_2PCl{=}NR \qquad (R = Ph, COPh, P\text{-}SO_2C_6H_4CH_3)$$

The *N*-phenyl compound is readily hydrolyzed to diphenyl phosphinic acid anilide[2294] and reacts with sodium azide to form *N*-phenyl azidodiphenyl phosphinous imide.[2267] Diphenyl chlorophosphine and hydrazoic acid react under photolytic conditions to form diphenyl phosphinimidic chloride, $Ph_2PCl{=}NH$, which readily undergoes dehydrochlorination to diphenyl phosphonitrile. A stable adduct $Ph_2PCl.HN_3$, m.p. 126°–126·5°, which is formed as a by-product in this reaction, was shown to have the isomeric phosphazide structure $Ph_2PCl{=}NH{-}N_2^-$.[2256]

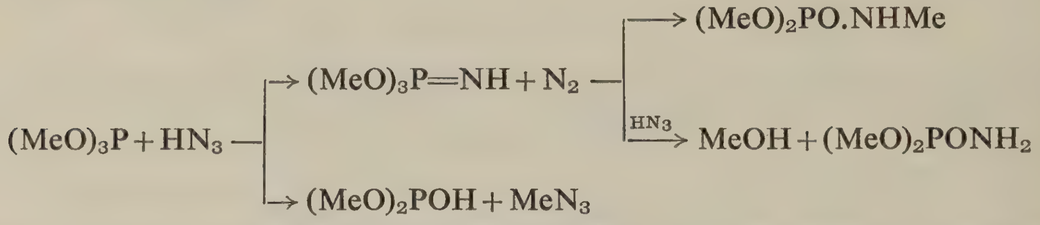
*Esters of Phosphorus(III) Acids*

Phosphorous acid triesters and organic azides readily form *N*-substituted phosphorimidic esters and nitrogen. Intermediates of the phosphazide type have not been isolated. The reaction may be written in the general form:

$$(RO)_3P + R'N_3 \rightarrow (RO)_3P{=}NR' + N_2$$

(where $R'N_3$ = alkyl azide or aryl azide,[2200, 2241] alkyl or aryl sulphonyl azides and aliphatic disulphonyl azides,[2199] acyl azides,[2196, 2198, 2241] dialkoxyphosphinyl azides,[2201–3] diarylphosphonyl azide[2194]; R = alkyl, aryl). Similar reactions have been demonstrated in using diesters of phosphonous acids[2196, 2241, 2303] to form *N*-substituted phosphonimidic esters $(RO)_2PR'{=}NR''$, esters of phosphinous[2303] acid to form *N*-substituted phosphinimidic esters $ROPR'_2{=}NR''$, and between trialkyl phosphorotrithioites and aliphatic $\alpha$-$\omega$-disulphonyl azides to form *N*-substituted phosphorimidic trithioates $(RS)_3P{=}NSO_2R'$.[2199] The reaction rate of compounds $(RA)_3P$ with sulphonyl azides decreases in the series: RA = EtO > EtS > PhO > PhS.[2199]

Hydrogen azide and trimethyl phosphite interact slowly at room temperature to form a mixture of dimethyl phosphoramidate, *N*-methyl dimethyl phosphoramidate and dimethyl phosphite[2201]:

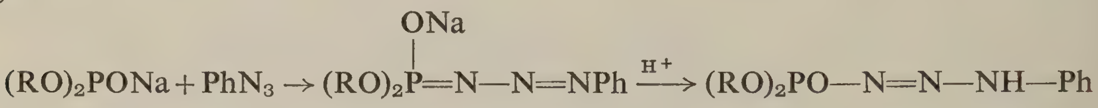


$$(MeO)_3P + HN_3 \rightarrow (MeO)_3P{=}NH + N_2 \rightarrow (MeO)_2PO.NHMe$$

$$(MeO)_3P{=}NH + N_2 \xrightarrow{HN_3} MeOH + (MeO)_2PONH_2$$

$$(MeO)_3P + HN_3 \rightarrow (MeO)_2POH + MeN_3$$

Salts of dialkyl hydrogen phosphites, but not the phosphites themselves, react with phenyl azide giving salts of dialkoxyphosphinyl triazine, which on acidification yield the free triazines. These are yellow solids which decompose on melting, losing nitrogen[2204]:



$$(RO)_2PONa + PhN_3 \rightarrow (RO)_2\overset{ONa}{\overset{|}{P}}{=}N{-}N{=}NPh \xrightarrow{H^+} (RO)_2PO{-}N{=}N{-}NH{-}Ph$$

REACTIONS OF PHOSPHORIMIDIC ESTERS AND AMIDES

Mild hydrolysis of trialkyl *N*-substituted phosphorimidates yields the corresponding *N*-substituted phosphoramidates:

$$(RO)_3P{=}NR' \xrightarrow{H_2O} (RO)_2PO.NHR' + ROH$$

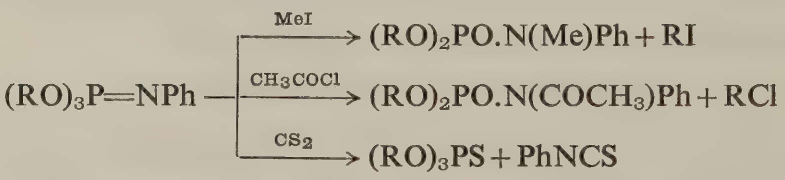
The stability towards hydrolysis is increased when the nitrogen atom carries electron-withdrawing groups such as alkyl/aryl sulphonyl or diaryl phosphinyl. Thus, when R′ is phenyl the compounds are slowly hydrolyzed by water[2200, 2232]; when R′ is acyl hydrolysis can be effected by boiling with water or treating with dilute alkali [2216–7, 2222]; when R′ is alkyl/aryl sulphonyl the compounds are hydrolyzed by heating with aqueous sodium hydroxide to form salts of the phosphoramidate which on acidification yield the free phosphoramidate[2212, 2223, 2288]:

$$RSO_2N{=}P(OR)_3 \xrightarrow{NaOH} [RSO_2N{-}PO(OR)_2]^- Na^+ \xrightarrow{H^+} RSO_2NHPO(OR)_2$$

Amides such as triaryl arylsulphonyl phosphorimidic triamide $ArSO_2N{=}P(NHAr)_3$ are remarkably stable to hydrolysis, even with hot alcoholic sodium hydroxide.[2219] In contrast triaryl aroyl phosphorimidic triamides $ArCON{=}P(NHAr)_3$ hydrolyze very readily on heating with aqueous alcohol or on exposure to water vapour to form diaryl aroyl phosphoric triamides $ArCONHPO(NHAr)_2$.[2234] The same products, together with aryl benzamide, are formed by heating with benzoic acid in pyridine solution:

$$ArCON{=}P(NHAr)_3 + PhCO_2H \rightarrow ArCONHPO(NHAr)_2 + PhCONHAr$$

Reactions of trialkyl *N*-phenyl phosphorimidates with methyl iodide, acetyl chloride and carbon disulphide are indicated below[2200]:

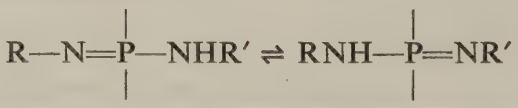


$$(RO)_3P{=}NPh \xrightarrow{MeI} (RO)_2PO.N(Me)Ph + RI$$

$$(RO)_3P{=}NPh \xrightarrow{CH_3COCl} (RO)_2PO.N(COCH_3)Ph + RCl$$

$$(RO)_3P{=}NPh \xrightarrow{CS_2} (RO)_3PS + PhNCS$$

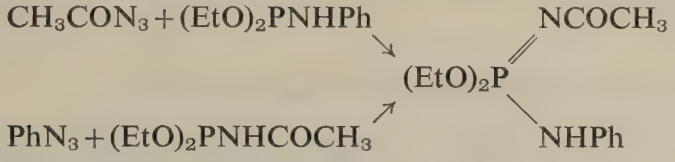
The existence of tautomerism:



$$R{-}N{=}\overset{|}{\underset{|}{P}}{-}NHR' \rightleftharpoons RNH{-}\overset{|}{\underset{|}{P}}{=}NR'$$

in phosphoramidimidic esters has been demonstrated by Kabachnik from infra-red studies. The position of equilibrium depends on the electrophilic nature of R and R′.

[2196] Supporting evidence for the tautomerism is the formation of a single compound diethyl phosphor-*N*-phenylamido-*N*-acetyl imidate from the two reactions indicated below[2196]:



*Reaction of Amino Compounds with Pentavalent Phosphorus Halides*

The reactions of phosphorus pentachloride and halogenophosphoranes with amino-compounds, especially amides, has been extensively investigated by Kirsanov and co-workers.[2278] Phosphorus pentachloride forms an *N*-substituted phosphorimidic trichloride (the trichlorophosphazo compounds of Kirsanov):

$$RNH_2 + PCl_5 \rightarrow RN{=}PCl_3 + 2HCl$$

The reactions are generally carried out in inert solvent at ambient or somewhat elevated temperature with rigorous exclusion of moisture. Examples of amino-compounds which have been used in the reaction are: aromatic amines,[2226, 2232] carboxylic acid amides[2211, 2214, 2218, 2296] and diamides,[2245] alkyl and aryl sulphonamides,[2209, 2289-91] urea,[2211] *N,N*-diphenyl urea,[2221] esters of oxamic acid,[2211, 2213, 2416] urethanes,[2211, 2229, 2242] sulphamide,[2203, 2209, 2246, 2259] amidines such as *N*-arylsulphonyl benzamidine,[2225] and phosphorus amides such as diphenyl phosphoramide[1718, 2220] and diphenyl phosphoroamidothionate.[2220] Bifunctional amino compounds such as urea, sulphamide and *p*-aminobenzene sulphonamide[2276] react with two equivalents of phosphorus pentachloride giving bis-phosphorimidic trichlorides $Cl_3P{=}N{-}A{-}N{=}PCl_3$. Oxamic esters react according to the equation[2213]:

$$RO_2CCONH_2 + PCl_5 \rightarrow POCl_3 + ROCCl_2CONH_2 \xrightarrow{PCl_5} ROCCl_2CON{=}PCl_3$$

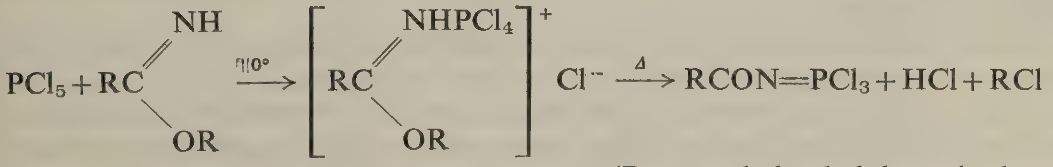
*Variation of the Phosphorus Component*

Aryl tetrachlorophosphoranes,[2227-31, 2233, 2277] diaryl trichlorophosphoranes,[1718, 2190, 2230-1, 2236, 2248, 2302] triaryl dihalogenophosphoranes[2190] and triarylphosphite dihalides[1718] react like phosphorus pentachloride with amino-compounds to form *P*-substituted phosphorus imines. Examples are: the formation of *N*-aryl phenylphosphonimidic dichlorides $ArN{=}PPhCl_2$ from aromatic amines and $PhPCl_4$[2233]; *N*-(toluene-*p*-sulphonyl)phenylphosphorimidic dichloride, $p\text{-}CH_3C_6H_4SO_2N{=}PC_6H_5.Cl_2$, from toluene *p*-sulphonamide[2227]; *N*- carbethoxy diphenylphosphinimidic chloride, $RO_2CN{=}P(C_6H_5)_2Cl$, from urethane and $Ph_2PCl_3$[2190]; and triphenyl *N*-aryl phosphorimidates $ArN{=}P(OPh)_3$ from $(PhO)_3PCl_2$ and aromatic amines.[1718] Diphenyl trichlorophosphorane and aromatic amine hydrochlorides form the quasiphosphonium salts $[ArNHP(C_6H_5)_2Cl]^+Cl^-$ which on treatment with pyridine yield the *N*-aryl diphenylphosphinimidic chloride $ArN{=}P(C_6H_5)_2Cl$.[2236]

Pentaphenoxy phosphorane reacts in a manner analogous to phosphorus pentachloride with aromatic amines and amides giving triphenyl *N*-substituted phosphorimidates[1718]:

$$(PhO)_5P + RNH_2 \rightarrow 2PhOH + (PhO)_3P{=}NR \qquad (R = Ph, (PhO)_2PO, (PhO)_2PS)$$

Imino-esters or their hydrochlorides react with phosphorus pentachloride at 0°C. to form ionic adducts which, on moderate heating, decompose to the *N*-acyl phosphorimidic trichloride[2277, 2279, 2281]:



(R = methyl, ethyl, benzyl, phenyl)

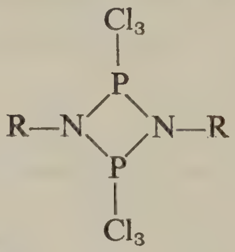
Removal of hydrogen chloride during the reaction is essential in the preparation of *N*-benzoyl phenylphosphonimidic dichloride from $PhPCl_4$ and methyl benzimino ether to prevent decomposition of the product to benzonitrile and phenyl phosphonyl dichloride.[2277]

### PROPERTIES AND REACTIONS OF PHOSPHORUS IMIDIC HALIDES

*N*-Substituted phosphorimidic chlorides are generally crystalline moisture-sensitive solids which can be crystallized from inert organic solvents. The *N*-methyl and *N*-chloromethyl compounds (**IX**: $R = CH_3$ or $CH_2Cl$) are dimeric in solution.[2224, 2239–40] Aromatic amines or their hydrochlorides react with phosphorus pentachloride in benzene solution to form either the momomeric *N*-aryl phosphorimidic trichloride **VIII**, or the dimer **IX**.

$RN{=}PCl_3$

**VIII**



**IX**

Aromatic amines having $K_b$ in the range $10^{-9}$ to $10^{-13}$ yield dimeric products, whilst amines of lower basicity yield monomers. Products derived from amines with $K_b$ $10^{-9}$ to $10^{-10}$ do not dissociate in benzene solution; those from amines with lower basicity dissociate in solution but the monomers cannot be isolated owing to dimerization which occurs when the solvent is evaporated. Derivatives of the low basicity amines are low melting-point solids which in chemical and physical behaviour resemble the monomeric *N*-acyl and *N*-sulphonyl compounds; they react with formic acid giving *N*-aryl phosphoramidic dichlorides. The dimeric compounds differ from the monomers in physical properties and chemical behaviour; they are high melting-point solids which react with formic acid giving chlorine-free glassy solids.[2226, 2232] The tendency of compounds of this type to dimerize is greatly reduced by replacing chlorine by aryl groups as in $PhN{=}PCl_2Ph$.[2223]

Mild hydrolysis of phosphorimidic trichlorides with water vapour, one equivalent of formic acid[2211, 2213, 2221, 2225, 2232, 2291] or with water in acetone[2215] gives the *N*-substituted phosphoramidic dichloride; similarly phosphonimidic dichlorides give the phosphonamidic chloride and phosphinimidic chlorides the phosphinamidate[2236, 2304]:

$$RN{=}PCl.R'R'' \xrightarrow[-CO,\ -HCl]{HCO_2H} RNH{-}PO.R'R'' \qquad (R', R'' = \text{halogen, alkyl, aryl})$$

Further hydrolysis with excess of water gives the phosphorus acid, amine and hydrochloric acid. *N*-(Diphenoxyphosphinyl) phosphorimidic trichloride $(PhO)_2PO.N{=}PCl_3$[2200] is hydrolyzed to *N*-(diphenoxyphosphinyl) phosphoramidic acid $(PhO)_2PO.NHPO_3H_2$ which is unusually stable to boiling water. This is attributed to hydrogen-bonding of the acidic group to the adjacent phosphoryl bond. In contrast, *N*-(diphenoxythionophosphinyl)phosphorimidic trichloride $(PhO)_2PS.N{=}PCl_3$ is readily hydrolyzed with water to orthophosphoric acid and diphenyl phosphoramidothionate.[2220]

*N*-Acyl phosphorimidic trichlorides decompose to phosphoryl chloride and a nitrile at temperatures near 100°C., and at lower temperatures in the presence of dry hydrogen chloride or phosphorus oxychloride.[2209, 2211, 2214, 2222, 2277] Introduction of aryl or aryloxy-groups on the phosphorus atom or electronegative substituents on the acyl group raises the decomposition temperatures of the pure compounds. Thus

*N*-benzoyl triphenyl phosphine imine decomposes at *ca.* 200° [2235]; *N*-trichloroacetyl phosphorimidic trichloride, $Cl_3CCON{=}PCl_3$, decomposes to phosphorus oxychloride and trichloroacetonitrile at 260° when pure and at 205°–210° in the presence of gaseous hydrogen chloride[2296]:

$$RCON{=}PCl_3 \xrightarrow{\Delta} RCN + POCl_3$$

*N*-Carbethoxyphosphorimidic trichlorides decompose at *ca.* 45° giving ethyl chloride and isocyanatophosphoryl dichloride[2211, 2242]:

$$EtOCON{=}PCl_3 \rightarrow EtCl + OCNPO.Cl_2$$

Some reactions of *N*-alkyl/aryl sulphonylphosphorimidic trichlorides are indicated in Chart XXII. Similar reactions have been carried out using *N*-acyl phosphorimidic trichlorides,[2215-8, 2222, 2234-5] *N*-diaryl phosphonyl phosphorimidic trichlorides[2220] and with *N*-substituted phosphonimidic and phosphinimidic halides.[2228-31, 2247, 2249]

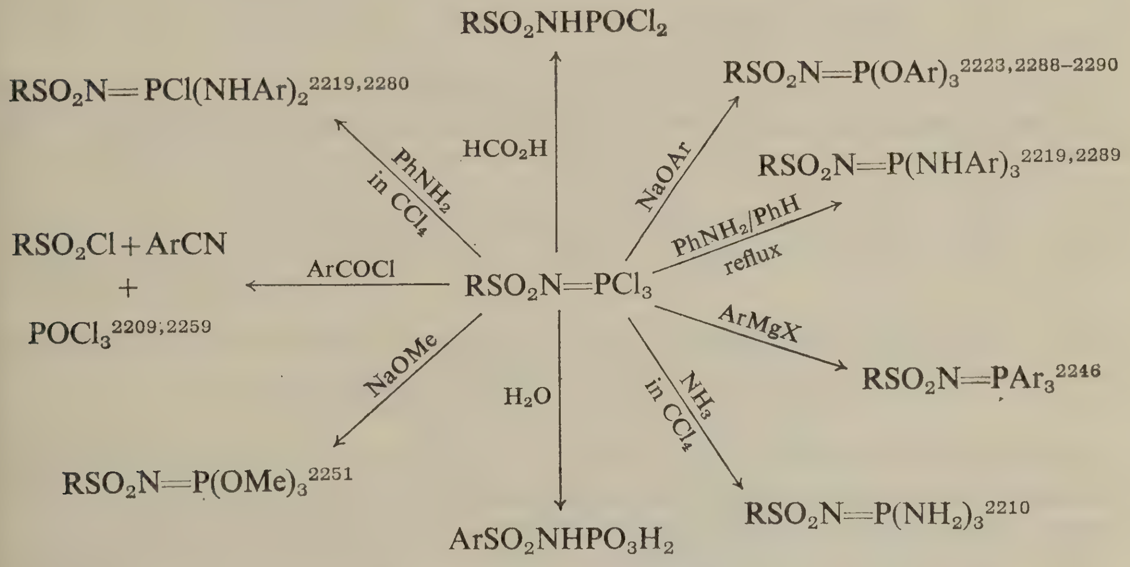


CHART XXII.—Reactions of *N*-sulphonylphosphorimidic trichlorides

### N-*Chloro Compounds and Tervalent Phosphorus Compounds*

Triaryl phosphines and chloramine-*T* react in anhydrous alcoholic solution to form *N*-(toluene-*p*-sulphonyl)triarylphosphine imines; trialkylphosphines behave similarly but the imine products are difficult to isolate[2287]:

$$ArSO_2NNaCl + PAr_3 \rightarrow ArSO_2N{=}PAr_3 + NaCl$$

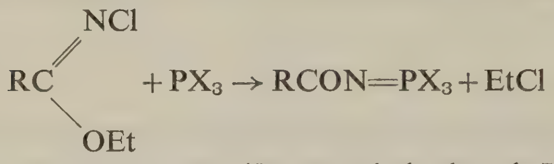
Trialkyl *N*-(toluene sulphonyl)phosphoramidate can be prepared similarly from trialkyl phosphite and chloramine-*T* in carbon tetrachloride solution.[637, 2212] In the presence of water the phosphite is oxidized by chloramine-*T* to triethyl phosphate.[637]

Phosphorus trichloride[2238] and tribromide[2237] react exothermically with chloramine-*T* in carbon tetrachloride to form the corresponding *N*-(toluene-*p*-sulphonyl)-phosphorimidic trihalides. In the absence of solvent the reaction is explosive. Phosphorus pentachloride and chloramine-*T* react under similar conditions to form chlorine and the phosphorimidic trichloride.[2243] *N,N*-Dichloroaryl sulphonamides react with phosphorus trichloride, aryl halogenophosphines and triarylphosphines in benzene solution at reflux temperatures to form *N*-(arylsulphonyl)phosphine imines[2302-3]:

$$ArSO_2N.NaCl + PX_3 \rightarrow ArSO_2N{=}PX_3 + NaCl \qquad (X = Cl, Br)$$
$$ArSO_2NCl_2 + PAr_nCl_{3-n} \rightarrow ArSO_2N{=}PAr_nCl_{(3-n)} + Cl_2 \qquad (n = 0, 1, 2, 3)$$
$$ArSO_2N,NaCl + PCl_5 \rightarrow ArSO_2N{=}PCl_3 + Cl_2 + NaCl$$

Compounds of the type $RSO_2N{=}POR'.X_2$ (R = alkyl, aryl; R′ = alkyl; X = F, Cl) are made by heating *N*,*N*-dichlorosulphonamides with alkyl phosphorodifluoridites or alkyl phosphorodichloridites.[2286]

Triphenylphosphine, halogenophenyl phosphines and triaryl phosphites have been shown to react in inert solvents with *N*-chloroimino ethers to form *N*-acyl phosphorus imines,[2191, 2282–3] and with diethyl chloriminocarbonate[2192–3] or with *N*,*N*-dichlorourethanes[2190] to form *N*-carbethoxy-phosphorus imines:



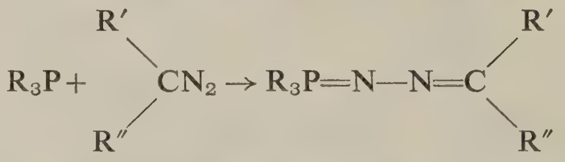
$$RC({=}NCl)OEt + PX_3 \rightarrow RCON{=}PX_3 + EtCl$$

(R = methyl, phenyl; X = phenyl, phenoxy, chlorine, cyano)

$$(EtO)_2C{=}NCl + PX_3 \rightarrow EtOCON{=}PX_3 \qquad (X = Ph, Cl, alkyl, OPh)$$
$$EtOCONCl_2 + (C_6H_5)_3P \rightarrow EtOCON{=}P(C_6H_5)_3$$

*Phosphazines*

Phosphazines were first prepared by Staudinger and co-workers[110, 177, 2292] by the reaction of tertiary phosphines with aliphatic diazo compounds[189, 2018, 2102–3, 2353]:



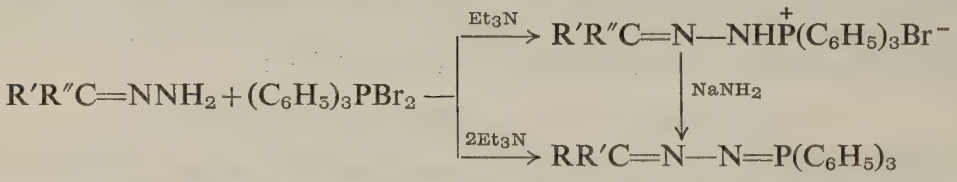
$$R_3P + R'R''CN_2 \rightarrow R_3P{=}N{-}N{=}CR'R''$$

Ortho- and para-quinone azides react like aliphatic diazo-compounds with triphenylphosphine giving quinone triphenyl phosphazines, e.g.,

$$p\text{-}O{=}C_6H_4{=}N{-}N{=}P(C_6H_5)_3{}^{1996,\,2295}$$

A kinetic study of the reaction of $p$-$XC_6H_4P(C_6H_5)_2$ with 9-diazofluorene in benzene solution to form aryldiphenyl-9-fluorenyl phosphazine shows the reaction to be of second order. Electron donating groups X enhance the reaction rate.[2206]

The range of known phosphazines has been considerably extended by Bestmann [2102, 2181] who allowed hydrazones to react with triphenyl dibromophosphorane in the presence of triethylamine. The intermediate $N^{\beta}$-alkylidene hydrazino-phosphonium salts may be prepared by using one equivalent of the amine; they have been converted to the phosphazines using sodamide in liquid ammonia[2254]:



$$\begin{tikzcd}
 & R'R''C{=}N{-}NH\overset{+}{P}(C_6H_5)_3Br^- \arrow[d, "NaNH_2"] \\
R'R''C{=}NNH_2 + (C_6H_5)_3PBr_2 \arrow[ur, "Et_3N"] \arrow[r, "2Et_3N"'] & RR'C{=}N{-}N{=}P(C_6H_5)_3
\end{tikzcd}$$

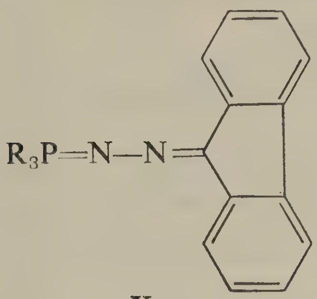
An alternative approach is the condensation of ketones with *N*-amino-triphenylphosphine imine which can be readily obtained by the action of strong bases on triphenyl hydrazine phosphonium salts[2414]:

$$Ph_3PBr_2 + N_2H_4 \xrightarrow{Et_3N} Ph_3\overset{+}{P}NHNH_2Br^-$$
$$Ph_3\overset{+}{P}NHNH_2Br^- \xrightarrow[R_2CO]{BuLi} Ph_3P{=}N{-}N{=}CR_2$$

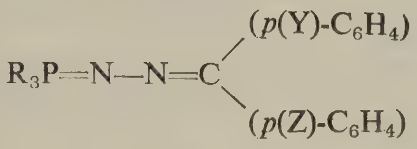
Phosphazines are a reactive class. Most compounds reported are solids, which, when R is phenyl, are generally stable under ambient conditions. Thermal decomposition can proceed either with loss of nitrogen to form a methylene phosphorane[177, 189, 2353] or to give tertiary phosphine and aliphatic diazo compounds depending on the nature of R, R′ and R″[2102]:

$$Ph_3P{=}N{-}N{=}CPh_2 \xrightarrow{\Delta} Ph_3P{=}CPh_2$$

The basicity and reactivity of phosphazines as nucleophiles depends on the inductive and mesomeric effects of the R, R′ and R″ groups.[2102] *P*-Triethyl compounds are strong bases, *P*-triphenyl compounds weak.[177] Dipole moments and molecular spectra of the triaryl phosphazines types **X** and **XI** have been interpreted as indicating a merocyanine-like mesomerism in the compounds[2301]:



**X**

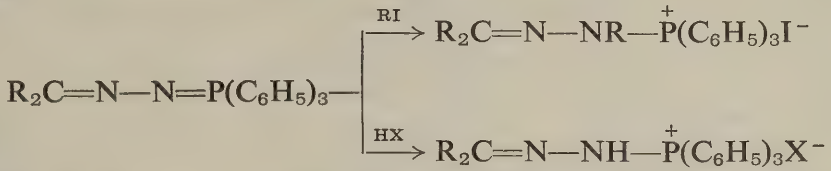


**XI**

Simple phosphazines such as formaldehyde triphenylphosphazine,

$$CH_2{=}N{-}N{=}P(C_6H_5)_3$$

and benzylidene triphenylphosphazine react with hydrogen halides or with alkyl halides to form $N^\beta$-alkylidene hydrazinophosphonium salts and $N^\beta$-alkylidene-$N^\alpha$-alkyl hydrazinophosphonium salts respectively.[2102, 2254] α-Keto phosphazines, formed from diazoketones and tertiary phosphines,[2103] react with methyl iodide accompanied by P–N bond fission to form the diazoketone and a normal phosphonium salt[2102-3]:

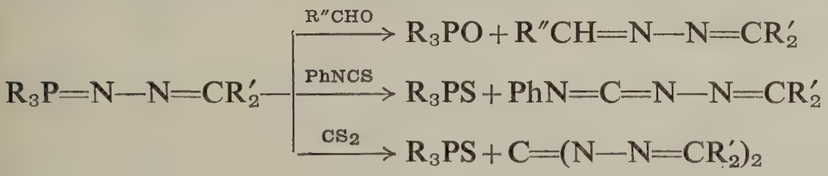


$$R_2C{=}N{-}N{=}P(C_6H_5)_3 \begin{cases} \xrightarrow{RI} R_2C{=}N{-}NR{-}\overset{+}{P}(C_6H_5)_3I^- \\ \xrightarrow{HX} R_2C{=}N{-}NH{-}\overset{+}{P}(C_6H_5)_3X^- \end{cases}$$

Phosphazines derived from quinone azides react with aqueous hydrochloric acid giving hydroxyaryl azotriphenylphosphonium chlorides, e.g.,

$$p\text{-}HOC_6H_4N{=}N{-}\overset{+}{P}(C_6H_5)_3Cl^{-}$$ [1996]

Phosphazines react with a variety of unsaturated oxygen and sulphur-containing compounds such as aldehydes,[2181] ketenes,[177, 2181] isocyanates,[177] carbon disulphide,[2292] phenyl isothiocyanate[177] and sulphur dioxide[2292] to form tertiary phosphine oxide/sulphide and an organic hydrazine derivative. They are readily hydrolyzed, particularly in basic media, to hydrazone and tertiary phosphine oxide[177]:



$$R_3P{=}N{-}N{=}CR'_2 \begin{cases} \xrightarrow{R''CHO} R_3PO + R''CH{=}N{-}N{=}CR'_2 \\ \xrightarrow{PhNCS} R_3PS + PhN{=}C{=}N{-}N{=}CR'_2 \\ \xrightarrow{CS_2} R_3PS + C{=}(N{-}N{=}CR'_2)_2 \end{cases}$$

Trialkyl phosphites react readily with diazomethane to form liquid trialkyl phosphorazines which can be distilled under vacuum.[2207] They react vigorously with carbon disulphide giving trialkyl phosphorothionates:

$$(RO)_3P + CH_2N_2 \rightarrow (RO)_3P{=}N{-}N{=}CH_2 \xrightarrow{CS_2} (RO)_3PS$$

Tri-*iso*propyl phosphite and diphenyl diazomethane give a quantitative yield of benzophenone tri-*iso*propyl phosphorazine which on hydrolysis, in contrast to the behaviour of phosphazines, gives propylene and *N*-diphenylmethylene phosphorohydrazidate[2208]:

$$Ph_2C{=}N{-}N{=}P(OC_3H_7)_3 \rightarrow C_3H_7 + Ph_2C{=}N{-}NHPO(OC_3H_7)_2$$

# SECTION XXXIV

# THE SPECTROSCOPY AND STRUCTURE OF PHOSPHORUS AND PHOSPHORUS COMPOUNDS

BY A. C. CHAPMAN

## ELEMENTAL PHOSPHORUS

### Atomic and Ionized Phosphorus

EMISSION SPECTRA

THE visible, ultra-violet,[52–6, 59–65, 67, 800–3] and far ultra-violet[57–8, 800–2] emission spectra of atomic phosphorus in various degrees of ionization up to P XIII have been investigated. References are as follow: P I,[61, 63] P II,[59, 62–4, 800, 812] P III,[55–6, 62, 64, 801, 811] P IV,[56, 62, 64, 802, 811, 817] P V,[52–3, 60, 62, 65, 67] P VI–XII,[65, 812] P XIII.[803] The use of the spectra for analytical purposes has been discussed.[67–71] Many of the spectral data are contained in published tables.[72–4, 804] Table I gives a list of the principal lines in the spectra of phosphorus; the data are taken from References 62, 63, 801 and 817 for lines of P III–P V and for wave-lengths below 2000 A., and from Reference 73 for the remainder. The electric-field gradients at the nucleus for various states of atomic phosphorus have been calculated from the spectra.[814] The excitation of forbidden lines between the sub-levels of the ground state has been studied.[948]

*Table I.—Emission Spectra of Phosphorus*(a)

(a) Persistent lines are indicated by P I, II, III, etc., and indicate lines classified as emitted by neutral, singly ionized, doubly ionized, etc., atoms respectively.

Wave-lengths below 2000 A. refer to vacuum and those above 2000 A. refer to air. Intensities of lines below 2000 A. and from P III–V are on an arbitrary scale; the remainder are on a scale of 9000.

### PARAMAGNETIC RESONANCE SPECTRA

The paramagnetic resonance spectrum of the ground state ($^4S_{3/2}$) of atomic phosphorus gives a *g*-value for the ground state of 2·0019 ± 0·0004, and shows a narrow doublet (separation 56·2 Mc/s) arising from a magnetic hyperfine interaction with the $^{31}P$ nucleus.[813] Both the hyperfine interaction and the low *g*-value are taken to indicate an admixture of higher states. More accurate data have been obtained from molecular beam[943] and spin-exchange optical polarization[944] experiments.

The hyperfine interaction constant is[944] $+55,055,691 \pm 8$ c/s. The *g*-value is[943] $-2{\cdot}00165 \pm 0{\cdot}00039$. The positive sign of the interaction constant has been disputed on theoretical grounds.[945]

### *X*-RAY SPECTRA

The *X*-ray spectra of phosphorus have been reinvestigated by several workers.[75–9, 754–9, 805–7, 815–6] Shifts of the lines as a function of chemical binding have been reported.[754–9, 815] The soft *X*-ray spectrum has also been examined.[80, 815] The $K_{\alpha_1\alpha_2}$ line of phosphorus lies at 6·1549 A., the $K_\beta$ at 5·8038 A., and the $K_\alpha$ absorption edge is at 5·7866 A.[807]

## Diatomic Phosphorus Vapour

The $P_2$ molecule is stable in the vapour only above about 800°C., and has been investigated by spectroscopic means.[66, 81–91, 537, 808–9, 949, 952, 1061] The absorption spectrum has been reported.[950] The equilibrium between diatomic and monoatomic phosphorus has been investigated by mass spectrometry.[951] The bond length in the ground state is 1·894 A., and the vibrational frequency is 780 $\text{cm.}^{-1}$, giving a force constant of 5·56 millidynes/A.[81–2]

## Tetra-atomic Phosphorus Vapour

Electron diffraction experiments[92] have shown that phosphorus vapour consists of symmetrical tetrahedral (point group $T_d$) $P_4$ molecules (Fig. 8). The tetrahedral structure implies interbond angles of 60°, as against the 90° expected for bonds formed from simple *p*-orbitals, and the bonds were regarded as formed from non-cylindrical *spd* hybrid orbitals.[93–5, 818–20] The bond length is 2·21 A.[92] A mass-spectrometer study[96] has confirmed that the sublimation from red phosphorus occurs in tetra-atomic molecules. The existence of $P_8$ molecules has been reported[105] but not confirmed.[96] Later work[946] has been based on the observation[946] of the absorption spectrum of phosphorus vapour in the 3000–1200 A. region. Transitions were observed at 5·1, 5·9, 6·89, 7·7 and 8·4 ev. A theoretical spectrum was calculated[946] on the basis of 3*p* atomic hybridization, and was in reasonable agreement with the experimental data. The calculation indicated strong $\pi$-bonding and delocalization, with a consequent lack of directed valency and elimination of the concept of bent bonds.[946]

## Liquid Phosphorus

The radial distribution curve for liquid phosphorus has been obtained from the *X*-ray diffraction pattern,[104] and the results show that the liquid consists of tetrahedral $P_4$ molecules. The value obtained for the P–P bond length is 2·25 A.

## White Phosphorus

Early work[106–7] on the structure of the cubic high-temperature form has not been confirmed. The latest work[108–9] shows that the cell is body-centred cubic, with $a = 18{\cdot}51$ A., space group probability $I\bar{4}3m$, and that it contains about 56 molecules. The radial distribution curve[108] confirms that tetrahedral $P_4$ molecules are still present. The intensities of the diffracted *X*-ray spots indicate considerable molecular motion, and this is confirmed by the narrow nuclear magnetic resonance line obtained from solid white phosphorus.[110]

The structure of the low-temperature form has not been determined. It is thought to have a low symmetry, probably hexagonal or trigonal, with a large unit cell.[107–8]

The infra-red and Raman spectra of phosphorus as vapour, liquid, solution in carbon disulphide, and as solid white phosphorus have been investigated.[97–103] The results for the different phases are similar and all confirm the presence of tetrahedral

$P_4$ molecules. The active fundamental frequencies, all of which may be described as P–P stretching, are 363 cm.$^{-1}$ ($\nu_2$, $E$, Raman depolarized), 465 cm.$^{-1}$ ($\nu_3$, $F_2$, Raman depolarized, infra-red), and 606 cm.$^{-1}$ ($\nu_1$, $A$, Raman polarized). Valence force constants have been calculated[99, 117, 821]; the value for the P–P stretching force constant in the most general force field, considering increments in the bond lengths as the internal co-ordinates, is 2·065–2·08 millidynes/A.[117, 821] When partial corrections for anharmonicity were made the value was raised to 2·33 millidynes/A.[117]

Nuclear magnetic resonance measurements have been made on phosphorus in carbon disulphide solution and on the liquid, as well as on solid white phosphorus.[110, 171, 637] The chemical shift, relative to 85% orthophosphoric acid, is positive and abnormally large (about +450 p.p.m.). This is attributed to the bent bonds. The shift in carbon disulphide solution is concentration-dependent[637]; this is attributed to interactions with the solvent.

## Red Phosphorus

Five different forms of red phosphorus have been reported,[111] two of which were reported previously.[112] These include triclinic, tetragonal and hexagonal forms, the triclinic form having the highest crystallinity.[111] A report of a cubic form has also appeared.[113] The radial distribution function of amorphous red phosphorus has been determined[104, 114, 953]; the P–P distance is 2·29 A. and the average interbond angle is 99°. The structure of red phosphorus may be regarded as comprising more or less disordered arrays of triply connected phosphorus atoms, the arrays being possibly terminated by impurity groups. The variety in form and properties has been interpreted in terms of different degrees of polymerization and different terminal impurity groups.[115]

In the latest work,[939] only two forms of red phosphorus were reported from preparations between 300° and 610°C. These were forms IV and V (of reference 111), which are reported to be tetragonal (probably) and triclinic respectively. These were characterized by visible fluorescence spectra as well as by $X$-ray diffraction patterns. The other 'forms' reported earlier were claimed to arise from poor crystallinity of forms IV and V.

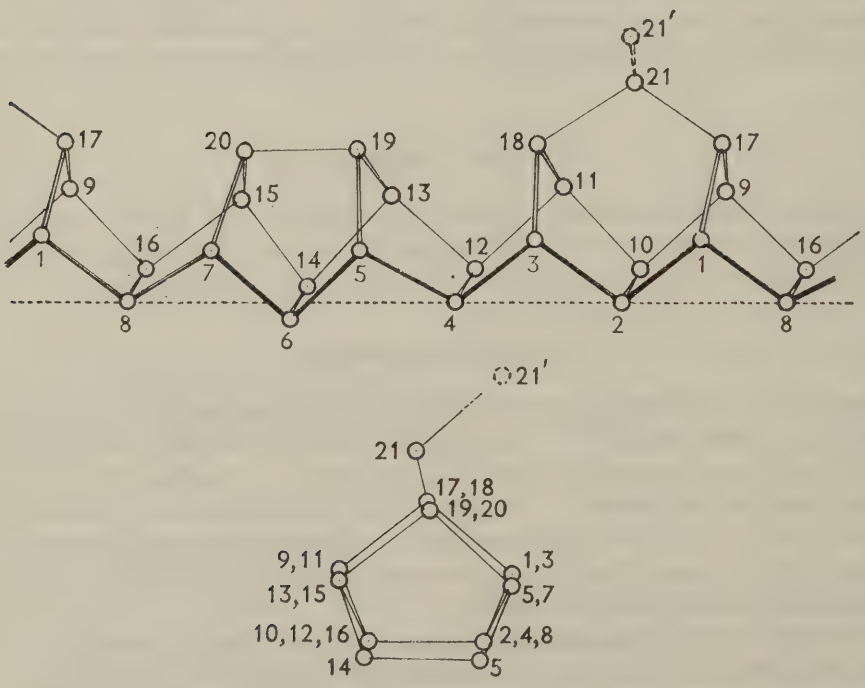

FIG. 1.—Section of a 'tube' of violet phosphorus. Above: parallel perspective. Below: projection parallel to the tube axis (end view)

Recent work[940] on violet (Hittorf) phosphorus, crystallized[941–2] from lead or bismuth at around 500°–600°C., has shown it to be monoclinic, space group $P2/c$, $a = 9{\cdot}21$, $b = 9{\cdot}15$, $c = 22{\cdot}59$ A., $\beta = 106{\cdot}1°$, with 84 atoms per unit cell. The structure is based on $P_8$ and $P_9$ groups linked by two further phosphorus atoms into infinite tube-like structures (Fig. 1). The tubes are packed parallel to each other in layers, successive pairs of layers being approximately perpendicular to each other.

## Black Phosphorus

The results of the first investigation of the structure of black phosphorus[116] are not supported by later work.[114] The structure has recently been refined.[947] The eight-atom cell is orthorhombic, with $a = 3{\cdot}3136$ A., $b = 10{\cdot}478$ A., $c = 4{\cdot}3763$ A., space group *Cmca.* Discrete molecules do not exist, and the atoms (Fig. 2) are in widely separated (5·25 A.) double layers (2·1 A. between layer halves). Each phosphorus atom has two nearest neighbours at 2·224 A. and a third at 2·244 A. The interbond angle in the layers is 96·34°, and the third bond is at 102·09° to the other two.[114] A sample of black phosphorus, showing a different structure, has also been reported, but no details are given.[114] The radial distribution function of amorphous black phosphorus shows a P–P distance of 2·27 A. and an interbond angle of 95·6°.[104]

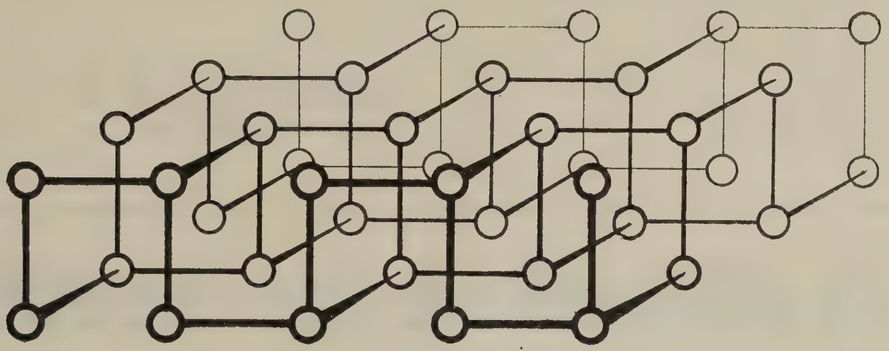

FIG. 2.—The arrangement of atoms in the corrugated planes found in crystalline black phosphorus

## PHOSPHIDES

This class includes the binary and ternary compounds of phosphorus with elements other than hydrogen and the members of Groups VIIA, VIA, and to some extent VA.

The salt-like phosphides, $Li_3P$ and $Na_3P$, are of some interest because of the possibility of a phosphorus negative ion. Unlike the transition metal phosphides, which are of an interstitial character, the alkali metal phosphides have metal–metal distances which are smaller than in the metals, implying covalent or ionic bonding between metal and phosphorus. The structures[1] are of the trisodium arsenide type, in which the phosphorus atom is surrounded by five alkali metal atoms at the corners of a trigonal bipyramid, with geometry very similar to that of the phosphorus pentahalides, suggesting[716] a covalently bonded structure with $sp^3d$ hybridization. There is therefore little evidence for a phosphorus negative ion in these compounds.

The alkaline-earth phosphides of known structure[7,8] have the phosphorus atom surrounded by six metal atoms at the corners of a tetragonal bipyramid. There are two types of phosphorus site, one in the centre of the bipyramid, and one displaced from the centre. All the phosphides of Group IIIA elements of which the structures have been investigated have the zinc blende three-dimensional polymer type of structure, with fourfold tetrahedral co-ordination of both the elements, indicating $sp^3$ hybridization. The monophosphides are isoelectronic with the elements of Group

(a) P on Ca sites; other atoms statistically distributed on F sites.
(b) Doubt has been cast on this structure.[154]

IVA, and those of aluminium, gallium and indium are semiconductors. The phosphides of the transition, rare earth and actinide metals are generally of an interstitial character. Most of the compounds show the typical expansion of the metal–metal interatomic distance relative to the pure metal. Zirconium, niobium and tantalum phosphides each occur in two forms, of which the α-phases are deficient in phosphorus, corresponding approximately to $MP_{0\cdot9}$.

The $^{57}$Fe Mössbauer spectra of three iron phosphides and the $^{31}$P NMR spectrum of FeP have been examined.[1062] FeP showed an isomer shift of 0·25 mm./sec. with respect to natural iron, a quadrupole splitting of 0·65 mm./sec., and an NMR chemical shift of $-375$ p.p.m. with respect to orthophosphoric acid. $Fe_2P$ at room temperature showed a singlet and a doublet, of equal intensity, unresolved, with isomer shifts of 0·16 (singlet) and 0·58 mm./sec. (doublet) and a doublet quadrupole splitting of 0·40 mm./sec. At liquid air temperatures, below the Curie point, it gave a complex superposition of two six-line patterns, one from each type of site. $Fe_3P$ gave a complex 18-line pattern, with six lines from each of three sites.[1062]

The infra-red spectra of the semiconducting phosphides have received attention from the point of view of determining the energy gap. The infra-red absorption and reflection,[49,50] Raman spectrum[976] and lattice vibrations of gallium phosphide, and the infra-red absorption of indium phosphide[51] have been investigated. The visible absorption spectrum of gallium phosphide at liquid nitrogen temperatures has been investigated.[1000]

Gallium phosphide and trizinc diphosphide have also been investigated by nuclear magnetic resonance.[830–1,971] The observed line widths of the $^{69}$Ga, $^{71}$Ga and $^{31}$P resonances (2·26, 2·26 and 2·9 gauss respectively) could not be accounted for by dipolar broadening alone; the additional broadening was thought to be due to indirect nuclear exchange interactions. In $Zn_3P_2$ the $^{31}$P NMR spectrum[971] showed two peaks of equal intensity, with chemical shifts $+217$ and $+250$ p.p.m. relative to 85% $H_3PO_4$, in accordance with the crystal structure.[13]

The series of transition-metal monophosphides of vanadium, chromium, iron, cobalt and manganese have been investigated by NMR[1117–8] and the results related to magnetic susceptibility measurements and to the electronic band structures. Resonance shifts of the $^{31}$P resonance, relative to that in red phosphorus, of 0·023, $-0·17$, 0·034, 0·36% were observed in VP, CrP, FeP, CoP respectively at room temperature.[1117] The $^{59}$Co resonance shift, relative to potassium hexacyanocobaltate, in CoP was $-0·36$% at 4·2 and 2°K.[1117]

The available structural data on phosphides are summarized in Table II.

## DIATOMIC AND TRIATOMIC MOLECULES CONTAINING PHOSPHORUS

All these molecules are unstable at room temperature and have been investigated only by spectroscopic means.

PN has been investigated by several workers[66,118–23,952,1044]; the bond length is 1·491 A.,[118,122] and the vibrational frequency 1337 cm.$^{-1}$, giving a force constant of 10·1 millidynes/A.[122] The bands arise from $'\pi \rightarrow {}'\Sigma$ transitions.

PO has a bond length of 1·45 A.[124–5]; the vibrational frequency is 1231 cm.$^{-1}$ and the force constant 9·4 millidynes/A.[124] The spectrum has also been investigated by several other workers.[91,118,125–31,311,541,810,1034–9,1043–4,1060,1146–9] There has been disagreement over the value of the dissociation energy.[91,125,1034–5] The latest work[1035] favours a value of 5·4 ev. The observed ultra-violet bands have been assigned to $^2\Sigma \rightarrow {}^2\pi$ and $^2\pi$–$^2\pi$ (ground state) transitions.

The PH molecule[132–5,533] has a bond length of 1·43 A. and a vibrational frequency of 2380 cm.$^{-1}$ giving a force constant of 3·25 millidynes/A.,[135] corresponding to a single bond. A complex band system was assigned to a $^3\pi_1 - {}^3\Sigma$ transition.

The molecule PC has been reported[136] as having a bond length of 1·5622 A.

The molecules PCl, PBr[137], PI[137–8], PS, PS$^+$ and PO$^+$ [90–1] have also been reported.

The relation of such molecules to other diatomic molecules has received considerable attention in discussions[139-43] of the regularities in the vibration spectra of diatomic molecules. The diatomic hydrides and PH have received particular attention.[144-6] The vibration frequencies of the molecule FPF have been stated[1161] to be 890, 775 and 376 cm.$^{-1}$, and mean amplitudes of vibration have been calculated.[1162]

The emission spectra of the molecules HPO and DPO have been reported.[1033, 1041-2]

## PHOSPHINE

Solid phosphine shows a phase transition at 88·5°K.[167]; at 103°K. it has a cubic crystal structure[147] with a four-molecule cell of side $a = 6{\cdot}31$ A. and space group *Fd*3 or *Pn*3*m*. The phosphorus atoms are stated to lie on a face-centred cubic lattice, but the data are also reported to be equally compatible with the ammonia structure.[154] The positions of the hydrogen atoms were not determined. The molecular dimensions of phosphine have been determined from the microwave rotational spectra of phosphine and deuterated phosphines,[148-9, 488, 1008-9] from the Coriolis coupling in the vibration–rotation spectra,[150, 156, 491] and from electron diffraction experiments.[340] The P–H bond length is 1·419 A., a value in agreement with a prediction[499] based on Badger's rule, and the H–P–H angle lies between 93° 20′ and 93° 50′. The intermixture of $sp^3$ hybridization with the $p^3$ is therefore small. The dipole moment is 0·58 Debye units.[149, 1008] Several authors have discussed the electronic structure[501-5, 1019, 1032] and the dipole moment[504, 506, 1019] from a theoretical viewpoint. The interbond angle has also been calculated theoretically, and a value in reasonable agreement with the experimental value obtained.[507-9]

The ultra-violet spectrum of phosphine has been examined[151-2, 163, 1006-7, 1017-8] in connection with its photochemical decomposition. The band structure of phosphine and deuterophosphine in the 1850–2500 A. region has been explained on the assumption that the upper state of $PH_3$ and $PD_3$ is pyramidal, with a barrier to inversion so low that all observed transitions are to levels above the barrier.[163, 1006-7] The Verdet constant of phosphine at 0°C., 760 mm. and 5780 A. is $57 \times 10^{-6}$.[500] The infra-red[150, 153, 156-63, 166, 173, 489, 491, 493, 496-7] and Raman[164-5, 494-5] spectra of phosphine and the deuterophosphines[153, 173, 493-5] have been investigated. The P–H stretching vibrations, $\nu_1(A)$ at 2323 cm.$^{-1}$ and $\nu_3(E)$ at 2328 cm.$^{-1}$ [491] are resolved with difficulty. The symmetrical and degenerate deformation vibrations, $\nu_2$ and $\nu_4$, occur at 990 and 1121 cm.$^{-1}$ respectively. In trideuterophosphine the P–D stretching vibrations appear at 1694 cm.$^{-1}$, and $\nu_2$ and $\nu_4$ at 730 and 806 cm.$^{-1}$ respectively.[153] The infra-red spectra of the two phases of solid phosphine and trideuterophosphine have been determined.[167, 1021] The force field of phosphine has been worked out by several authors[168, 1023-5, 1012] by considering the spectra of phosphine, deuterated and tritiated phosphines, anharmonicities, rotation distortion constants and Coriolis coupling constants.[1024-5, 1012] The valence stretching force constant is 3·328 millidynes/A.[168] 3·3326,[1024] 3·10,[1025] 3·1222.[1012] Earlier treatments of the force field[163, 169, 492, 498, 827] involved various assumptions. The absolute intensities of the fundamental infra-red bands of phosphine have been determined[163] and an attempt was made to determine the bond dipole moments. The results are not entirely self-consistent; it appears that the vibrational bond moments could not be identified with the static ones. The mean amplitudes of vibration of phosphine have been calculated.[1026] The potential barrier to inversion in phosphine has been calculated approximately as 17·1 kcal./mole[490, 498] and racemization rate has been calculated.[155] The vibrational relaxation has been investigated[1022] and overall relaxation times of 1·96 and $3{\cdot}43 \times 10^{-7}$ sec. obtained for $PH_3$ and $PD_3$ respectively.[1022]

The phosphorus nuclear magnetic resonance spectrum of liquid phosphine at −90°C. has been determined.[110, 171, 225] The chemical shift is positive and large (+238 p.p.m.). This is correlated[171] with the nearly pure $p^3$ hybridization. The phosphorus–proton spin-spin coupling is 179 c/s.[225] The proton NMR spectrum of phosphine has been investigated in a variety of solvents.[1063] Both the chemical shift and the coupling constant show considerable solvent and temperature dependence, ranges of 8·10–8·45 $\tau$ and 183–190 c/s being observed.[1063]

The mass spectrum of phosphine has been investigated.[1027–9] The ionization potential is 10·02 ± 0·05 ev.[1029]

The $PH_2$ radical has been observed in the ESR spectrum of $\gamma$-irradiated phosphine in a krypton matrix at 4·2°K.[1013] The *g*-value is 2·0087. The electronic structure of the radicals PH and $PH_2$ has been treated theoretically[1014] with results in reasonable agreement with the experimental data[1015–6, 1020] obtained from observations of the flash photolysis of phosphine.

## Phosphine Derivatives

Biphosphine, $H_2PPH_2$, has been investigated independently by infra-red spectroscopy (vapour and solid) and *X*-ray powder photography[174] and by Raman spectroscopy of the liquid.[641–2] The characters of the bands in the vapour-phase infra-red spectrum suggest a gauche configuration of the $PH_2$ groups, with $C_2$ molecular symmetry. A similar suggestion was based on the number of lines in the Raman spectrum.[641] Values of 2·99 and 1·85 millidynes/A. for the P–P and P–H stretching force constants respectively were obtained from the totally symmetric vibrations. Eight of the nine lines expected for $C_2$ symmetry were observed but two of these, at 412 and 456 cm.$^{-1}$, are difficult to assign satisfactorily, and later work[642] on the Raman spectrum of the deuterated compound suggests that these lines may arise from higher phosphorus compounds. The deduction of $C_2$ symmetry for biphosphine cannot therefore be regarded as conclusive.

The compounds $H_2PSH$ and $D_2PSD$, identified by their mass spectra, show a sharp infra-red absorption at 477 cm.$^{-1}$ assigned to the P–S single bond.[1005]

The *X*-ray data suggest a monoclinic two-molecule cell with $a = 3{\cdot}6$ A., $b = 6{\cdot}6$ A., $c = 3{\cdot}2$ A., $\beta = 104°$, space group *Pm* or $P_2$.[174] These deductions are again not regarded as conclusive. The NMR spectrum[1010] of diphosphine is consistent with rapid interconversion between two skew forms of the molecule. The PH spin-spin coupling constant is close to that in phosphine, suggesting similar bond lengths and hybridizations between the two molecules.

The spectra of a number of silicon- and germanium-substituted phosphines have been studied.[1004, 1030–1, 1040] Trisilylphosphine, $(SiH_3)_3P$, is deduced to have a planar or near-planar skeleton, from the non-appearance in the infra-red of the breathing frequency which gives a strong polarized Raman band at 414 cm.$^{-1}$[1030] The asymmetric P–$Si_3$ stretch is at 455 cm.$^{-1}$[1030] In the infra-red spectrum[1031] of disilylphosphine, $(SiH_3)_2PH$, the following assignments were made[1031]: PH 2300 cm.$^{-1}$, SiH 2150, $SiH_3$ asym. deformation 942/932. $SiH_3$ sym. deformation 888/878. In disilanylphosphine, $Si_2H_5PH_2$, infra-red assignments were as follows[1031]: 736–724 cm.$^{-1}$ $SiH_3$ wag, 1073 $PH_2$ deformation, 784 $PH_2$ wag, 637/628 $PH_2$ twist, 515–475 (weak) SiP stretch. The infra-red spectrum of monosilylphosphine, $H_3SiPH_2$, has been reported and a vibrational assignment made.[179] The P–H stretching vibrations absorb at 2312 cm.$^{-1}$, the $PH_2$ deformation at 1068·5 cm.$^{-1}$, and the Si–P stretching at 454 cm.$^{-1}$. NMR data on these compounds[1031, 1040] are as follows: $H_3SiP$, 6·3$\tau$; $((H_3Si)_2PH)$, 6·27$\tau$; $(H_3SiPH_2)$ (HP), 9·60$\tau$; $H_3SiSi(P)$, 6·81$\tau$; $SiSiH_2P$, 6·43$\tau$; $H_2P$, 8·75$\tau$ $(Si_2H_5PH_2)$, 8·69$\tau$ $(SiH_3PH_2)$. $J_{\mathrm{PH}}$ 184·0 c/s, $J_{\mathrm{HP(Si}H_3)_2}$ 17·5 c/s, $J_{\mathrm{H_2PSi}H3}$ 16·2 c/s, $J_{\mathrm{Si_2H_5}PH_2}$ 182·5 c/s, $J_{\mathrm{SiH_3}PH_2}$ 180 c/s, $J_{\mathrm{Si}H_2\mathrm{PH_2}}$ 18·5 c/s, $J_{\mathrm{H_2}P\mathrm{SiH_2Si}H_3}$ 2·0 c/s, $J_{H_2\mathrm{PSi}H_2-}$ 5·8 c/s, $J_{\mathrm{P-Si}H_2\mathrm{Si}H_3}$ 3·0 c/s, $J_{(\mathrm{Si}H_3)_2\mathrm{P}H}$ 5·1 c/s, $J_{\mathrm{Si}H_3\mathrm{PH_2}}$ 204 c/s.

Trigermylphosphine, $(GeH_3)_3P$, has been studied by infra-red and Raman spectra, which suggest a non-planar skeleton.[1004] NMR data on germylphosphine, $GeH_3PH_2$, are as follows: $PH_2$ 8·39$\tau$, $GeH_3$ 6·33$\tau$, $J_{\mathrm{HH}}$ 4·8 c/s, $J_{\mathrm{PH_2}}$ 180 c/s, $J_{P\mathrm{Ge}H_3}$ 15·3 c/s.[1040]

The crystal structure of phosphonium iodide, $PH_4I$, has been investigated.[175] The structure is a distortion of the cæsium chloride arrangement, with a two-molecule tetragonal unit cell of dimensions $a = 6{\cdot}34$ A., $b = 4{\cdot}62$ A., with space group *P*4/*nmm*, and it is similar to the low-temperature phase III ammonium bromide and ammonium iodide structures.[177, 312] The infra-red spectrum has been investigated[177, 259] over a wide range of temperatures[177] and the Raman spectrum has also been reported[176,1011]; all the spectra are consistent with the room temperature crystal structure.[177] The strong bands in the infra-red spectrum, at 932–54 and 2372 cm.$^{-1}$, are derived from the triply degenerate bending and stretching modes respectively of an isolated $PH_4^+$ ion. The symmetrical breathing mode appears in the Raman spectrum at 2304 cm.$^{-1}$ The infra-red spectrum of the deuterated derivative was also investigated[177]; the strong bands are at 683–701 and 1740 cm.$^{-1}$ The proton nuclear magnetic resonance spectra of crystalline phosphonium iodide and phosphonium bromide have been examined[178] and used to deduce a value for the P–H bond length of $1{\cdot}42 \pm 0{\cdot}02$ Å., which is close to that of phosphine. The infra-red spectra of phosphonium bromide and phosphonium chloride have been investigated.[1021] The spectra were very similar to that of phosphonium iodide, and the same space group (*P*4/*nmm*) was proposed.[1021] The electronic structure of the phosphonium ion has been treated theoretically.[1019, 1032]

The $^1H$ and $^{31}P$ nuclear magnetic resonance spectra of phosphonium ions in strong acid solution have been observed.[1064] The proton chemical shift covers a range from $3{\cdot}61$–$3{\cdot}96\tau$; the phosphorus chemical shift is +217 p.p.m. from $P_4O_6$, and the spin-spin coupling constant has a range from 545·7–548·3 c/s.[1064] Proton NMR data have been reported for the $PH_2^-$ ion in liquid ammonia.[1305] The chemical shift is $11{\cdot}4$–$11{\cdot}5\tau$ and the coupling constant 139–140 c/s.[1065]

The infra-red spectra of phosphonium tetrachloroborate and trichlorofluoroborate have been reported, and the two active frequencies of the phosphonium ion found to lie in the regions 945–82 cm.$^{-1}$ and 2345–445 cm.$^{-1}$ [259]

The infra-red spectrum (vapour phase) of difluorophosphine has been assigned as follows[1074]: 2251/2240/2233 ($\nu_s$PH), 1016/1008 $\delta_{as}$PH, 851 ($\nu_s$PF), 838/825 ($\nu_{as}$PF), 367/348 $\delta_s$FPF. The proton NMR chemical shift in the vapour is $8{\cdot}7\tau$, which shows a complex coupling pattern.[1074] In the liquid the molecules are associated, giving a large change in chemical shift. The proton shift in the liquid is $2{\cdot}35\tau$, and the coupling constants $J_{PH}$ 182·4, $J_{FH}$ 41·7, $J_{PF}$ $1134 \pm 4$ c/s.[1074] Mass spectral data were also reported.[1074]

## PHOSPHORUS TRIHALIDES

The molecular structures of the phosphorus trihalides have been determined by electron diffraction[180]; the molecules are all pyramidal, as expected. For phosphorus trichloride and trifluoride bond lengths have been obtained also from microwave spectra. The available data on bond lengths and angles are given in Table III. The bond angles are typical of $p^3$–$sp^3$ hybrid bonding.

The Stark splitting of the microwave spectra[190–2] of phosphorus trifluoride has given a value for the molecular dipole moment of $1{\cdot}025 \pm 0{\cdot}009$ Debye units.[190–1]

The only trihalide which has been investigated by *X*-ray diffraction is the tri-iodide[187]; it crystallizes in a two-molecule hexagonal cell with $a = 7{\cdot}11$ Å., $c = 7{\cdot}24$ Å. The crystal is isomorphous with iodoform.

The nuclear quadrupole coupling constants have been determined for solid phosphorus trichloride[228]; at 77°K. two lines are observed for each chlorine isotope, showing that there are two non-equivalent chlorine positions in the lattice. A similar conclusion was reached in the case of the tribromide.[229]

The ultra-violet absorption spectra of phosphorus trichloride,[193–5, 1017] tribromide[194] and tri-iodide[196–7] have been investigated. Phosphorus trichloride shows a strong maximum at 217 mμ.[1017] Phosphorus tribromide shows two flat maxima at 2695 and 2495 Å. Phosphorus tri-iodide shows two maxima near 2850 and 3800 Å.

The Verdet constant of liquid phosphorus trichloride at 5780 Å. is $2{\cdot}52 \times 10^{-2}$.[198]

The Raman[165] and infra-red[215–8] spectra of phosphorus trifluoride have been investigated. The Raman and early infra-red work[165, 217] agree on the spectra, though not on assignment, but later infra-red work[216] shows that a band reported earlier at 531 cm.$^{-1}$ was absent. It seems likely that this band is due to an impurity. The frequencies are[216] as follow: 892 ($\nu_1$, *A*, symmetrical stretch), 860 ($\nu_3$, *E*, degenerate

*Table IV.—Force Constants of Phosphorus Trihalides*

| Molecule | Stretching force constant, $F_d$ millidynes/A. | Deformation force constant, $F_\alpha$ millidynes/A. | Reference |
|---|---|---|---|
| $PF_3$ | 5·342 ± 0·005 | 0·631 ± 0·009 | 1052 (and see 848, 216) |
| $PCl_3$ | 2·047 ± 0·040 | 0·343 ± 0·005 | 1052 (and see 826, 221, 848, 823) |
| $PBr_3$ | 1·83 | 0·23 | 1132 (and see 221) |
| $PI_3$ | 1·21 | 0·18 | 619 |
| $PFCl_2$ | P–F 4·10<br>P–Cl 2·70 | ClPF 0·25<br>ClPCl 0·61 | 752 |

rather than by racemization. Bond dipole moments and dipole moment derivatives have been calculated from the infra-red intensities for phosphorus trifluoride.[218] Values of about 1·07–1·20 Debye units, which were consistent among the different symmetry species and with the static molecular moment, were obtained for the bond dipole moments. The 'umbrella' frequency ($\nu_2$) of phosphorus trichloride is reported from the ultra-violet spectrum to lie between 230–65 cm.$^{-1}$ when the molecule is in an excited state.[224] A linear relation between the force constant of the phosphorus–halogen bond and the ionization potential has been suggested.[302]

Phosphorus nuclear magnetic resonance spectra have been determined for phosphorus trifluoride,[110, 225] difluoride chloride,[1050] fluoride dichloride,[1055] difluoride bromide,[1055] fluoride dibromide,[1055] difluoride iodide,[1051] trichloride,[110, 171, 226, 612] chloride dibromide,[834] bromide dichloride,[834] tribromide[110, 171, 226, 612] and tri-iodide.[110] The chemical shifts are respectively −97, −176, −224, −218, −255, −242·2, −219·4, −224·2, −226·9, −227·4, −178 p.p.m., relative to 85% orthophosphoric acid. The fluorine NMR spectra of the trifluoride,[225] difluoride chloride,[1057] fluoride dichloride,[1057] difluoride bromide,[1055] fluoride dibromide[1055] and difluoride iodide[1051] have been observed. Chemical shifts are respectively −43·4, −39·9, −20·7, −36·5, −6·2, 31·9 p.p.m. with respect to trifluoracetic acid. P–F spin-spin coupling constants are as follows: $PF_3$ 1405,[225] $PF_2Cl$ 1390–1380,[1051, 1057] $PFCl_2$ 1320,[1057] $PF_2Br$ 1388–95,[1055] $PFBr_2$ 1292–1301,[1055] $PF_2I$ 1037–1040.[1051] The decrease in shielding at the phosphorus atom in the order fluoride, iodide, chloride, bromide has been interpreted[110] as being due to a superposition of two opposing effects. These are the change in ionic character, which decreases the shielding in the order I, Br, Cl, F, and the effect of double bonding which tends to increase the shielding and which is expected to be greatest for fluorine, followed by chlorine. Arguments based on the bond lengths and angles and on the dipole moments, have also been advanced in support of multiple bonding in phosphorus trifluoride.[227] A dipole moment of 0·34 Debye units was obtained for phosphorus tri-iodide from dielectric constant measurements.[1056]

In a study of the electron-impact spectroscopy of phosphorus trichloride in a mass spectrometer,[1059] both positive and negative ($Cl^-$ and $PCl_2^-$) ion formation was reported and appearance potentials studied.

## Phosphorus Dihalides

The crystal structure of phosphorus di-iodide, $P_2I_4$, has been determined.[230] The molecule has a symmetrical trans-configuration, symmetry $C_{2h}$, with a P–P distance of 2·21 ± 0·06 A., and a P–I distance of 2·475 ± 0·028 A. The monomolecular cell is triclinic, space group $P\bar{1}$, with $a = 4·56$ A., $b = 7·06$ A., $c = 7·40$ A., $\alpha = 80° 12'$, $\beta = 106° 58'$ and $\gamma = 98° 12'$. The configuration of the $P_2I_4$ molecule in solution has been the subject of some disagreement.[1048–9, 1056, 1065–6] A staggered configuration was

*Table III.—Molecular Structures of Phosphorus Trihalides*

| Compound | Bond length A. | Interbond angle | Technique used | References |
|---|---|---|---|---|
| $PF_3$ | 1·537 ± 0·004 | 98·2 ± 0·6° | Electron diffraction | 181, 182, 1046 |
| | 1·546 ± 0·008 | 104° ± 3° (assumed) | Microwave spectra | 188 |
| $PCl_3$ | 2·00 ± 0·02 | 101° ± 2° | Electron diffraction | 181, 182, 183 |
| | 2·039 ± 0·014 | 100·27° ± 0·09° | Electron diffraction | 822, 1045 |
| | 2·043 ± 0·003 | 100°6′ ± 20′ | Microwave spectra | 189 |
| $PBr_3$ | 2·23 ± 0·01 | 100° ± 2° | Electron diffraction | 184 |
| $PI_3$ | 2·52 ± 0·01 | 98° ± 4° | Electron diffraction | 184 |
| | 2·43 ± 0·04 | 102·5° ± 2·5° | Electron diffraction | 185 |
| $PFCl_2$ | P–Cl 2·02 ± 0·03<br>P–F 1·55 ± 0·05 | FPCl = ClPCl = 102° ± 3° | Electron diffraction | 186 |

stretch, 487 ($\nu_2$ *A*, symmetrical deformation) and 344 cm.$^{-1}$ ($\nu_4$, *E*, degenerate deformation). For phosphorus trichloride the Raman spectra of the vapour,[824] liquid[199–204, 1047, 213–4, 824] (with depolarization ratio[202–3, 824]) and solid,[301] and the infra-red spectrum[215, 219–20, 1047, 1132] (including vapour, liquid and solid[1047]) have been determined. The four frequencies in the vapour phase have been reported as[824, 1047] $\nu_1$ 'A' 514 (Raman); $\nu_3$ 'E' 482 (Raman), 507 (IR); $\nu_2$ 'A' 256 (Raman) 259 (IR); $\nu_4$ 'E' 184 (Raman), 187 (IR). The frequencies of phosphorus tribromide determined from the Raman spectrum[201–2, 204] are 400 ($\nu_3$), 380 ($\nu_1$), 162 ($\nu_2$) and 116 ($\nu_4$) cm.$^{-1}$ The frequencies determined from the infra-red spectrum[1132] are 392 ($\nu_3$), 392 ± 5 ($\nu_1$), 161 ($\nu_2$) and 116 ($\nu_4$) cm.$^{-1}$ The Raman[619, 898] and infra-red[1048, 1049] spectra of phosphorus tri-iodide have been determined. The fundamental frequencies[1049] are 328 ($\nu_3$), 306 ($\nu_1$), 112 ($\nu_2$), 80 ($\nu_4$) cm.$^{-1}$ Raman[209–12] and vapour-phase infra-red[1055] spectra have been reported for $PFCl_2$ and $PFBr_2$. Observed Raman frequencies are as follow ($p$ = polarized): $PFCl_2$, 200 ($p$), 271, 327 ($p$), 496, 524 ($p$), 827 ($p$); $PFBr_2$, 126 ($p$), 220, 257 ($p$), 393, 421 ($p$), 817 ($p$) cm.$^{-1}$ The infra-red spectrum of $PF_2Br$[1055] is as follows: 391, 459, 849, 858 cm.$^{-1}$ The infra-red[1050] and Raman[209–12] spectra of $PF_2Cl$ exhibit fundamentals[1050] 864 ($\nu_sPF_2$), 852 ($\nu_{as}PF_2$), 545 ($\nu$PCl), 411 ($\delta_s$FPF), 308 ($\delta$PCl) cm.$^{-1}$ Approximate stretching force constants of 4·81 (PF) and 2·87 millidynes/A. (PCl) were obtained. Raman spectra have also been reported for PFClBr,[209–12] $PCl_2Br$ and $PClBr_2$,[200, 204–8, 898–900] $PBrI_2$ and $PBr_2I$.[898] The infra-red spectrum of $PF_2I$ as far as 200 cm.$^{-1}$ has been reported,[1051] with fundamentals at 850 ($\nu_sPF_2$), 845 ($\nu_{as}PF_2$), 412 ($\delta_s$FPF), 378 ($\nu_s$PI) cm.$^{-1}$ with $\delta_{as}PF_2$ and $\delta$PI expected below 200 cm.$^{-1}$ The observed frequencies of PFClBr are as follow: 161, 231, 302, 415, 500, 822 cm.$^{-1}$ Force constants have been worked out (Table IV) for phosphorus trifluoride,[216–7, 221–3, 848, 1052–3] fluoride dichloride,[752] trichloride,[221–2, 823, 848, 1052–4, 1132–3] tribromide[221–2, 1053, 1132] and tri-iodide.[619, 1053] For $PF_3$ and $PCl_3$ centrifugal distortion constants obtained from millimetre wave spectra have been used in conjunction with the vibrational data to give more accurate force constants.[1052]

The complete potential function for the trichloride[823] has been derived from the vibration frequencies[824] and vibrational amplitudes[822] in the vapour phase. The energy barriers for inversion[172] are respectively 45·1, 68·1 and 52·7 kcal./mole. for the fluoride, chloride and bromide respectively, and the separation of optically active trihalides at room temperature appears to be limited by chemical decomposition originally suggested[1056] on the basis of the dipole moment (0·45 Debye units, from dielectric constant measurements). This was supported by infra-red work[1048, 1066] in which four IR-active PI stretching fundamentals were assigned at 354, 332, 328 and 313 cm.$^{-1}$ thereby excluding the *trans*-$C_{2h}$ structure which would give only two infra-red active PI modes. Later workers,[1048, 1065] on the basis of Raman as well as infra-red data, suggested that 354 cm.$^{-1}$ was an overtone, and that 332 cm.$^{-1}$ was of doubtful validity, and concluded from the mutual exclusion of infra-red and Raman spectra that the molecule retained its *trans*-$C_{2h}$ structure in solution. The $^{31}$P NMR shift of $P_2I_4$ in $CS_2$ solution is $-108$ p.p.m. relative to 85% orthophosphoric acid.[110, 1259]

The infra-red and Raman spectra of diphosphorus tetrachloride, $P_2Cl_4$, have been assigned[1047] on the basis of a *trans*-configuration of $C_{2h}$ symmetry, similar to the tetra-iodide, in the solid liquid and vapour. Assignments were as follow: $a_g$ (Raman, *p*), 494, 410, 238, 149; $a_u$ (IR), 501, 201, 91; $b_g$ (Raman), 480, 189; $b_u$ (IR), 508, 275, 139 cm.$^{-1}$ [1047] The $^{31}$P chemical shift of $P_2Cl_4$ is $-155$ p.p.m. relative to 85% $H_3PO_4$.[1067]

A *trans*-configuration has also been suggested[1068-9] for diphosphorus tetrafluoride on the basis of infra-red[1068-71] and Raman[1068-9] data. Assignments[1068] were as follow: IR 847/839, 834/829 ($\nu$PF), 365, 361 ($\phi PF_2$); Raman 825 *p*, 803 ($\nu$PF), 541 *p* ($\nu$PP), 453 ($\omega PF_2$), 377 ($\delta PF_2$) cm.$^{-1}$ The NMR spectrum[1068, 1070] is a complex $X_2AA'X_2$ pattern. The chemical shifts[1068] are: $^{31}$P, $-226$ p.p.m. relative to 85% $H_3PO_4$; $^{19}$F, 37·6 p.p.m. relative to trifluoracetic acid. The P–F coupling constant is about 1100 c/s.[1068] The $X_2AA'X_2'$ pattern is more complex than that derived theoretically for this system,[1072] probably because $J_{FPPF'} \neq 0$.[1068] The compound showed an electron spin resonance spectrum, attributed to $PF_2$ radicals, with a *g*-value of 2·00129.[1068] Mass spectral data have been reported.[1070]

The compound $\mu$-oxobisdifluorophosphine, $F_2POPF_2$, identified by NMR, infra-red and mass spectrometry, has been reported.[1068, 1070, 1155] The $^{31}$P chemical shift is $-114·6$ relative to orthophosphoric acid[1155]; the $^{19}$F spectrum was analysed as an $X_2AA'X_2'$ system,[1068, 1070] with parameters[1068] $\delta_F = -39·9$ p.p.m. (relative to trifluoracetic acid), $J_{PF} = 1358$, $J_{PF} = -14$, $J_{PP} = 4$ c/s. $J_{FF'}$ was assumed to be zero. Infra-red bands were assigned[1068] at 682 ($\nu_s$POP), 976 ($\nu_{as}$POP), 842/853/863 ($\nu$PF).

### Adducts of Phosphorus Trihalides and Dihalides

The Raman spectra of the liquid compounds phosphorus trifluoride-borane, $F_3P,BH_3$, and phosphorus trifluoride-borane-$d_3$, have been determined at $-80$°C.[643] and polarization measurements made. The spectra were assigned on the basis of a staggered $C_{3v}$ configuration. The P–B stretching frequency was assigned as 607 cm.$^{-1}$ (572 cm.$^{-1}$ in the deuterated compound).

The compound titanium phosphorus chloride, $TiPCl_7$ (presumably $TiCl_4,PCl_3$), crystallized from a mixture of titanium tetrachloride and phosphorus trichloride, is orthorhombic, space group *Pbca*, with $a = 12·61$, $b = 13·59$, $c = 12·70$ A., $Z = 8$.[644] The similar compound, titanium phosphorus bromide ($TiP_2Br_{10}$ or $TiBr_4,2PBr_3$), prepared by addition of titanium tetrachloride to phosphorus tribromide, is orthorhombic, space group $P222_1$ or $P2_12_12$, with $a_0 = 14·84$, $b_0 = 8·61$, $c_0 = 7·24$ A., $Z = 2$.[645]

The Raman spectrum of tetrakis(trifluorophosphine) nickel has been determined.[639-40] The numbers of polarized and depolarized lines are in agreement with a regular tetrahedral arrangement (point group *Td*), and are assigned on this basis. The totally symmetric ($A_1$) P–F stretching vibration appears at 954 cm.$^{-1}$, and the corresponding $E$ and $F_2$ vibrations at 851 and 888 cm.$^{-1}$ respectively. The Ni–$P_4$ symmetrical stretching ($A_1$) vibration is at 195 cm.$^{-1}$, and the corresponding asymmetrical ($F_2$) vibration at 219 cm.$^{-1}$ Factorized valence force constants were calculated for the totally symmetric species only, with results of 7·73 millidynes/A. for P–F stretching, 2·71 millidynes/A. for Ni–P stretching and $k\delta/r^2 = 0·53$ millidynes/A. for the $PF_3$ 'umbrella' deformation. The Ni–P force constant is lower than expected, as the bond might be expected to have some double-bond character arising from back co-ordination on to vacant *d* orbitals on the phosphorus. Some infra-red data for hexakis(trifluorophosphine) chromium have been reported.[1058] P–F stretching vibrations were observed at 916 and 851 cm.$^{-1}$

The crystal structure of the compound AuCl,PCl$_3$ has been determined.[835] The unit cell is monoclinic, with space group $P2_1/c$, and $a = 7{\cdot}23$ A., $b = 14{\cdot}62$ A., $c = 6{\cdot}19$ A., $Z = 4$. Molecules of Cl$_3$P → Au–Cl have almost linear P → Au–Cl linkages. The Au–P distance is 2·19 A., and the PCl distances of 1·84, 1·98 and 2·07 A. appear to be on average shorter than in free PCl$_3$, supporting a suggestion[836] that stronger bonds go with higher co-ordination. The accuracy of the determination, however, is insufficient for this difference to be significant.

The infra-red spectra of the solid adducts PI$_3$,BBr$_3$, P$_2$I$_4$,2BBr$_3$ [1048] and PI$_3$, BI$_3$ [1048, 1073] have been reported. B–Br stretching vibrations were assigned at around 681 ($^{10}$B) and 647 ($^{11}$B) cm.$^{-1}$, BI stretches at 590/598 ($^{10}$B) and 564 ($^{11}$B) cm.$^{-1}$, PI stretches at 302–361 cm.$^{-1}$, and P–B stretches at 384–412 cm.$^{-1}$ [1048] An approximate P–B stretching constant of 1·0 millidynes/A. in PI$_3$,BI$_3$ has been reported.[1073]

## PHOSPHORUS PENTAHALIDES AND HALOPHOSPHORANES

The structures of phosphorus pentafluoride[186, 254, 1046, 1075, 1313] and pentachloride[232–3] in the vapour state have been determined by electron diffraction; the molecules are trigonal bipyramids. An electron diffraction study[186] of phosphorus dichloride trifluoride proposed a structure with the three fluorine atoms equatorial and the two chlorines axial but recent work (below) has shown this to be erroneous. Bond lengths are as follow:

| Molecule | Bond | Length A. | Reference |
|---|---|---|---|
| PF$_5$ | Axial PF | $1{\cdot}549 \pm 0{\cdot}005$ | 1046 |
| | | $1{\cdot}577 \pm 0{\cdot}005$ | 1075 |
| | Equatorial PF | $1{\cdot}499 \pm 0{\cdot}004$ | 1046 |
| | | $1{\cdot}534 \pm 0{\cdot}004$ | 1075 |
| PCl$_5$ | Axial PCl | $2{\cdot}19 \pm 0{\cdot}06$ | 232,233 |
| | Equatorial PCl | $2{\cdot}04 \pm 0{\cdot}06$ | |

The crystal structures of solid phosphorus pentachloride[234–6] and pentabromide[237–8] have been determined. The molecular structures in the solid are quite different from those in the vapour phase. Solid phosphorus pentachloride is composed of alternate tetrachlorophosphonium, PCl$_4^+$, and hexachlorophosphate, PCl$_6^-$, ions. These crystallize in a tetragonal four-molecule cell with $a = 9{\cdot}22$ and $c = 7{\cdot}44$ A.; the space group is $P4/n$. The P–Cl bond lengths are 1·97 A. in the tetrachlorophosphonium ion, which is tetrahedral, and 2·04–2·08 A. in the hexachlorophosphate ion which is approximately a regular octahedron. Solid phosphorus pentachloride prepared by sublimation is stated to have a different structure, similar to that of the compound PCl$_{4{\cdot}67}$Br$_{0{\cdot}33}$.[719] The chlorine nuclear quadrupole resonance of PCl$_5$ has been examined.[257] Three lines were reported but the results have apparently not been correlated with the crystal structure. Chlorine nuclear quadrupole resonance data have been obtained for the molecular forms of phosphorus tetrachloride fluoride, trichloride difluoride, dichloride trifluoride[1076–7] and chloride tetrafluoride.[1078] These show that in the solid state the molecules retain the trigonal bipyramidal structures deduced by spectroscopic methods (below) for the liquid and gaseous states. For PCl$_4$F two $^{35}$Cl resonance signals are observed at 32·54 (triplet, intensity 3) and 28·99 (intensity 1) Mc/s, assigned to equatorial and axial chlorines respectively, indicating that the single fluorine is axial. PCl$_3$F$_2$, PCl$_2$F$_3$, and PClF$_4$ all give signals assignable to equatorial chlorines only at 31·26/31·89 Mc/s, 31·49 and 32·14 Mc/s respectively, indicating that the fluorines adopt axial positions preferentially.[1076–8]

Solid phosphorus pentabromide is composed of tetrabromophosphonium ions, $PBr_4^+$, and bromide ions, $Br^-$, which crystallize in an orthorhombic four-molecule cell with $a = 5{\cdot}62$, $b = 16{\cdot}91$, $c = 8{\cdot}29$ A. The space group is *Pbcm.* The tetrabromophosphonium ion is a slightly irregular tetrahedron, with P–Br bond lengths of 2·02–2·18 A. The shortest $Br^-$–P distance is 4·3 A.[238]

An approximate structure has been suggested[719] for the compound $PCl_{4\cdot67}Br_{0\cdot33}$. This crystallizes in a face-centred cubic structure with a cell edge of 12·38 A., containing twelve 'molecules', i.e. the cell contents are $P_{12}Cl_{56}Br_4$. The suggested structure is a cæsium chloride-type array of $8PCl_4^+$, $4PCl_6^-$ and $4Br^-$ ions.

The infra-red spectrum of phosphorus pentafluoride vapour[217, 249, 1079–84] and the Raman spectrum of the liquid[1079–81, 1083] have been studied. The spectra confirm the trigonal bipyramidal structure.[1079, 1083] A normal co-ordinate calculation was used[1083] to investigate the rates of internal exchange[1085] of axial and equatorial fluorine atoms. Bond stretching force constants have been calculated[839, 1082, 1087–8] and are 6·58 and 3·13 millidynes/A. for equatorial and axial P–F bonds respectively.[1082] Assignments are as follows[1083]: 1025 (Raman, IR, $\nu_{as}PF_3$ $E'$), 946·6 (IR, $\nu_{as}PF_2$ $A_2''$), 817 (Raman, *p*, $\nu$PF in phase $A_1'$), 640 (Raman, *p*, $\nu$PF ax/eq out of phase $A_1'$), 575 (IR, $PF_3$ umbrella $A_2''$), 532 (Raman, IR in plane bend, $E'$), 514 (Raman, degen. $PF_3$ bend, $E''$), 300 (IR, degen. axial bend $E'$) $cm.^{-1}$

The infra-red and Raman spectra of phosphorus chloride tetrafluoride[1078] support a trigonal bipyramidal structure of $C_{2v}$ symmetry with an equatorial chlorine atom. Assignments are as follows[1078]: 921 (Raman, IR, $\nu PF_2$, $b_1$), 903 (Raman, IR, $\nu PF_2'$, $b_2$), 895 (Raman, *p*, IR, $\nu_s PF_2$, $a_1$), 691 (Raman, *p*, IR, $\nu_s PF_2'$, $a_1$), 560 (Raman, IR, out-of-plane bend, $b_2$), 510 (Raman, *p*, IR, $\gamma PF_2$, $a_1$), 490 (Raman, IR, $PClF_2$ in-plane bend, $b_1$), 434 (Raman, *p*, IR, $\nu$PCl, $a_1$), 356 (Raman, IR, $PF_2$ twist and rock, $a_2 + b_2$?), 144 (Raman, *p*, IR, $PF_2'$ bend, $a_1 + b_1$?) $cm.^{-1}$

The infra-red[720, 1079, 1086] and Raman[1079] spectra of phosphorus dichloride trifluoride have been studied. Different workers[1079, 1086] agree in rejecting the $D_{3h}$ axial-chlorine structure originally proposed from electron diffraction work[186] in favour of a structure of $C_{2v}$ symmetry with two fluorine atoms axial. However, there is considerable disagreement about the vibrational assignments[1079, 1086]; those of the later workers[1086] are as follows: 925 ($PF_2$eq. stretch $a_1$), 895 ($PF_2'$ax. asym. stretch $b_2$), 667 ($\nu_{as}PCl_2$, $b_1$), 650 ($PF_2$ax. sym. stretch, $a_1$), 562 (PF bend, $b_1$), 490 (PF bend, $b_2$), 429 ($PF_2$ax. bend, $a_1$), 407 ($\nu_s PCl_2$, $a_1$), 337 ($PF_2'$ wag, $b_1$) $cm.^{-1}$ Low-frequency assignments[1079] are 368 ($a_2$), 124 ($a_1 + b_2$?) $cm.^{-1}$

The infra-red and Raman spectra of phosphorus trichloride difluoride[1079] are consistent with a trigonal bipyramidal structure of $D_{3h}$ symmetry, with the fluorine atoms in axial positions. Assignments are as follows[1079]: 867 ($\nu_{as}PF_2$, IR, $a_2''$), 633 ($\nu_s PF_2$, Raman, *p*, $a_1'$), 625 ($\nu_{as}PCl_3$, Raman, IR, $e'$), 404 ($\delta PCl_3$, Raman, IR, $e'$), 387 (Raman, *p*, $\nu_s PCl_3$), 357 (Rocking, Raman, $e''$), 328 ($\delta PCl_3$, IR, $a_2''$), 122 (Raman, IR, $PF_2$ax. bend, $e'$) $cm.^{-1}$

The infra-red and Raman spectra of the molecular form of phosphorus tetrachloride fluoride[1079] have been interpreted in terms of a $C_{3v}$ structure, with the fluorine atom on an axial site. Assignments are: 778 ($\nu$PF, $a_1$), 601 ($\nu_{as}PCl_3$, $e$), 422 ($\nu_s PCl_3$, $a_1$), 388 ($\nu$PCl, $a_1$), 339 ($\delta_{as}PCl_3$, $e$), 297 (Rock/bend, $e$), 265 ($\delta_s PCl_3$, $a_1$), 110 (Rock/bend, $e$).

The ionic compound of composition $PCl_4F$ has also been studied by infra-red spectroscopy.[1089] It was suggested that the structure should be formulated as $PCl_4^+$ $PCl_4F_2^-$ rather than as $PCl_4^+F^-$.

Force constants have been reported[1088] for the series of phosphorus chlorofluorides $PF_4Cl$, $PF_3Cl_2$, $PF_2Cl_3$ and $PFCl_4$. Axial PF stretching constants are 4·62, 4·37, 4·10 and 3·92 millidynes/A. respectively. Equatorial PCl stretching constants are 3·45, 3·45, 3·07 and 3·07 millidynes/A. respectively. Equatorial PF stretching constants in $PF_4Cl$ and $PF_3Cl_2$ are 6·25 and 5·82 millidynes/A. respectively. The axial PCl stretching constant in $PFCl_4$ is 1·94 millidynes/A.[1088]

The Raman[1088] and infra-red[1088, 1090] spectra of trifluorophosphorane, $PH_2F_3$, have been studied. It was concluded[1088] that in the gas phase the molecule was a trigonal bipyramid of symmetry $C_{2v}$ with the two fluorine atoms axial. In condensed phases molecules associate through fluorine bridges.[1088] Assignments[1088] for the vapour phase spectra were as follows: 2538 ($\nu_s PH_2$, $A_1$), 2465 ($\nu_{as} PH_2$, $B_1$), 1292 ($\delta PH_2$, $A_1$), 1026 ($\nu_{as} PF_2'$, $B_2$), 995 ($\nu_s PF$, $A_1$), 867 ($\gamma PH_2F$, $B_2$), 820 ($\nu_s PF_2'$, $A_1$), 765 ($\delta FPH_2$, $B_1$), 655 ($\delta HPF'$, $A_2$), 471 ($\delta PF_2'$, $A_1$), 389 ($\delta_{as} PF_2'$, $B_1$), 329 ($\delta PF_2/PHF$, $B_2$). Approximate valence force constants were worked out, as follows[1088]: PH stretching 3·59, $PF_{(ax)}$ 7·18, $PF_{(eq)}$ 5·77 millidynes/A.

The infra-red spectrum of tetrafluorophosphorane, $PHF_4$, has been reported.[1090] The principal bands are at 2478, 1027, 890, 881, 866, 832, 538 and 532 cm.$^{-1}$

The Raman spectrum of phosphorus pentachloride has been extensively investigated in the solid,[239–42] liquid[240–1] and vapour[241] phases, and in solution.[241, 243] The spectra confirm the trigonal bipyramidal structure and the different structure in the solid.[240–1, 244–5] Infra-red studies in various solvents have led to the conclusion that phosphorus pentachloride exists as the molecular form in solution in phosphorus oxychloride, benzene, *cyclo*hexane and dichlorethane, the ionic form in acetonitrile solution (but the Raman[1110] spectrum suggests that a small proportion of the molecular species is present), and as a dimer, $P_2Cl_{10}$, in carbon tetrachloride solution.[1091] Force constants have been worked out.[242–3, 246–7] The infra-red[259, 1092–3] and Raman[242, 1092] spectra of solid phosphorus pentachloride have recently been reported, together with the spectra of other compounds containing the tetrachlorophosphonium ion. In the latest work[243, 1092–4] on the vibrational spectra of molecular phosphorus pentachloride, the infra-red[1092–3] spectrum was observed in the vapour and solution and the Raman spectrum[1092, 1094] in solution, with measurement of the depolarization ratios. There has been considerable disagreement[243, 1092–5, 1110–11] over the vibrational assignments. Force constants have been calculated,[243, 1087–8, 1095–7] but apparently none of the calculations used the latest assignments[1110–1] (see Table V*a*). Table V also gives assignments[1092, 1110] for the tetrachlorophosphonium and hexachlorophosphate ions in ionic phosphorus pentachloride. The latter were obtained[1110] from phosphorus pentachloride in the solid and in acetonitrile solution, and also from related derivatives such as $Et_4NPCl_6$ and pyH.$PCl_6$.pyHCl. Force constants[1098–9] and mean amplitudes of vibration[1100–1] have been calculated for the tetrachlorophosphonium ion.

The infra-red spectrum of phosphorus trifluoride dibromide has been reported[1086] and assigned as follows (by comparison with that of $PF_3Cl_2$) on the basis of a trigonal bipyramidal structure of symmetry $C_{2v}$, with equatorial bromine atoms: 913 ($\nu$PFeq., $a_1$), 878 ($\nu_{as} PF_2'$ ax., $b_2$), 607 ($\nu_s PF_2'$ ax., $a_1$), 587 ($\nu_{as} PBr_2$, $b_1$), 510 ($\delta$PF, $b_1$), 458 ($\delta$PF, $b_2$), 420 ($\delta PF_2'$ ax., $a_1$), 335 ($\delta PF_2'$, $b_1$) 318 ($\nu_s PBr_2$, $a_1$) cm.$^{-1}$

The Raman spectrum of solid phosphorus pentabromide has been investigated.[248] The following frequencies were assigned to the tetrabromophosphonium ($PBr_4^+$) ion: 72 ($E$), 140 ($F_2$), (both deformation modes), 227 ($A_1$) and 474 cm.$^{-1}$ ($F_2$) (both stretching modes). Force constants[248, 1098] and mean amplitudes of vibration[1101] have been calculated. The stretching force constant of the PBr bond, calculated from these frequencies using a Urey–Bradley force field, is 2·19 millidynes/A.[248]

The bonding in the phosphorus pentahalides has been discussed by several authors.[250–2] It is considered[252] that the phosphorus *d* orbitals are normally too diffuse to take part in bonding and can only take part in the formation of $sp^3d$ hybridization, as in the pentahalides, when they are contracted by the influence of electronegative elements bonded to the phosphorus. The bonding in the chloride fluorides and other derivatives with mixed substituents has received particular attention,[1106–9] and attempts have been made to explain the structural features of these molecules on the basis of electron-pair repulsion theories[1106] and Hückel molecular-orbital calculations.[1107–8] These have suggested[1108] that the stability of the observed isomers is a function of $\sigma$-bonding rather than $\pi$-bonding or *d*-orbital participation although these are both present. The equatorial phosphorus orbitals are stated to be more electronegative, thereby concentrating the *s*-orbitals of the

*Table V*

(*a*) Fundamental frequencies of phosphorus pentachloride[243, 1110]

| Frequency cm.$^{-1}$ | Assignment |
|---|---|
| 100 | $E'$ $PCl_3$ in-plane bending |
| 261 | $E''$ $Cl_{ax}PCl_{ax}$ linear rocking |
| 273 | $E'$ $Cl_{ax}PCl_{ax}$ linear bending |
| 282 | $A_1'$ $PCl_{ax}$ symmetrical stretching |
| 300 | $A_2''$ $PCl_3$ out-of-plane bending |
| 393 | $A_1'$ $PCl_{eq}$ symmetrical stretching |
| 448 | $A_2''$ $PCl_{ax}$ unsymmetrical stretching |
| 581 | $E'$ degenerate $PCl_3$ stretching |

(*b*) Fundamental frequencies of the tetrachlorophosphonium ion[1092]

| Frequency cm.$^{-1}$ | Assignment |
|---|---|
| 171 | $E$ Deformation |
| 252 | $F_2$ Deformation |
| 459 | $A_1$ PCl stretching |
| 658 | $F_2$ PCl stretching |

(*c*) Fundamental frequencies of the hexachlorophosphate ion[1110]

| Frequency cm.$^{-1}$ | Assignment |
|---|---|
| 285 | $F_{1u}$ Deformation (IR) |
| 238 | $F_{2g}$ Deformation (Raman) |
| 262–283 | $E_g$ PCl stretching (Raman) |
| 353–360 | $A_{1g}$ PCl stretching (Raman, *p*) |
| 444–454 | $F_{1u}$ PCl stretching (IR)<br>(see also ref. 242) |

phosphorus and strengthening these bonds relative to the axial ones as reflected by the structural and force constant data. Electronegative substituents then tend to favour the (electropositive) axial bonds, accounting for the occurrence of the observed isomers.[1108]

The ultra-violet absorption spectra of phosphorus pentachloride[194, 253] and pentabromide[194] have been reported. The pentachloride shows continuous absorption below about 2130 A., with a maximum at 2310 A.[194]; the pentabromide shows a maximum at about 2744 A.

The dipole moments of phosphorus tetrafluoride chloride[1078] (0·78 Debye units) and trifluoride dichloride[1105] (0·68 Debye units, in agreement with the $C_{2v}$ symmetry) have been determined from the temperature variation of the gas-phase dielectric constant. The same method has been used to confirm that the dipole moment of phosphorus difluoride trichloride is zero.[1105] The dipole moment of phosphorus fluoride trichloride is 0·21 Debye units, from measurements on the gas-phase nonresonant absorption at microwave frequencies.[1105]

The fluorine nuclear magnetic resonance in phosphorus pentafluoride[225] shows a single chemical shift, suggesting that the five fluorine atoms might be equivalent; an earlier report[753] suggesting non-equivalence has been discounted. In view of the trigonal bipyramidal structure such equivalence would be surprising. Suggested explanations have included intra-[1085] and inter-molecular fluorine exchange and 'accidental' equivalence of chemical shifts.[255] However, recent work[1083] on the vibrational potential function has enabled the height of the barrier to intramolecular fluorine exchange to be calculated, and has predicted exchange rates which suggest that the axial/equatorial NMR shifts are unlikely to be resolved at low temperatures. These shifts have, however, been resolved in phosphorus trifluoride dichloride and dibromide (below).

The fluorine NMR spectrum of phosphorus tetrafluoride chloride in *iso*pentane solution is reported[1084] to show a single doublet at +23·5 p.p.m. from $CCl_3F$, with a P–F coupling of 1000 c/s. Since the NQR and vibrational data (above) indicate a trigonal bipyramidal structure of $C_{2v}$ symmetry with an equatorial chlorine atom, these values are presumably averages resulting from intramolecular exchange of axial and equatorial fluorine atoms.

The fluorine NMR spectrum of phosphorus trifluoride dichloride at 25°C.[1057, 1102–4] likewise shows a single fluorine chemical shift (−108 to 112 p.p.m. from trifluoroacetic acid) and a single PF coupling constant (1048–50 c/s). In solution below −120°C., however,[1077, 1102–3] the intramolecular fluorine exchange showed sufficiently for the signals from axial and equatorial fluorines to be resolved. Axial fluorines have a shift of −144 p.p.m. relative to trifluoroacetic acid.[1102] with a P–F coupling constant of 1023 c/s. Equatorial fluorines have a shift of −36 p.p.m. and a coupling constant of 1085 c/s. The axial-equatorial fluorine coupling is 142 c/s.[1102] The activation energy for intramolecular fluorine exchange has been calculated from the variation of the NMR spectrum with temperature, and found to be 7·2 kcal./mole.[1102]

Phosphorus difluoride trichloride shows a fluorine NMR spectrum[1057, 1077] with a simple doublet ($J_{PF} = 1045$ c/s) which does not change in appearance or in chemical shift (−191·8 p.p.m. relative to trifluoroacetic acid) from −22°C. to 140°C., indicating a single type of fluorine environment (axial) with no intramolecular fluorine exchange, in agreement with the vibrational and NQR data (above). In phosphorus fluoride tetrachloride the situation is similar,[1057, 1077] with a shift of −220·0 p.p.m. and a coupling constant of 996 c/s.[1057]

The proton and fluorine NMR spectra of trifluoro- and tetrafluorophosphorane have been studied.[1090] The results suggested that, at the lowest temperatures studied, both molecules are undergoing intramolecular fluorine exchange, the PH and PF coupling being retained. The temperature dependence of the spectra of trifluorophosphorane also suggests that this molecule is self-associated in the condensed state, in agreement with the conclusions from the vibrational data.[1088] The chemical shifts range from 2·68–3·10 $\tau$ and 29–48 p.p.m. relative to $CCl_3F$, depending on the temperature. The coupling constants are $J_{PH} = 841$–894 c/s, $J_{PF} = 770$–860 c/s.[1090] For tetrafluorophosphorane at higher temperatures an intermolecular exchange with PF bond breakage is proposed[1090] to explain the NMR data. Chemical shifts are 2·48–2·62 $\tau$ and 47·1–50·2 p.p.m. relative to $CCl_3F$. Coupling constants are $J_{PH}$ 1075–1093 c/s, $J_{PF}$ 892–980 c/s and $J_{HF}$ 91 c/s.[1090]

The fluorine NMR spectrum of phosphorus trifluoride dibromide[1102–4] shows resolution of the axial and equatorial fluorine signals below −120°C. Chemical shifts of axial and equatorial fluorines are −181 and −43 p.p.m. respectively relative to trifluoroacetic acid. PF coupling constants are 1141 c/s (axial) and 1143 c/s (equatorial). The $F_{ax.}F_{eq.}$ coupling constant is 124 c/s. The exchange activation energy was deduced to be 7·2 kcal./mole.[1102]

Phosphorus nuclear magnetic resonance spectra have been observed for $PF_5$ (vapour and liquid[225]) but the chemical shift has apparently not been reported. The phosphorus chemical shift in phosphorus fluoride tetrachloride is $-56 \pm 2$ p.p.m. relative to 85% orthophosphoric acid.[1057] The chemical shifts of trifluoro- and tetrafluorophosphorane are reported to be approximately +180 and +191 p.p.m. respectively from trimethyl phosphate.[1090] The phosphorus NMR spectrum of molecular phosphorus pentachloride has been determined,[171] and the spectrum of solid $PCl_5$ has been examined under high resolution by an elegant technique[256, 971] and the chemical shifts of the $PCl_4^+$ and $PCl_6^-$ ions resolved. Chemical shift data for the various phosphorus–chlorine containing species (relative to 85% orthophosphoric acid) are as follow: $PCl_3$ −219, $PCl_4^+$ −96, $PCl_5$ +80 and $PCl_6^-$ +281 p.p.m. The chemical shift in phosphorus oxychloride solution of the $PCl_6^-$ ion (in the compound $[Ph_2ClP{=}N{-}PCl_3]^+PCl_6^-$ is reported to be 305 p.p.m. relative to 85% $H_3PO_4$.[1109]

## TETRACHLOROPHOSPHONIUM COMPOUNDS

The crystal structure of tetrachlorophosphonium dichloroiodide, $PCl_4^+.ICl_2^-$, has been determined.[258] This compound crystallizes in a tetragonal two-molecule cell with $a=9{\cdot}26$ A., $c=5{\cdot}68$ A. The space group is $P\bar{4}2_1m$. The bond length of the $PCl_4^+$ tetrahedra is 1·98 A. which is in good agreement with that in solid $PCl_5$. An infra-red spectrum attributed to the tetrachlorophosphonium ($PCl_4^+$) ion has been resolved from the spectra of tetrachlorophosphonium tetrachloroborate, $PCl_4^+.BCl_4^-$, chlorotrifluoroborate, $PCl_4^+.BF_3Cl^-$, and chlorosulphonate, $PCl_4^+.SO_3Cl^-$.[259] The spectrum was partly assigned, but the band at 584 cm.$^{-1}$ is probably[1093] due to phosphoryl chloride. Some infra-red data have also been reported[1093] for tetrachlorophosphonium hexachloroantimonate, $PCl_4^+.SbCl_6^-$.

It has been proposed,[1110] on the basis of infra-red and other evidence, that the compound $PCl_5,AsCl_5$, previously formulated as $AsCl_4^+.PCl_6^-$, should in fact be formulated as $PCl_4^+.AsCl_6^-$.

## HEXAFLUOROPHOSPHATES

The crystal structures of hexafluorophosphoric acid, $HPF_6,H_2O$, and its sodium, potassium, ammonium, cæsium, rubidium, silver and thallium salts have been investigated.[341–6, 1112] There is large variation among the dimensions reported for the hexafluorophosphate ion in the different compounds. The acid[341] is cubic, space group *Im*3*m*, with a unit cell having $a=7{\cdot}679$ A. and containing two molecules. The six fluorine atoms lie around the phosphorus atom in an octahedral arrangement; the P–F distance is reported to be 1·73 A. The hexafluorophosphate ion lies at the centre of a cage of 24 oxygen atoms. The structure of sodium hexafluorophosphate monohydrate, which has been investigated in considerable detail,[342] is orthorhombic, space group *Imma*, with $a=7{\cdot}962$ A., $b=10{\cdot}594$ A., $c=6{\cdot}116$ A., $Z=4$. Four of the fluorine atoms lie in a plane around the phosphorus atom, with a P–F distance of 1·58 A.; the other two lie perpendicular to this plane on opposite sides of the phosphorus atom and 1·73 A. from it. In anhydrous sodium hexafluorophosphate, $NaPF_6$,[343] the sodium and hexafluorophosphate ions are arranged in a sodium chloride-like array, with the orientations of the hexafluorophosphate ions disordered, giving space group symmetry *Fm*3*m*. The unit cell has $a=7{\cdot}61$ A. and contains four molecules. The $\alpha$-form of potassium hexafluorophosphate, $KPF_6$,[344] which is stable below about $-25$°C., has a tetramolecular cubic cell with $a=7{\cdot}71$ A. Hexafluorophosphate ions with a P–F distance of 1·58 A. lie on a sodium chloride-like array of space group *Pa*3, as in sodium hexafluoroantimonate, disproving an earlier suggestion[345] that tetrafluorophosphonium ions are present. Ammonium and cæsium hexafluorophosphates are isomorphous with $\alpha$-potassium hexafluorophosphate.[344] Thallous hexafluorophosphate is also cubic with $a=7{\cdot}94$ A.[346] Other hexafluorophosphate compounds for which *X*-ray data have been reported[154] are hexammine-cobaltous hexafluorophosphate, $Co(NH_3)_6(PF_6)_2$, and hexammine-nickel hexafluorophosphate, $Ni(NH_3)_6(PF_6)_2$, (both are cubic with the potassium hexachloroplatinate, $K_2PtCl_6$, structure, $Z=4$, and $a=11{\cdot}942$ and 11·912 A. respectively), and hexammine-cobaltic hexafluorophosphate, $Co(NH_3)_6(PF_6)_3$, which is cubic with the ammonium hexafluoroferrate, $(NH_4)_3FeF_6$, structure; the unit cell has $a=11{\cdot}670$ A., with space group *Fm*3*m*, and contains four molecules. Tetrachlorophosphonium hexafluorophosphate, $[PCl_4]^+[PF_6]^-$, is reported[718] to be isomorphous with solid phosphorus pentachloride, $[PCl_4]^+[PCl_6]^-$.

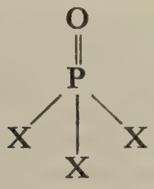
The wide-line fluorine NMR spectra of sodium, potassium, rubidium and cæsium hexafluorophosphates have been investigated from 77 to 400°K.[1113] In all cases the hexafluorophosphate ion was found to be reorientating at random about its octahedral axes above 200°K. The ease of reorientation increases with cation size and in the case of the cæsium salt the line was still narrow at 77°K. The line shapes were remarkably sensitive to physical state and, in the case of the rubidium salt, the thermal history of the samples.[1113]

The Raman and infra-red spectra of the hexafluorophosphate ion have been reported.[260-2, 838] Potassium hexafluorophosphate shows peaks in the infra-red spectrum at 840 and 555 cm.$^{-1}$ [262, 838] A strong peak, which has been assigned[261] to the symmetrical 'breathing' frequency of the hexafluorophosphate ion, appears in the Raman spectrum of aqueous ammonium hexafluorophosphate at 741 cm.$^{-1}$ [260-1] In a melt of potassium hexafluorophosphate this band occurs at 735 cm.$^{-1}$, and other bands appear at 462 and 563 cm.$^{-1}$ [838] A P–F stretching force constant of 4·3 millidynes/A. was obtained.[838] The infra-red spectrum of the solid complex of nitryl fluoride and phosphorus pentafluoride has been interpreted[534] as indicating a structure corresponding to nitronium hexafluorophosphate, $NO_2^+.PF_6^-$. A band at 855 cm.$^{-1}$ was assigned to the hexafluorophosphate ion, in agreement with the spectrum of potassium hexafluorophosphate.

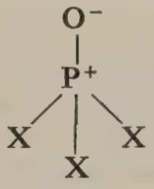
The phosphorus and fluorine nuclear magnetic resonance spectra of the hexafluorophosphate ion have been reported for the acid and the potassium salt. The phosphorus chemical shift is 118 p.p.m. (relative to 85% orthophosphoric acid),[110] the fluorine shift −5·5 p.p.m. (relative to trifluoroacetic acid), and the phosphorus–fluorine spin-spin coupling 713 c/s.[225, 634] The observed coupling pattern confirms the existence of the hexafluorophosphate ion in solution and indicates that all the fluorine atoms are equivalent and that the ion has $O_h$ symmetry. The e.s.r. spectra of $\gamma$-irradiated ammonium and potassium hexafluorophosphates have been investigated.[1113-5] The radicals $N_2H_4^+$, $PF_2$ and $PF_4$ have been identified. In the radical $PF_4$, the unpaired electron was found to cause a distortion from tetrahedral symmetry,[1114] although the average configuration at room temperature was tetrahedral, with all fluorines equivalent, because of intramolecular inversion.[1116]

## PHOSPHORYL AND THIOPHOSPHORYL HALIDES

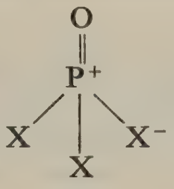
The nature of the P–O bond in phosphoryl compounds, as determined from physical data such as interatomic distances, dissociated energies, bond angles, dipole moments and force constants, has been discussed in some detail.[784] In most cases the structure is regarded as a resonance hybrid mainly of structures (I) and (II) below. When strongly electronegative substituents are present, the structure is thought to be mainly (I) with a small contribution from (III), while with amino and other mesomeric groups the structure may be mainly (II) with some (IV).



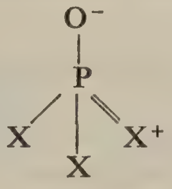
(I)



(II)



(III)



(IV)

The structures of most of these molecules have been determined by electron diffraction[186, 263-6]; they all have an approximately tetrahedral configuration. Structural data have also been obtained from microwave spectra.[267-9] The crystal structure of $PSBr_3$ has been determined.[270-1] The crystal is cubic with an eight-molecule cell, $a = 11{\cdot}03$ A., space group *Pa*3. Structural data for the phosphoryl and thiophosphoryl halides are summarized in Table VI. The microwave spectra have been investigated by several other workers[190, 192, 272-4, 638] and the dipole moment of $POF_3$ (1·77 ± 0·02 D) has been determined.[190]

The phosphoryl and thiophosphoryl halides have been very extensively investigated by Raman[199, 202, 210, 212, 275-85, 334, 1121, 1125, 1127] and infra-red[215, 217, 286, 664, 1120-2, 1124-30] spectroscopy as follows: phosphoryl fluoride,[215, 217, 275-6, 1124] chloride,[199, 202, 215, 275, 277-9, 664] bromide,[215, 279-80] chloride difluoride,[275-6, 1121, 1127-8] bromide difluoride,[275-6, 1121-2] fluoride dichloride,[275, 281, 1121, 1128] fluoride dibromide,[212, 275, 281, 1121-2] fluoride chloride bromide,[281] bromide dichloride,[279]

*Table VI.—Structural Data for Phosphoryl and Thiophosphoryl Halides*

chloride dibromide[279] and thiophosphoryl fluoride,[276, 1120–1, 1127, 1129] chloride,[215, 278, 282–3, 286, 334, 664, 1127] bromide,[283, 1121] chloride difluoride,[215, 276, 1121, 1127, 1130] bromide difluoride,[276, 1121, 1130] fluoride dichloride,[284, 1125–7] fluoride dibromide,[284, 1126] fluoride chloride bromide,[284] bromide dichloride,[283] and chloride dibromide.[283] The results of these investigations are consistent with the data from electron diffraction and microwave experiments; the Raman and infra-red bands are all coincident with experimental error, allowing for phase changes, as should be the case for molecules of $C_{3v}$ or lower symmetry. It has recently been pointed out[1121] that the large differences in PO stretching frequency between the liquid and gaseous state in these compounds has frequently not been taken into proper account in frequency–electronegativity relationships,[773] and also[1121] that the P=S stretching frequency is influenced more by the degree of coupling with PF and PCl stretching motions than by bond order and electronegativity considerations. The observed vibrational frequencies of these compounds are given in Table VII.

The force constants of phosphoryl fluoride,[287, 825, 848, 1123] chloride,[287–9, 848, 1123] bromide[280, 287, 289, 1123] and thiophosphoryl fluoride,[825, 1123] chloride[287, 289, 1123] and bromide[289, 825, 1123] have been calculated, and the results are given in Table VIII. An attempt has been made[828] to produce a force field applicable to $POF_3$, $POCl_3$, $PSF_3$ and $PSCl_3$ by making the assumption that analogous bonds in the different molecules have identical force constants. A fit was only obtained by using an excessive number

The Verdet constant of phosphoryl chloride at 5780 A. is $2{\cdot}18 \times 10^{-2}$.[198] The ultraviolet spectrum of phosphoryl chloride has been reported[194, 1017] as showing a broad maximum around 196–185 mμ.[1017]

The nuclear magnetic resonance spectra of phosphoryl fluoride,[225, 832] chloride,[110, 171, 226, 290, 612, 833] bromide,[226, 612, 833] fluoride dichloride, chloride difluoride,[110, 225, 290–1] fluoride dibromide, bromide difluoride,[1122] bromide dichloride and chloride dibromide,[833] thiophosphoryl fluoride,[1131] chloride difluoride,[1131] bromide difluoride,[1131] chloride,[226, 612, 833] bromide,[226, 833] chloride dibromide and bromide dichloride[833] have been examined. Phosphorus chemical shifts (relative to 85% orthophosphoric acid) are as follow:

(a) Relative to trifluoroacetic acid.
(b) Relative to fluorotrichloromethane.

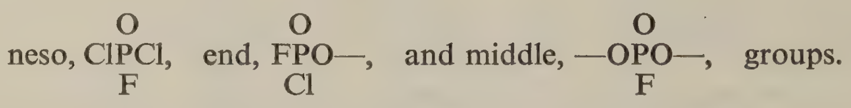
The chlorine nuclear quadrupole resonance of phosphoryl chloride (at 77°K.) and fluoride dichloride (at 20°K.) have been investigated.[228] In both cases two lines per chlorine isotope were observed, indicating two non-equivalent chlorine positions in the lattice.

The infra-red and $^1H$ and $^{19}F$ NMR spectra of hydrothiophosphoryl difluoride, $SPF_2H$, have been reported.[1135] The low $\tau$-value (1·93) of the proton resonance and the large phosphorus–proton spin-spin coupling (725 c/s), as well as the presence of PH stretching and bending vibrations and a P=S stretching vibration at 2458, 1016 and 705 $cm.^{-1}$ in the infra-red spectrum, support the proposed structure based on quinquevalent phosphorus. The fluorine chemical shift is +46·1 p.p.m. relative to $CCl_3F$ and the remaining coupling constants are $J_{PF} = 1153·3$ c/s, $J_{PH} = 99·0$ c/s.

## PYROPHOSPHORYL HALIDES AND RELATED COMPOUNDS

The Raman and $^{19}F$ NMR spectra of pyrophosphoryl fluoride, $P_2O_3F_4$, have been investigated.[901] The NMR spectrum shows a simple doublet, suggesting a symmetrical structure. The Raman spectrum shows 19 lines assignable to fundamentals, and some are depolarized, indicating symmetry in the molecule. The spectra are therefore consistent with the structure $F_2(O)POP(O)F_2$.

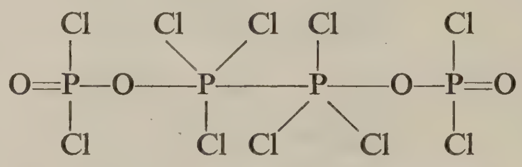
The infra-red[902] and $^{31}P$ NMR[1136–7] spectra of pyrophosphoryl dichloride difluoride, $P_2O_3Cl_2F_2$, have been reported.[1136] A symmetrical doublet (chemical shift +19 p.p.m. relative to 85% $H_3PO_4$ [1136]) indicates that the molecule has the symmetrical structure ClF(O)POP(O)ClF. The spectrum has been analysed as an $A_2X_2$ system[1137] with the following parameters $J_{P_1F_1}=J_{P_2F_2}=1121$ c/s, $J_{P_1P_2}=21$ c/s, $J_{P_1F_2}=J_{P_2F_1}=2$ c/s $>J_{F_1F_2}\geqslant 0$, with the sign of $J_{P_1F_1}$ opposite to that of $J_{P_1F_2}$. An NMR study[1137] has shown that this compound slowly reorganizes at 50°C. to a combination of



$$\text{neso, } \mathrm{Cl\underset{F}{\overset{O}{P}}Cl},\quad \text{end, } \mathrm{F\underset{Cl}{\overset{O}{P}}O}\text{—},\quad \text{and middle, } \text{—}\mathrm{O\underset{F}{\overset{O}{P}}O}\text{—},\quad \text{groups.}$$

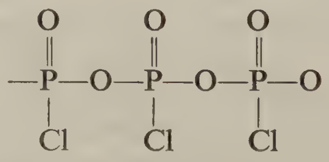
NMR parameters of these groups are as follows (relative to trifluoroacetic acid and 85% $H_3PO_4$): neso, $\delta_F=-70{\cdot}2$, $\delta_P=-0{\cdot}8$, $J_{PF}=1179$ c/s; end, $\delta_F=-41{\cdot}0$, $\delta_P=+19{\cdot}0$, $J_{PF}=1121$ c/s; middle, $\delta_F=-9{\cdot}8$, $\delta_P=+44{\cdot}0$, $J_{PF}=1050$ c/s.

The infra-red and Raman spectra of pyrophosphoryl chloride, $P_2O_3Cl_4$, have been determined.[292, 336] The Raman spectrum[336] showed 18–19 lines, with a single polarized phosphoryl band at 1312 cm.$^{-1}$, indicating that the phosphoryl groups are very weakly coupled and must be on different phosphorus atoms. A number of depolarized lines indicated that the molecule had some symmetry. The structure is evidently $Cl_2(O)POP(O)Cl_2$. Recent work[901] on the infra-red spectrum led to some reassignment of the earlier data. The Raman and infra-red spectra of a compound[292, 335, 337, 937–8] having the empirical formula $P_4O_4Cl_{10}$ have been investigated.[292] Infra-red absorption attributed to P=O, P–O–P, and P–Cl linkages led to the suggestion that the compound was sym-bis(dichlorophosphato)hexachlorodiphosphorane,



The phosphorus nuclear magnetic resonance spectrum was also reported as indicating a symmetrical ABBA type of structure. Recent work, however,[933] suggests that the compound is in fact $P_2NOCl_5$ (see page 506).

In a nuclear magnetic resonance investigation[837] of a series of polyphosphoryl chlorides over a range of composition, $^{31}P$ resonance peaks at $+50\pm 3$, +28–32, +7–11 p.p.m. (relative to 85% orthophosphoric acid) were assigned to branching, middle and end groups of the form $(O\frac{1}{2})_3PO$, $(O\frac{1}{2})_2P(O)Cl$ and $O\frac{1}{2}P(O)Cl_2$ respectively, where $(O\frac{1}{2})$ denotes an oxygen atom shared with an adjacent phosphorus atom. Pyrophosphoryl chloride itself was found to have a chemical shift of 9·9 p.p.m. The infra-red spectrum of a polyphosphoryl chloride of composition $PO_2Cl$ has been interpreted in terms of a structure[1134]:



$$-\underset{\underset{\mathrm{Cl}}{|}}{\overset{\overset{\mathrm{O}}{\|}}{\mathrm{P}}}-\mathrm{O}-\underset{\underset{\mathrm{Cl}}{|}}{\overset{\overset{\mathrm{O}}{\|}}{\mathrm{P}}}-\mathrm{O}-\underset{\underset{\mathrm{Cl}}{|}}{\overset{\overset{\mathrm{O}}{\|}}{\mathrm{P}}}-\mathrm{O}$$

The infra-red and $^{31}P$ NMR spectra of a compound described as $P_2S_2I_4$ were interpreted[1138] as indicating the structure $I_2(S)PP(S)I_2$. Bands were assigned to

P=S and $PI_2$ stretching at 725 and 329 (antisym.) and 301 (sym.) cm.$^{-1}$ respectively, and the NMR spectrum shows a singlet peak at $-106$ p.p.m. relative to 85% $H_3PO_4$.

## Adducts of Phosphoryl Halides

The interaction of phosphoryl chloride with various acceptor molecules has been investigated by infra-red and Raman spectroscopy.[293-4] The decrease in frequency of the phosphoryl vibration has been correlated with the interaction of the donor function of the oxygen with different acceptor molecules. The interaction of phosphorus oxychloride with arsenic trichloride or antimony trichloride is considered to be dipolar, while that with stannic chloride or antimony pentachloride leads to adduct formation by an acceptor-donor mechanism.[294] A Raman-effect study of the phosphoryl chloride–bismuth trichloride system[654] suggested that it is of a similar type to the complexes with arsenic and antimony trichlorides. The crystal structure of the phosphoryl chloride–stannic chloride adduct, $2POCl_3,SnCl_4$ [295] shows that both phosphoryl chloride molecules are bonded in the same way to the stannic chloride, discounting an earlier suggestion[293] that one is free.

The structures of the phosphoryl chloride–aluminium trichloride and phosphoryl chloride–gallium trichloride adducts have been investigated by Raman and infra-red spectroscopy.[296] The alternatives considered were a dissociated structure, an ionic structure of the type $POCl_2^+.AlCl_4^-$, and a co-ordinated structure of the type $Cl_3POAlCl_3$. It was concluded that the co-ordinated type of structure was probably correct.

Raman spectroscopic investigations of the phosphoryl chloride–antimony pentachloride system[293-4, 297, 655] suggested that the structure was ionic, with oxydichlorophosphonium, $POCl_2^+$, ions and hexachloroantimonate, $SbCl_6^-$, ions in both liquid and solid. This suggestion has been confirmed for the liquid by potentiometric measurements,[298] but has been disproved for the solid by the crystal structure determination[299, 300, 1140] which shows a co-ordinated structure with no transfer of a chlorine ion. The structure is orthorhombic with a four-molecule cell, $a=8{\cdot}06$, $b=16{\cdot}42$, $c=8{\cdot}93$ A. The space group is *Pnmb* and bond lengths are P–O = 1·52 A., Sb–O = 2·11 A.; the angle POSb = 146·5°. The adducts of tantalum and niobium pentachlorides with phosphoryl chloride are isostructural with that above, having $a=8{\cdot}1$, $b=16{\cdot}4$, $c=9{\cdot}0$ A.[1141] and $a=8{\cdot}07$, $b=16{\cdot}23$, $c=8{\cdot}83$ A. respectively.[1142]

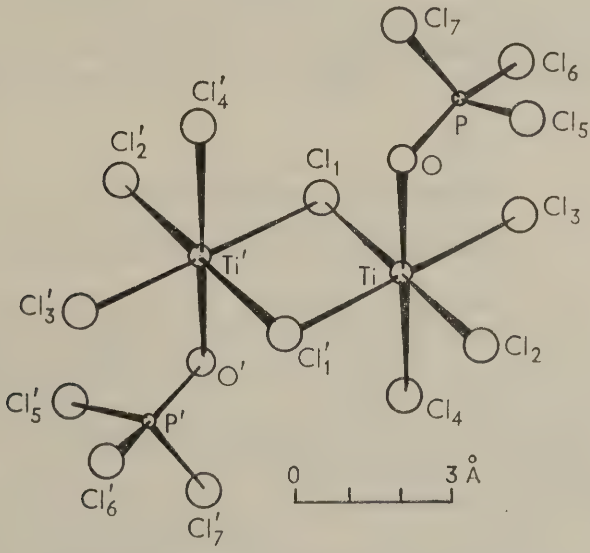


FIG. 3.—The molecule of the addition compound $(TiCl_4,POCl_3)_2$

The infra-red spectra of adducts of phosphoryl chloride with boron trifluoride and boron trichloride have been reported[259] and suggest co-ordination structures $Cl_3PO \rightarrow BF_3$ and $Cl_3PO \rightarrow BCl_3$.

Infra-red and Raman spectra of a series of adducts of phosphoryl chloride and bromide with boron trichloride and tribromide, aluminium trichloride and tribromide, and gallium, indium, and thallium trichlorides[1139] were interpreted as indicating co-ordination through the oxygen atoms, from the observed reductions in PO stretching frequency.

The crystal structure of the adduct of titanium tetrachloride and phosphorus oxychloride, $(TiCl_4,POCl_3)_2$, has been determined.[653] The structure is orthorhombic, with $a = 12{\cdot}42$, $b = 12{\cdot}76$, $c = 13{\cdot}51$ A., space group *Pbca*. Two monoclinic modifications, with cell dimensions $a = 9{\cdot}9$, $b = 8{\cdot}7$, $c = 12{\cdot}3$ A., $\beta = 98°$, and $a = 13{\cdot}9$, $b = 12{\cdot}1$, $c = 19{\cdot}1$ A., $\beta = 105°$, were also reported. The orthorhombic structure is built up of dimeric molecules $(TiCl_4,POCl_3)_2$ with double chlorine bridges between the two titanium atoms of the dimer (Fig. 3). The co-ordination around the titanium atoms is octahedral, with the oxygen of the phosphoryl chloride acting as donor. The approximately tetrahedral configuration of the phosphoryl chloride is preserved. Bond lengths are P–O 1·44, Ti–O, 2·10, P–Cl 1·96 (av.), Ti–Cl 2·20–2·54 A., and the angle P–O–Ti = 152°.

The crystal structure of the adduct of tin tetrachloride with two moles of phosphoryl chloride, $SnCl_4,2POCl_3$, has been determined.[1143] The structure is orthorhombic, space group *Pnnm*, with $a = 14{\cdot}53$, $b = 14{\cdot}24$, $c = 8{\cdot}02$ A. The structure contains discrete molecules of $SnCl_4,2POCl_3$ in which the tin atom is octahedrally co-ordinated to the four chlorines and two $OPCl_3$ groups which are *cis*- to each other. The $OPCl_3$ groups are crystallographically non-equivalent, but preserve their tetrahedral form. Bond lengths are: Sn–O, 2·30, 2·25; P–O, 1·41, 1·49; PCl 1·96 (av.) A., and the Sn–O–P angles are 144° and 151°. The adduct $TiCl_4,2POCl_3$ is isostructural with $SnCl_4,2POCl_3$.[1141]

The chlorine nuclear quadrupole resonance spectra of the adducts $SbCl_5,POCl_3$, $SnCl_4POCl_3$ and $(TiCl_4,POCl_3)_2$ have been reported.[1144] Signals were assigned on the basis of the crystal structures. The temperature dependence of the spectra suggested that the $PCl_3$ groups were capable of restricted rotation.

The infra-red spectra of adducts of pyrophosphoryl chloride with antimony pentachloride and tin tetrachloride, $2SbCl_5,P_2O_3Cl_4$, and $SnCl_4,P_2O_3Cl_4$, have been reported.[1145]

## OXIDES OF PHOSPHORUS

### Phosphorus Pentoxide, $P_4O_{10}$

The structure of the phosphorus pentoxide molecule has been determined by electron diffraction.[303–4, 378, 1150] The cage-like structure (Fig. 4) has four phosphorus atoms, each carrying an oxygen atom, at the corner of the cage. Each phosphorus is bonded to two of the six oxygens which lie in the walls of the cage. Recent electron diffraction work[1150] has led to more accurate data, as follows: PO $1{\cdot}604 \pm 0{\cdot}003$ A., PO (apical) $1{\cdot}429 \pm 0{\cdot}004$ A., POP $123{\cdot}5 \pm 0{\cdot}7°$.

The condensed phases of phosphorus pentoxide include at least three crystalline forms, glasses and two liquid forms.[305–7] The *H* (hexagonal) form[308] consists of discrete $P_4O_{10}$ molecules having the same form as those in the gaseous state, and similar dimensions. The rhombohedral unit cell has $a = 7{\cdot}43$ A., $\alpha = 87°$, contains two molecules of $P_4O_{10}$, and the space group is $R3_c$. This structure has recently been refined,[744] resulting in bond lengths of $1{\cdot}60 \pm 0{\cdot}02$ A. for P–O (internal) and $1{\cdot}40 \pm 0{\cdot}02$ A. for P–O (apical), with a P–O–P angle of $124\frac{1}{2}°$. The polymeric *O* (orthorhombic) form of phosphorus pentoxide has a cell[309] with $a = 16{\cdot}3$ A., $b = 8{\cdot}12$ A., $c = 5{\cdot}25$ A., containing eight molecules, with space group *Fdd*2. The structure[309] consists of infinite sheets of linked $PO_4$ tetrahedra which form a series of interlocking rings (Fig. 5). There are no discrete molecules.

The stable, *O′*, form of $P_4O_{10}$ [310] also has a polymeric structure. The orthorhombic

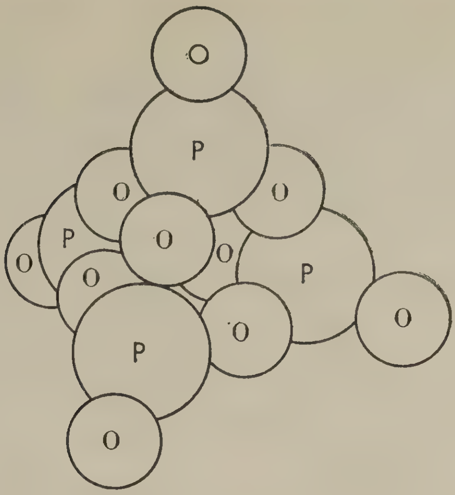

FIG. 4.—The structure of $P_4O_{10}$

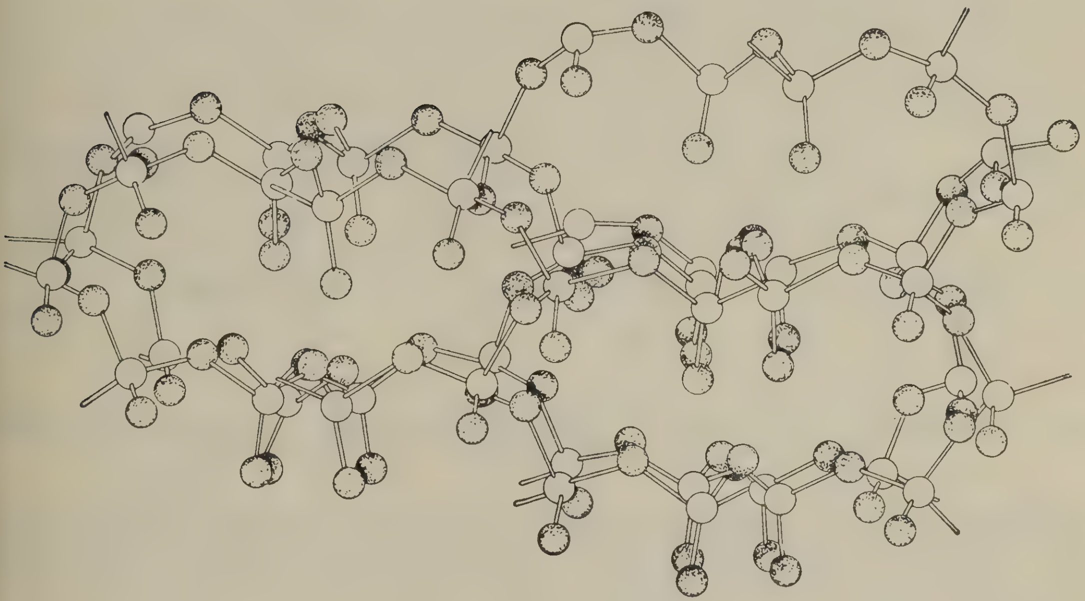

FIG. 5.—Structure of the *O*-form of phosphorus pentoxide. The white balls represent phosphorus atoms and the shaded balls oxygen atoms

unit cell contains 4 molecules of $P_2O_5$ and has $a=9{\cdot}23$ A., $b=7{\cdot}18$ A., $c=4{\cdot}94$ A. The space group is *Pnam*. In this form of $P_2O_5$ the $PO_4$ tetrahedra form a system of corrugated sheets (Fig. 6).

When the *H* form is melted, a limpid mobile liquid is obtained, presumably composed of $P_4O_{10}$ molecules. When the other forms are melted a viscous liquid is obtained, probably with a polymeric structure. The limpid liquid eventually polymerizes to give the more viscous form.[307]

The Raman[319] and infra-red[215, 322, 664] spectra of the *H* form of phosphorus pentoxide have been determined. The spectra may be satisfactorily assigned on the basis of $T_d$ molecular symmetry, in agreement with the *X*-ray structure. The symmetric ($A_1$) apical P=O breathing frequency was assigned at 1417 cm.$^{-1}$ and the other $A_1$ frequencies were assigned at 721 and either 424 or[1151] 559 cm.$^{-1}$ Strong infra-red bands at 1390, 1015, 764 and 573 or[1151] 424 cm.$^{-1}$, were assigned to $F_2$ vibrations, and the other $F_2$ vibrations to Raman bands at 329 and 257 or[1151] 278 cm.$^{-1}$ *E* vibrations were assigned at 952, 650 or[1151] 329, and 278 or[1151] 257 cm.$^{-1}$ [319, 322] Force constants have been estimated,[320, 1151] and values of $F_{PO}$ (bridge) $= 3{\cdot}9$

and $F_{PO}$ (apical) = 10·84 millidynes/A. proposed.[1151] Recent work[1152] on the infra-red and Raman spectra has led to some revision of the earlier assignments. The infra-red spectrum was obtained as far as 200 cm.$^{-1}$ and showed the three lowest $F_2$ fundamentals to be 573, 424 and 278 cm.$^{-1}$ Weak lines at 650 and 329 cm.$^{-1}$ in the Raman spectrum were not confirmed. The Raman counterpart of the infra-red band at 573 was observed separately from the strong band at 556, indicating that the latter was the remaining $A_1'$ fundamental. The band at 257 cm.$^{-1}$ is clearly an $E''$ fundamental but the assignment of the others remains uncertain. Force constants have been calculated as follows: $F_{PO}$ (bridge) 5·26, $F_{P=O}$ (apical) 10·95 millidynes A.[1152] Phosphorus pentoxide shows no ultra-violet absorption as far as 2100 A.,[311] and complete absorption beyond 2200 A.[194]

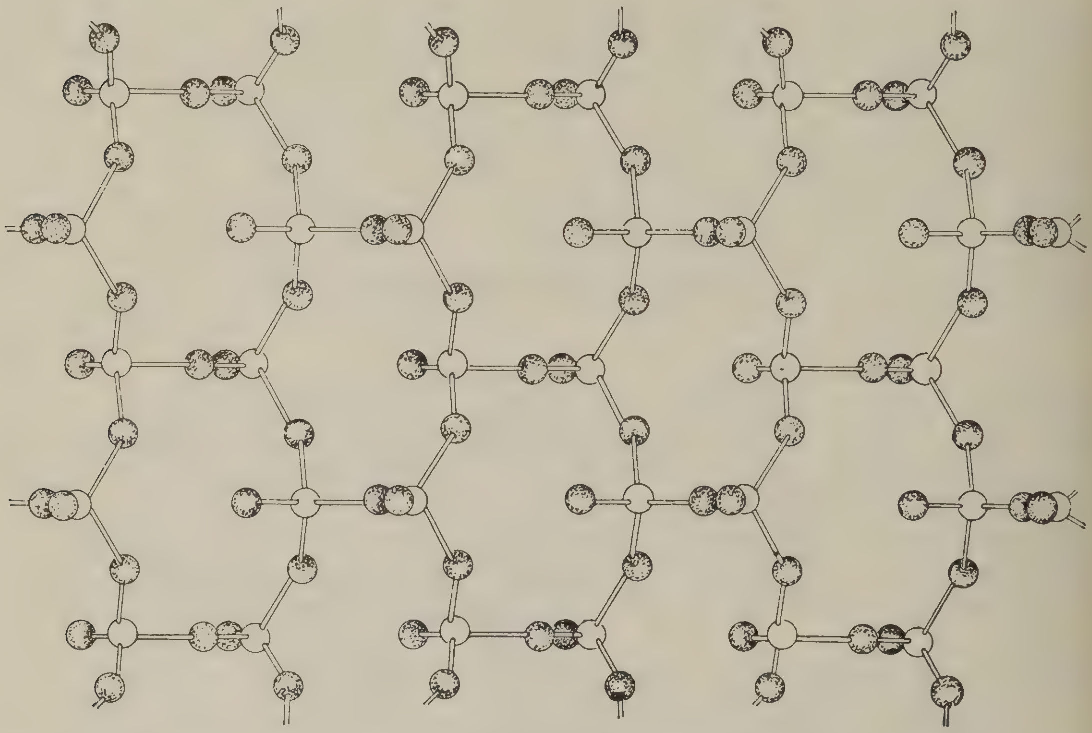

FIG. 6.—Structure of the *O′*-form of phosphorus pentoxide. The white balls represent phosphorus atoms and the shaded balls oxygen atoms

## Phosphorus Trioxide, $P_4O_6$

The structure of the phosphorus trioxide molecule has been determined by electron diffraction.[303-4] The molecule is cage-like, similar to that of phosphorus pentoxide with the four apical oxygens removed (Fig. 7). These results confirm those of early

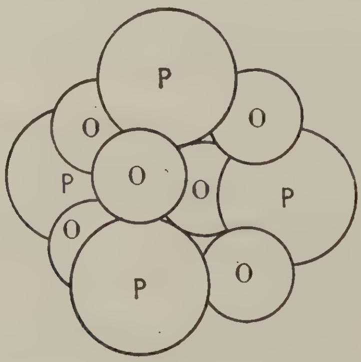

FIG. 7.—The structure of $P_4O_6$

molecular weight determinations.[313] The P–O bond length is 1·65±0·02 A., and the angles, P–O–P = 127·5±1°, O–P–O = 99±1°. The Raman[314–6] and infra-red[542] spectra have been determined, and assigned on the basis of $T_d$ symmetry, in agreement with electron diffraction results. The two totally symmetric ($A_1$) vibrations were thought[314, 1151] to be accidentally degenerate at 613 cm.$^{-1}$ $F_2$-type vibrations were assigned to strong infra-red bands, which also appear in the Raman spectrum, at 911 and 636 cm.$^{-1}$ and to Raman bands at 302 and 407 cm.$^{-1}$ $E$-type modes were assigned to Raman bands at 1029 and 465 cm.$^{-1}$ [314, 542] or 723 and 302 cm.$^{-1}$ [1151] The P–O stretching force constant has been estimated at 4·75 [320] or 3·8[1151] millidynes/A. These results refer to the Raman spectrum of the liquid and the infra-red spectrum of the solid; an incomplete Raman spectrum of the solid[314] is similar to that of the liquid, and it is clear that the solid contains discrete $P_4O_6$ molecules. A different polymorph of solid phosphorus trioxide has, however, been prepared,[315] possibly having a polymeric structure analogous to the orthorhombic forms of phosphorus pentoxide.

Recent work[1153] has led to some revision of these assignments. Far infra-red spectra (to 200 cm.$^{-1}$) confirm the assignment of the $F_2$ fundamentals at 919, 643, 402 and 302 cm.$^{-1}$ A second polarized Raman band at 563 cm.$^{-1}$ was assigned to the second $A_1$ fundamental, which is not therefore coincident with 613 cm.$^{-1}$ The lines previously reported at 370 and 465 cm.$^{-1}$ were found to be due to dissolved phosphorus and the band at 1029 cm.$^{-1}$ was not confirmed. Proposed assignments for the two $E$ modes were 691 and 285 cm.$^{-1}$ Force constants were calculated, the value for the PO valence stretching constant being 3·41.[1153]

The $^{31}P$ NMR spectrum of $P_4O_6$ [1154] gives a single very sharp peak, and its use as a standard for referencing $^{31}P$ NMR spectra has been proposed.[1154] The chemical shift from 85% orthophosphoric acid is −112·5±0·1 p.p.m.[1154]

NMR spectra of a number of addition compounds of $P_4O_6$ have been reported, as follows:

| Compound | Chemical shifts | | H | $J_{POP}$ | Reference |
|---|---|---|---|---|---|
| | co-ord. P[(a)] | unco-ord. P[(a)] | | c/s | |
| $P_4O_6,BH_3$ | −90·4 | −118·2 | 9·3τ | 27·5 | 1155 |
| $P_4O_6,2BH_3$ | −98·7 | −119·2 | 9·35 | 24·7 | 1155–6 |
| $P_4O_6,3BH_3$ | −103·6 | −114·6 | — | 21 | 1155 |

[(a)] p.p.m. relative to 85% $H_3PO_4$.

The ultra-violet absorption spectrum of phosphorus trioxide has been determined[311]; there is continuous absorption, possibly due to solid phosphorus pentoxide, in the visible region, as well as two-band systems which have been partly analysed.

### 'Phosphorus Tetroxide', $(PO_2)_n$

Vapour density measurements on this oxide[317] indicated molecular weights in the range 293–721, suggesting a cage-like molecule larger than that of phosphorus pentoxide.[318] The electron diffraction pattern has been reported[303] to be almost identical with that of phosphorus pentoxide.

Recent work[1157] has shown that there are two phases around this composition, and the crystal structures of these phases have been determined.[1158–9] The α-phase,[1157] consisting of $P_4O_9$ molecules, can accept up to 90% of $P_4O_8$ molecules without change in structure. The β-phase of $P_4O_8$ molecules can similarly accept considerable substitution of $P_4O_7$ molecules.

The structure[1158] of $P_4O_9$ is rhombohedral, with $a = 10{\cdot}05$ A. and $\alpha = 57{\cdot}0°$, space group $R\bar{3}c$. The alternative monoclinic cell has $a = 9{\cdot}66$, $b = 10{\cdot}05$, $c = 13{\cdot}90$ A., $\alpha = 93{\cdot}0°$. The $P_4O_9$ resembles a molecule of $P_4O_{10}$ with one apical oxygen removed. This structure has recently been refined[1150] and more accurate bond lengths obtained. The molecular dimensions, which resemble those of $P_4O_{10}$ for the $P_V$ part of the molecule and $P_4O_6$ for the $P_{III}$ part, are as follows: PO apical $1{\cdot}418 \pm 0{\cdot}014$, $P_V$–O–($P_{III}$) $1{\cdot}605 \pm 0{\cdot}017$, $P_{III}$–O $1{\cdot}661 \pm 0{\cdot}013$, $P_V$–O–($P_V$) $1{\cdot}590 \pm 0{\cdot}012$ A., $P_VOP_V$ $122{\cdot}8 \pm 0{\cdot}7$, $P_V$–O–$P_{III}$ $114{\cdot}3/114{\cdot}9 \pm 0{\cdot}8$, $OP_{III}O$ $96{\cdot}7 \pm 0{\cdot}7$, $(P_V)OP_VO(P_{III})$ $102{\cdot}5/103{\cdot}1 \pm 0{\cdot}8$, $(P_V)OP_VO(P_V)$ $100{\cdot}9 \pm 0{\cdot}8°$.

The structure[1159] of $P_4O_8$ is monoclinic with $a = 9{\cdot}66$, $b = 10{\cdot}10$, $c = 6{\cdot}93$ A., $\beta = 96{\cdot}8°$, $Z = 4$, space group $C2/c$. The $P_4O_8$ and $P_4O_7$ molecules resemble $P_4O_{10}$ molecules with two or three apical oxygens removed. Molecular dimensions are: P=O 1·40, $P_V$–O–($P_V$) 1·60, $P_V$–O–($P_{III}$) 1·58, $P_{III}$–O–($P_V$) 1·65, $P_{III}$–O–($P_{III}$) 1·61 A., $P_VOP_V$ 122°, $P_VOP_{III}$ 124/126°, $P_{III}OP_{III}$ 132°.

$P_4O_9$ molecules have been reported to be in vapour equilibrium with $P_4O_{10}$ in a mass-spectrometric study[1160] of commercial phosphorus pentoxide.

### Phosphorus Suboxides

There is little structural information on these products, which are amorphous materials of variable composition. A compound of composition $P_4O$ has been investigated[953] by *X*-ray methods and the radial distribution function for the phosphorus atoms determined. A structure was proposed, in agreement with the radial distribution function, in which the phosphorus atoms are linked into sheets of 6-membered non-planar fused rings. These sheets are stacked together in a staggered configuration giving two types of distorted cubic polyhedra (shown schematically in the figure), each having six edges of P–P bonds and six of Van der Waals contacts. The first type consists of a non-planar six-membered ring with Van der Waals contacts to single phosphorus atoms in sheets above and below. The second type consists of two network points ($P_4$ groups) in adjacent sheets, linked by Van der Waals contacts. The second type of polyhedron is said to be bigger and to be the preferred oxygen site.

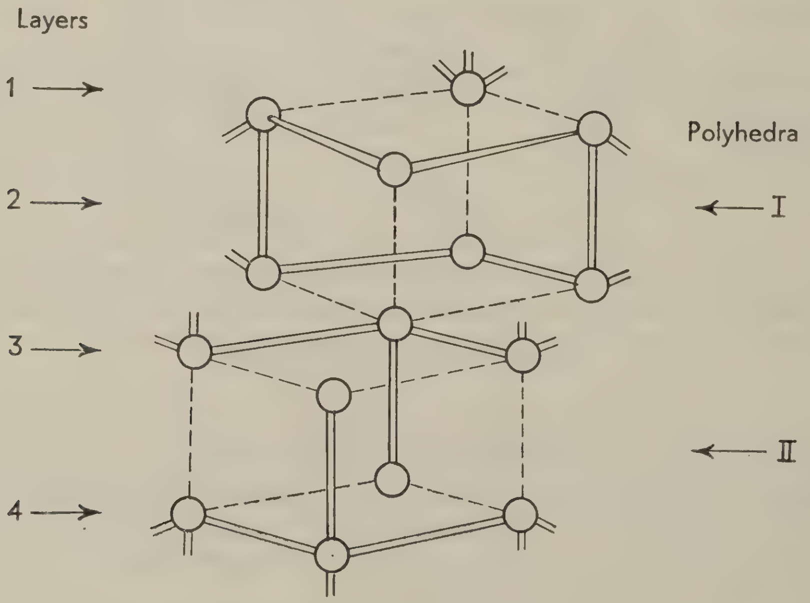

FIG. 8.—Arrangement of phosphorus atoms in $P_4O$

## PHOSPHORUS SULPHIDES

The crystal structure of the crystalline form of tetraphosphorus decasulphide, $P_4S_{10}$, has been determined.[323] The molecular structure (Fig. 9) is similar to that of phosphorus pentoxide. Molecular parameters from a recent[1163] refinement of the structure are: P–S (cage) $2{\cdot}097 \pm 0{\cdot}015$ A., P–S (apical) $1{\cdot}908 \pm 0{\cdot}015$ A., PSP = 109·8°, S=P–S = 109·6°, S–P–S = 109·3°. The crystal is triclinic, with a two-molecule cell having[1163] $a=9{\cdot}072\pm0{\cdot}003$, $b=9{\cdot}199\pm0{\cdot}003$, $c=9{\cdot}236\pm0{\cdot}003$ A., $\alpha=92{\cdot}58\pm0{\cdot}07°$, $\beta=100{\cdot}90\pm0{\cdot}1°$, $\gamma=110{\cdot}18\pm0{\cdot}07°$. The space group is $P\bar{1}$. The $^{31}$P NMR spectrum of the rapidly rotating solid[971] shows a single peak at $-45$ p.p.m. relative to 85% $H_3PO_4$.

The crystal structure of phosphorus heptasulphide, $P_4S_7$, has also been determined[323, 324] and recently refined.[1163] The molecule has an unusual cage structure with two triply bonded and two quadruply bonded phosphorus atoms (Fig. 9). The molecular symmetry approximates to $C_{2v}$. The bond lengths (all $\pm0{\cdot}007$ A., see Fig. 9) are:

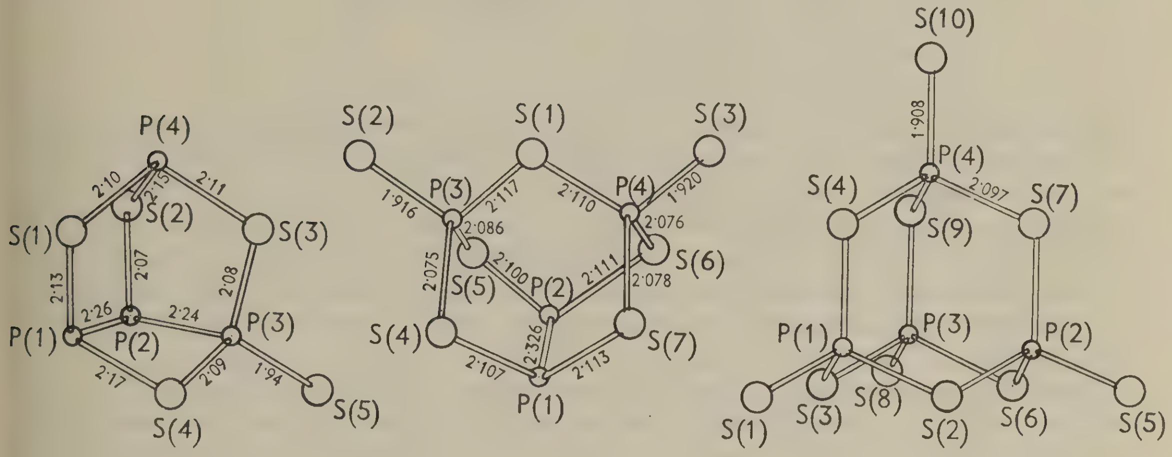

FIG. 9.—From left to right: molecules of $P_4S_5$, $P_4S_7$ and $P_4S_{10}$ with bond lengths in A. For $P_4S_{10}$ average values are given for bonds which are equivalent for the assumed $\bar{4}3\,m$ symmetry

| | A. | | A. |
|---|---|---|---|
| $P_1P_2$ | 2·326 | $P_3S_4$ | 2·075 |
| $P_1S_4$ | 2·107 | $P_3S_5$ | 2·086 |
| $P_2S_5$ | 2·100 | $P_4S_1$ | 2·110 |
| $P_2S_6$ | 2·111 | $P_4S_3$ | 1·920 |
| $P_3S_1$ | 2·117 | $P_4S_6$ | 2·076 |
| $P_3S_2$ | 1·916 | $P_4S_7$ | 2·078 |

Angles ($\pm0{\cdot}7°$, averaged as for $C_{2v}$ symmetry, see Fig. 9) are:

| | | | |
|---|---|---|---|
| $S_2P_3S_1$ | 107·7° | $S_4P_3S_5$ | 102·8° |
| $P_3S_1P_4$ | 110·1° | $P_3S_4P_1$ | 102·4° |
| $S_2P_3S_4$ | 114·0° | $S_4P_1P_2$ | 102·7° |
| $S_4P_3S_1$ | 109·1° | $S_4P_1S_7$ | 103·9° |

The crystal is monoclinic, space group $P2_1/n$, with a four-molecule cell of $a=8{\cdot}895\pm0{\cdot}004$, $b=17{\cdot}44\pm0{\cdot}015$, $c=6{\cdot}779\pm0{\cdot}004$, $\beta=92{\cdot}73\pm0{\cdot}1°$.

Tetraphosphorus pentasulphide, $P_4S_5$,[325] has an even more curious structure than that of $P_4S_7$. It is completely unsymmetrical (Fig. 9).

The molecular parameters from the later refinement[1163] are as follows (see Fig. 9, bond lengths $\pm0{\cdot}015$ A., angles $\pm0{\cdot}7°$):

| | | | |
|---|---|---|---|
| $P_1P_2$ | 2·26 A. | $P_3S_4$ | 2·09 A. |
| $P_1S_1$ | 2·13 A. | $P_3S_5$ | 1·94 A. |
| $P_1S_4$ | 2·17 A. | $P_4S_1$ | 2·10 A. |
| $P_2P_3$ | 2·24 A. | $P_4S_2$ | 2·15 A. |
| $P_2S_2$ | 2·07 A. | $P_4S_3$ | 2·11 A. |
| $P_3S_3$ | 2·08 A. | | |

| | | | |
|---|---|---|---|
| $S_1P_4S_2$ | 100·3° | $S_3P_3P_2$ | 106·0° |
| $S_1P_4S_3$ | 103·9° | $S_3P_3S_4$ | 110·8° |
| $S_2P_4S_3$ | 99·6° | $S_3P_3S_5$ | 108·4° |
| $P_1S_1P_4$ | 107·2° | $S_5P_3S_4$ | 115·0° |
| $P_2S_2P_4$ | 100·4° | $S_5P_3P_2$ | 125·5° |
| $P_3S_3P_4$ | 103·4° | $P_1P_2P_3$ | 83·0° |
| $S_1P_1P_2$ | 101·1° | $P_2P_3S_4$ | 89·6° |
| $S_1P_1S_4$ | 107·0° | $P_3S_4P_1$ | 88·7° |
| $S_2P_2P_1$ | 104·9° | $S_4P_1P_2$ | 87·0° |
| $S_2P_2P_3$ | 100·7° | | |

The crystal is monoclinic, space group $P2_1$, with a two-molecule cell, $a = 6{\cdot}412 \pm 0{\cdot}003$, $b = 10{\cdot}903 \pm 0{\cdot}005$, $c = 6{\cdot}694 \pm 0{\cdot}003$ A., $\beta = 111{\cdot}66 \pm 0{\cdot}1°$. The $^{31}$P NMR spectrum of solid $P_4S_5$ showed[971] three lines at $-200$, $-20$ and $+120$ p.p.m. with the line at $-200$ p.p.m. of greater intensity. The apical phosphorus atom was tentatively assigned to $-200$ p.p.m. and the quadruply connected atom to $+120$ p.p.m.

In all three compounds the bond lengths have been interpreted[318] as indicating no $\pi$ bonding for the cage bonds, and approximately 0·4 $\pi$ bonds/$\sigma$ bond for the apical P=S bonds.

Phosphorus sesquisulphide has been investigated by electron diffraction,[326] *X*-ray diffraction,[327–9] nuclear magnetic resonance[330, 1164] and Raman spectroscopy.[743] The molecule has a trigonal cage structure of $C_{3v}$ symmetry, containing a strained three-membered ring of phosphorus atoms. The crystal has a transition point at 39 ± 1°C.[329] and only the low-temperature modification has been investigated. This is orthorhombic, with an eight-molecule cell having $a = 9{\cdot}660$, $b = 10{\cdot}597$ and $c = 13{\cdot}671$ A. The bond lengths[329] are P–P = 2·235 A., both types of P–S = 2·090 A., and angles, P–S–P = 103·0°, S–P–S = 99·4°, S–P–P = 103·1°. The phosphorus nuclear magnetic resonance spectrum[330] confirms the structure as determined by diffraction techniques. The resonance of the ring phosphorus atoms lies at very high fields; chemical shift = +120 p.p.m. (relative to 85% orthophosphoric acid). This is probably due to the presence of bent bonds as in phosphorus. The apical phosphorus resonance lies at $-72$ p.p.m. The NMR spectrum of the rapidly rotating solid[971] gives shifts of $+103$ and $-73$ p.p.m., confirming that the shifts are little affected by the state of aggregation. The $^{31}$P NMR spectra of phosphorus–sulphur melts of different mole ratios have been used to measure the proportion of total phosphorus present as $P_4S_3$. At S/P ratios of 1·00 and 1·25, 59% and 33% respectively of the phosphorus was in this form.[1164]

The Raman spectrum[743] was determined for the solid, liquid and solution in carbon disulphide. The spectrum of the solution differed from the others, suggesting that decomposition was taking place; this was supported by a strong increase in turbidity when the solutions were irradiated. The infra-red spectrum of the solid was also reported, showing broad bands at 430 and 473 cm.$^{-1}$. The Raman spectrum was assigned on the basis of $C_{3v}$ symmetry, bands at 442, 420, 290 and 87 cm.$^{-1}$ being assigned to $A_1$ vibrations, and bands at 486, 384, 341, 221 and 154 cm.$^{-1}$ to $E$ vibrations. This assignment should not be regarded as conclusive, because the polarization data were incomplete and some assumptions were made. Approximate force constants were calculated as follow: $F_{sp}$ (apical) = 1·63 millidynes/A., $F_{sp}$ (basal) = 1·67 millidynes/A., $F_{pp}$ = 1·07 millidynes/A.

The infra-red spectra of the phosphorus sulphides have been reported.[331, 664, 1167] Absorption occurs around 530 and 686 cm.$^{-1}$ for the decasulphide, at 672–689 cm.$^{-1}$ for the heptasulphide, and at 668–674 cm.$^{-1}$ for tetraphosphorus pentasulphide.

The question of the existence of an alleged phosphorus trisulphide, $P_2S_3$ has been considered.[331] It was suggested on the basis of *X*-ray powder photographs and chromatography that this material is a mixture of other known sulphides. However, although all the lines given by this material could be assigned to $P_4S_7$ or $P_4S_5$, several of the strongest lines of these two compounds did not appear. A later report[321] describes a powder pattern which is quite distinct from those of the other phosphorus sulphides and is obtained from a new phase of variable composition $P_4S_{5\cdot5}$–$P_4S_{6\cdot75}$. This phase was prepared from melts of composition $P_4S_5$–$P_4S_{6\cdot9}$, and from the reaction of phosphorus trichloride with hydrogen sulphide. It is stable only between 200°C. and 250°C., but it is metastable for several months at room temperature. The structure is orthorhombic, with space group *Pbcn*, cell dimensions $11{\cdot}4_{(+)}$, $11{\cdot}4_{(-)}$, 8·2 A., and with four molecules (of $P_4S_{6\cdot6}$) per unit cell. The cell dimensions decrease by about 1% as the sulphur content falls from $P_4S_{6\cdot75}$ to $P_4S_{5\cdot5}$. The crystal structure of this material (of composition $P_4S_{6\cdot5}$) has recently been determined,[1165] showing it to be a defect form of $P_4S_7$. Accurate cell data are as follows: $a = 8{\cdot}14$, $b = 11{\cdot}43$, $c = 11{\cdot}39$ A., $Z = 4$ space group *Pbcn*. The molecules of $P_4S_7$ are of the same type as those in the stable heptasulphide phase, except that they possess an exact twofold axis. There is strong crystallographic evidence for a deficiency of electron density at the apical sulphur sites, in accordance with the composition. It is not known whether the deficiencies occur singly, giving defect molecules of $P_4S_6$, or in pairs, giving defect molecules of $P_4S_5$ (of a different structure from those in stable $P_4S_5$). Bond lengths are as follows: PP 2·26, PS 1·89, $P_V$–S–($P_V$) 2·12, $P_V$–S–($P_{III}$) 2·05/2·08, $P_{III}$–S–($P_V$) 2·08/2·13. The angles are similar to those in $P_4S_7$.[1163]

The radial distribution function in amorphous solid solutions of sulphur/phosphorus pentasulphide has been investigated by *X*-ray methods.[1171] It was suggested that up to 3% of phosphorus, cross-linking between the sulphur chains by short (1·9 A.) P–S bonds took place. Between 4 and 20% of phosphorus a different structure was proposed, with bonds of 2·05–2·15 A. Above 20% a 1·9 A. bond reappears, and this was taken to indicate the formation of $P_4S_{10}$ molecules.

### Phosphorus Sulphoxide

Phosphorus sulphoxide, $P_4O_6S_4$, has been examined by electron diffraction.[332] The structure is similar to that of phosphorus pentoxide with the apical oxygen atoms replaced by sulphur atoms. Bond lengths are $P{-}O = 1{\cdot}62 \pm 0{\cdot}02$ A., $P{-}S = 1{\cdot}85 \pm 0{\cdot}02$ A., and angles, $P{-}O{-}P = 123{\cdot}5 \pm 1°$, $O{-}P{-}O = 101{\cdot}5 \pm 1°$, $O{-}P{-}S = 116{\cdot}5 \pm 1°$. The angles and the P–O bond length are the same as in phosphorus pentoxide. The bond lengths lead to estimates[318] of 0·2 $\pi$ bonds/$\sigma$ bond for P–O bonds and about 1·0 $\pi/\sigma$ for P–S bonds. The crystal structure has recently been determined.[1166] The unit cell is tetragonal, with $a = 9{\cdot}065$, $c = 13{\cdot}55$ A., $Z = 4$, space group $I\bar{4}c2$. The molecules do not deviate significantly from *Td* symmetry. The molecular dimensions, in agreement with the electron diffraction results, are: $PO_{(av.)} = 1{\cdot}61$, $PS_{(av.)} = 1{\cdot}86$ A., $POP = 124{\cdot}5°$, $OPO = 100{\cdot}8°$, $OPS = 117{\cdot}2°$. An unusual feature of the structure is the fact that each molecule has near-neighbour contacts with 18 other molecules. The Raman spectrum of phosphorus sulphoxide has been reported[333] for the liquid and solid. Strongly polarized lines are found, indicating a cubic point group, consistent with the electron diffraction results. Lines at 400, 694 and 897 cm.$^{-1}$, all strongly polarized, are assigned to the three totally symmetrical ($A_1$) vibrations. Other strong lines appear at 89, 148, 353, 666 and 930 cm.$^{-1}$ The spectrum of the solid is similar to that of the liquid, and the solid is evidently also composed of discrete molecules of cubic symmetry. The stretching force constant of the P=S bond has been estimated as 5·5 millidynes/A.[320] The nuclear magnetic resonance spectrum of phosphorus sulphoxide has been investigated, and the phosphorus chemical shift reported as $-16 \pm 1$ p.p.m. (relative to 85% orthophosphoric acid).[171]

### Phosphorus Thioiodide

The crystal structure of phosphorus thioiodide, $P_4S_3I_2$, has been determined.[535] The crystal is triclinic, with a four-molecule cell having $a = 7{\cdot}31$, $b = 7{\cdot}35$, $c = 19{\cdot}61$ A., $\alpha = 94°\ 24'$, $\beta = 90°\ 10'$, $\gamma = 90°\ 55'$ and space group $P\bar{1}$. The cell contains two pairs of optical isomers, each pair related by a centre of symmetry. The molecule (Fig. 10) is composed of two five-membered rings fused to form a six-membered ring.

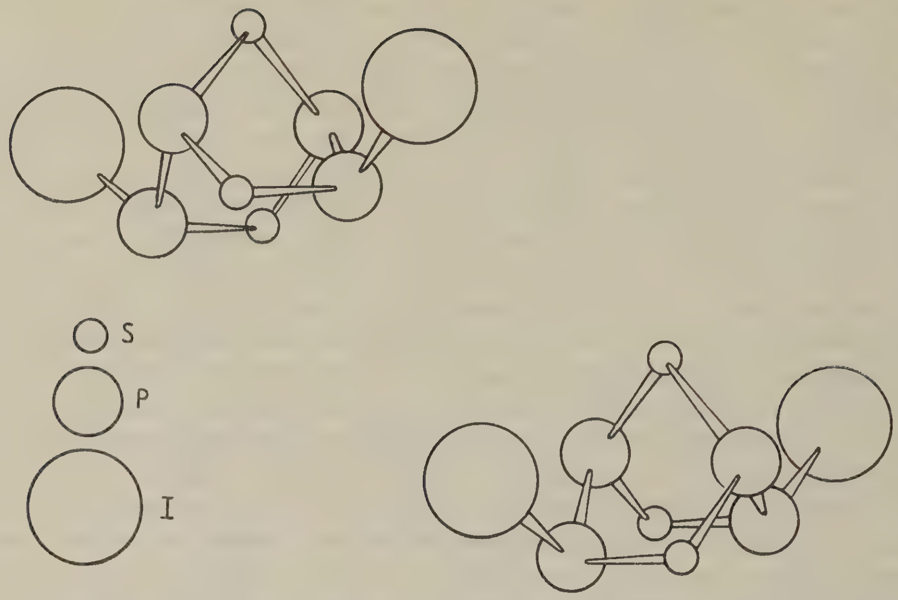

FIG. 10.—The two optically active molecules of phosphorus thioiodide, $P_4S_3I_2$

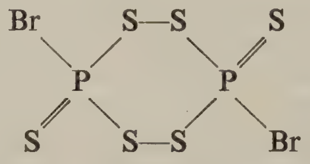
This compound may be prepared from phosphorus sesquisulphide by reaction with iodine in carbon disulphide solution, but this involves breaking a P–P bond and rearranging the skeleton, since the positions of the phosphorus and sulphur atoms in one of the five membered rings are reversed. The P–P and P–S bonds evidently have a high mobility. Bond lengths are P–I $2{\cdot}48 \pm 0{\cdot}03$, P–P $2{\cdot}20 \pm 0{\cdot}04$, P–S $2{\cdot}10 \pm 0{\cdot}04$ A.: angles S–P–S = 105°, P–S–P = 104°, P–P(I)–S = 102°, P–P(S)–S = 91°. The low value of the last angle leads to a non-bonded P–S distance of 3·1 A., 0·6 A. less than the sum of the (Pauling) Van der Waals radii.

The crystal structure of diphosphorus hexathiobromide,[1167] $P_2S_6Br_2$, has been determined.[1168] The cell is tetragonal with $a = 9{\cdot}79$, $c = 11{\cdot}51$ A., $Z = 4$, space group $P\bar{4}2_1c$. The molecules (below), which contain two PSSP bridges,



have a skew boat configuration, with average bond lengths P–Br $2{\cdot}07 \pm 0{\cdot}02$, P=S $1{\cdot}88 \pm 0{\cdot}03$, P–S $2{\cdot}10_2 \pm 0{\cdot}014$, S–S $2{\cdot}034 \pm 0{\cdot}015$ A., and angles $PSS_{(av.)}$ 99·7°, SPS 106·3°. The terminal sulphur and bromine atoms are completely disordered. The infra-red spectra of this compound, and of $P_2S_5Br_4$, have been reported.[1167]

## Phosphorus Selenide

Phosphorus sesquiselenide, $P_4Se_3$,[536] has the same space group, *Pnmb*, as the low temperature form of phosphorus sesquisulphide, but they are not isostructural. The orthorhombic sixteen-molecule cell has $a = 9{\cdot}739$, $b = 11{\cdot}797$, $c = 26{\cdot}270$ A. The molecular structure is similar to that of phosphorus sesquisulphide, and the molecules are arranged approximately in hexagonal close packing. Bond lengths are P–P = $2{\cdot}25 \pm 0{\cdot}03$ A., P–Se = $2{\cdot}24 \pm 0{\cdot}01$ A., which is in good agreement with the sum of the atomic radii. The angles are Se–P–Se = 99·9°, P–Se–P = 100·1°, Se–P–P = 105·3°, P–P–P = 60°. Infra-red and Raman data were reported[1169] for this molecule as follows: 601 (R), 525 (vw IR), 420 (w IR), 360/363 (s, R, IR), 317 (s, R, IR), 214 (? R) cm.$^{-1}$ The bands at 360 and 317 were assigned to $\nu_s(PSe_3)$ and $\nu_s(P_3Se_3)$ respectively. The $^{31}P$ NMR spectrum[1169] shows a doublet ($J = 85$ c/s) at +106 p.p.m., and quartet at −38 p.p.m., relative to 85% orthophosphoric acid, confirming the structure of the molecule. The ultra-violet spectrum[1169] shows bands at 384 (w) and 236 (s) mμ.

## ORTHOPHOSPHORIC ACID AND ORTHOPHOSPHATES

### Orthophosphoric Acid

In the monoclinic structure of anhydrous phosphoric acid,[379, 473–4] hydrogen atoms are associated with three of the oxygens of the $PO_4$ group; the P–O bond length for these oxygen atoms is 1·57 A. The other P–O bond is shorter at 1·52 A. The bond angles are 106° between the (H)–O–P bonds and 112° between these and the fourth bond. The bond lengths indicate substantial double-bond character, the shortest length evidently being an almost pure double bond.[473] The molecules are connected into sheets by hydrogen bonds of length 2·53, 2·53 (both to the 'keto' oxygen) and 2·84 A. between the 'hydroxyl' oxygens of molecules related by translation within the sheets. Structural data are summarized in Table IX.

Aqueous solutions of phosphoric acid have also been investigated[512] by *X*-rays. In 86% solution the phosphate ions are interconnected by hydrogen bonds, the O–H–O distance being 2·85 A. if the P–O distance is taken as 1·56 A. In 54% solution the ions are tetrahedrally hydrogen bonded to water molecules. The packing of unbonded oxygen atoms in neighbouring ions leads to an O–O distance of 3·2 A.

### Orthophosphates

This class of compounds includes the large group of apatites and almost all other phosphate minerals, as well as the heteropoly acids and their salts. Crystallographic data on these groups are summarized in Tables IX–XII respectively.

Two limiting kinds of crystalline orthophosphates may be distinguished: those containing isolated $PO_4^{3-}$ ions, and those in which the $PO_4$ groups share electrons with the metal atom to form a three-dimensionally bonded network similar to that of silica. The first group is typified by the orthophosphates of the alkali and alkaline-earth metals. The alkali dihydrogen orthophosphates have received considerable attention because of their ferro-electric properties; crystallographic,[390–5, 475–8, 1180] infra-red,[511, 527, 891–6, 1174–6] Raman,[1178, 1312] double-refraction dispersion,[1177] nuclear quadrupole resonance,[1179] and nuclear magnetic resonance[849–51, 883–7, 891] techniques have been employed. Slater[479] has explained the ferro-electric behaviour of potassium dihydrogen phosphate below 123°K. by assuming a double potential minimum for the O–H···O proton. The low-temperature ferro-electric phase has the protons ordered, and the high-temperature phase has them disordered, between the two potential minima. This theory has been confirmed by neutron diffraction experiments.[394, 477–8] The high polarization, however, apparently arises from displacements of other atoms, particularly the potassium atom.[510] The infra-red absorption of the OH stretching and bending vibrations does not change significantly through the Curie point.[511] The corresponding ammonium salt is apparently antiferro-electric.[403–6]

Anhydrous dicalcium phosphate, $CaHPO_4$ (monetite), has a structure[365, 852] consisting of discrete $PO_4^{3-}$ tetrahedra and $Ca^{++}$ ions, the latter co-ordinated by a shell of oxygen atoms. Double chains of Ca–$PO_4$–Ca extend along the *a* axis. The two types of calcium have respectively seven and eight nearest oxygen neighbours in their co-ordination shell. The hydrogen atoms probably lie between oxygen atoms of neighbouring phosphate groups. The structure is thus a three-dimensional network of tetrahedral $PO_4^{3-}$ anions, with $Ca^{++}$ ions in the interstices, holding the anions together by highly ionic bonds with the oxygen atoms. Nuclear magnetic resonance data have been said to indicate a change in structure with temperature[891] but later work[852] has not confirmed this. Dicalcium phosphate dihydrate, $CaHPO_4$, $2H_2O$ brushite), has a structure[367, 368, 853] in which the single Ca–$PO_4$–Ca chains are bonded together by contact between calcium and oxygen atoms in neighbouring chains resulting in a corrugated sheet of composition $CaPO_4$. These sheets are held together by the water molecules. It has recently been suggested from nuclear magnetic resonance data[545] that the single hydrogen atom is located between the oxygen atoms of two adjacent phosphate groups. A recent refinement[853] of the structure suggested that the space group was the non-centrosymmetric *Ia*, unlike the original refinement which was based on a centrosymmetrical space group. Infra-red data[852, 891] suggest a close similarity between the phosphate groups in monetite and brushite and are consistent with the existence of two or three kinds of hydrogen bond in monetite.

Anhydrous dibarium phosphate, $BaHPO_4$,[361–2] has a structure somewhat similar to that of the corresponding calcium salt with separate phosphate tetrahedra linked into chains by barium ions. The barium co-ordination, however, is different from that of calcium; each barium atom is surrounded by ten oxygen atoms, three of which are at substantially greater distances than the other seven.

Monocalcium phosphate monohydrate, $Ca(H_2PO_4)_2,H_2O$, also has corrugated sheets of composition $CaPO_4$.[370, 852] In this case the sheets are separated by phosphate ions as well as water molecules, lowering the symmetry from monoclinic to triclinic. The corrugated sheets in these structures are very similar to the sheets of composition $CaSO_4$ which occur in gypsum.[369]

The two forms of tricalcium phosphate have not been fully investigated.[364, 480–1] The data on the $\beta$-form of tricalcium phosphate (whitlockite) are anomalous.[364] It has been suggested[1170] that the water in whitlockite is trapped and is not an essential component of the structure which was formulated as $\beta$-$Ca_3(PO_4)_2$. The structures of the analogous barium and strontium salts, $Ba_3(PO_4)_2$ and $Sr_3(PO_4)_2$, have been developed on tetrahedral phosphate groups (P–O distance of 1·56 A. assumed), in an unimolecular rhombohedral cell. There are two types of metal site with twelvefold and tenfold co-ordination.

## APATITES

The most important group of phosphate minerals, the apatites, comprises a large number of different materials which preserve very closely similar structures and cell dimensions over a wide range of composition. All the structures are hexagonal, space group $P6_3/m$, with a unimolecular cell of dimensions a $\sim$ 9 A., c $\sim$ 7 A. Structural data for phosphorus-containing apatites are summarized in Table X. The general formula for an apatite is $M_{10}X_2(RO_4)_6$ where X is F, OH, Cl or Br, and R may be As, V, S or Si as well as P. The most detailed structural work has been carried out on fluorapatite, $Ca_{10}F_2(PO_4)_6$ [429, 431] and hydroxyapatite, $Ca_{10}(OH)_2(PO_4)_6$.[546, 793–4, 1181] A projection of the hydroxyapatite structure down the *a* axis, based on the refinement,[546] is shown in Fig. 11.

The fluoride or hydroxyl ions are normally placed on the $6_3$ (threefold plus twofold screw) axes, at the same height ($\frac{1}{4}$ and $\frac{3}{4}$) as, and in the centre of, the triangular groups of three calcium ions. To do this with chloride ions in chlorapatite would lead to improbably short interionic distances from the calcium ions, and the chloride ions have been placed at 0 and $\frac{1}{2}$. It is doubtful if the precise locations of these ions along this axis can be regarded as fully established. Recent neutron diffraction work[1181] has shown that in hydroxyapatite the hydroxyl oxygen is displaced by about 0·3 A. from the plane of the three calcium ions. This implies a short range ordering of the hydroxyl ions.

A group of 'carbonato-apatites', some of which form the basis of mammalian bones and teeth, has been the subject of considerable controversy, and the situation is far from clear. Some authors have claimed[788, 795–6, 854–6, 1249] that the carbonate ion may replace the fluoride or hydroxyl ion in the apatite structure, particularly when the lattice is enlarged by the replacement of calcium by strontium.[796, 854, 856] Other workers[429, 797] maintain that the carbonate ions are present in macroscopic inclusions of calcium carbonate. McConnell[428, 790–2, 798–9] has pointed out that the

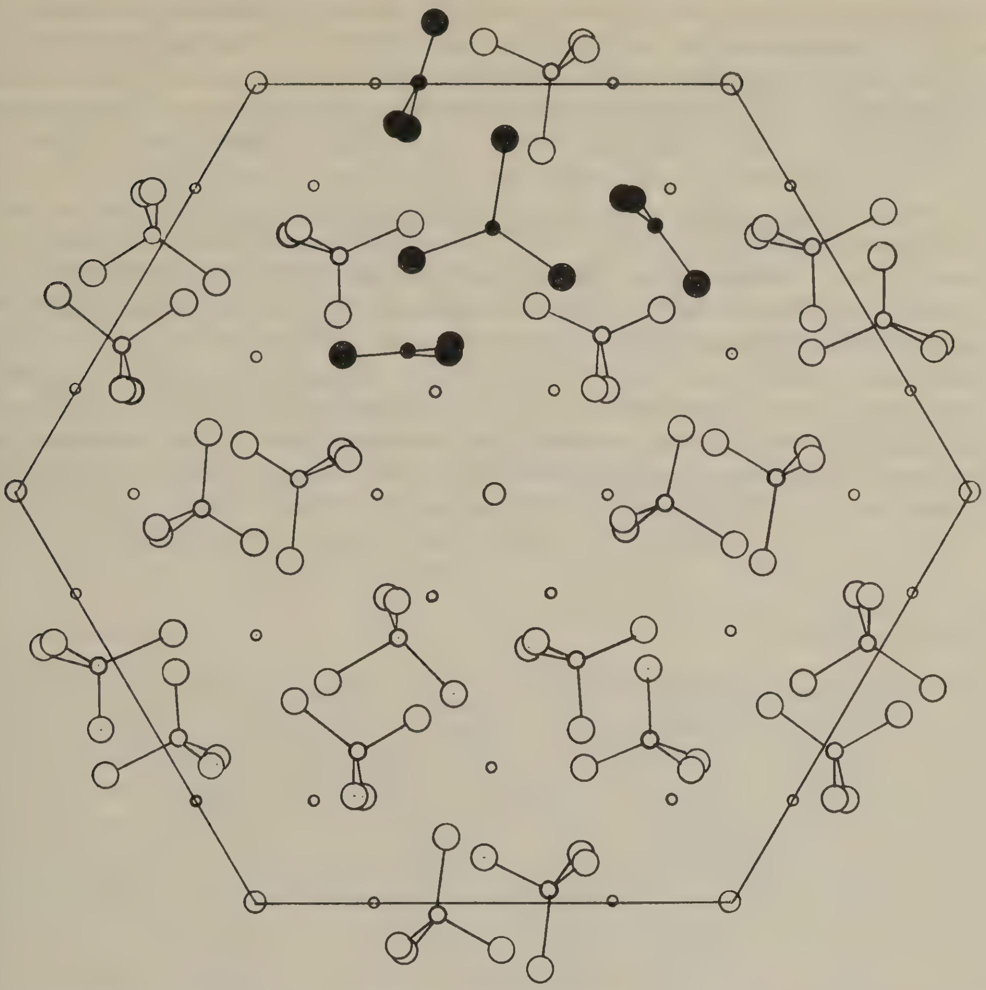


FIG. 11.—A projection of the hydroxyapatite structure[546] down the *a* axis. The upper part of the diagram shows a replacement of phosphate groups by carbonate groups, according to the ideas of McConnell[428, 790-2, 798-9] as described in the text. The carbonate oxygen atoms are shown in their original positions; slight displacement would be necessary to give the correct dimensions for the carbonate group.

∘ calcium

substitution of carbonate ions for hydroxyl ions leads to impossibly short interatomic distances, and that in some cases the total of fluoride or hydroxyl and carbonate ions exceeds the number of available sites. He has proposed a structure in which four carbon atoms replace two calcium ions and three phosphorus atoms, the carbon atoms, however, not lying on the same sites as the replaced atoms. The oxygen atoms of the displaced phosphate groups are rearranged to form carbonate groups. Such a replacement is shown in the upper part of Fig. 11. The use of formulae indicating isomorphous replacement of calcium or phosphorus by carbon is misleading since the carbon atoms do not occupy the same sites. Other workers[1182] have concluded that phosphate ions may be replaced by fluoride and hydroxyl ions as well as by carbonate groups. It has also been proposed[1183] that the phosphate groups may be replaced by the unusual ion $O_4H_4^{4-}$, for which there is evidence elsewhere.[1185–6]

The structure of apatites which are calcium-deficient has been considered by several workers.[872–6, 1184, 1246] It has been suggested, on the basis of a correlation of the intensity of an OH stretching bond in the infra-red spectrum with the Ca/P ratio,[872] that the deficiency is accounted for by hydrogen atoms which are hydrogen-bonded between the oxygen atoms of adjacent phosphate groups. This suggestion has also been made by other workers[873, 876] although there has been controversy[873–5] over the detailed interpretation of the results, and over the suggestion[873, 875–6] that there is a deficiency of hydroxyl ions as well as calcium ions. Some of the arguments used in reference 874 have recently been criticized.[877]

Octacalcium phosphate, $Ca_4H(PO_4)_3,xH_2O$, though structurally related to hydroxyapatite, is not isostructural.[1189–91] The structure is triclinic, with apatitic layers parallel to the *bc* plane, separated by hydrated layers. The hydration is not constant, and it has been suggested[1191] that part of the water is zeolitic. The unit cell dimensions of $Ca_4H(PO_4)_3,2{\cdot}5H_2O$[1189] are $a=19{\cdot}87$, $b=9{\cdot}63$, $c=6{\cdot}87_5$ A., $\alpha=89°\ 17'$, $\beta=92°\ 13'$, $\gamma=108°\ 57'$, $Z=Ca_8H_2(PO_4)_6,5H_2O$, space group $P\bar{1}$.

## SILICA-LIKE NETWORK

The three-dimensional silica-like network type of orthophosphates is typified by the phosphates of aluminium, boron, ferric iron and gallium.[350–8, 377] While the co-ordination number of the alkali and alkaline-earth metals in their phosphates lies between six and eight, in the covalent network type of phosphate the co-ordination of the metal atom is tetrahedral, like that of the phosphorus. The network is thus analogous to a $Si(SiO_4)$ network and the crystals could well be considered as double oxides. The aluminium, boron and gallium phosphates show polymorphism similar to that of silica, but ferric phosphate has so far been found only in the hexagonal low-quartz form.[351–2] Gallium phosphate has low-quartz and low-cristobalite forms stable at room temperature, and a high-cristobalite form above about 900°C.[487] The structure of the low-cristobalite form has been investigated.[377] Boron phosphate has the high cristobalite structure at room temperature,[355] but a quartz analogue has been prepared at high pressures.[356–8] Aluminium phosphate shows polymorphism almost completely analogous to that of silica, with high- and low-quartz, tridymite and cristobalite forms. The structure of the low-cristobalite form[377] is discussed below.

Bond lengths of 1·54 A. for P–O bonds and 1·44 A. for B–O bonds in high-cristobalite-type boron phosphate have been reported.[355] This P–O bond length is typical for phosphates and indicates up to $\frac{1}{3}\pi$ bond per $\sigma$ bond, which implies a shift of electronic charge into the P–O bond, making this negatively charged and the boron positive. In the low-cristobalite forms of gallium phosphate and aluminium phosphate[377] the phosphate tetrahedra were assumed to be completely regular, with a P–O distance of 1·56 A., and this led to satisfactory agreement between observed and calculated scattering intensities. The $AlO_4$ and $GaO_4$ tetrahedra were found to be somewhat distorted, but this may be exaggerated, because the distortion is probably shared between the $MO_4$ and $PO_4$ tetrahedra.

## PHOSPHORUS HETEROPOLYACIDS AND THEIR SALTS

The 12-heteropolyacids of phosphorus, of general formula $H_3(PO_4.12XO_3)_2,nH_2O$ where X = Mo or W, are composed of anions in which a central phosphate tetrahedron is surrounded by twelve interlinked octahedra of $WO_6$ or $MO_6$.[857–8] A 9(18)-heteropolyacid salt, $K_6(P_2W_{18}O_{62}),14H_2O$, has been assumed[427] to have an anion constructed from a packing of two phosphate tetrahedra surrounded by eighteen octahedra of $WO_6$ sharing edges and corners. Extensive series of hydrates are formed by these compounds; the number of water molecules per formula unit varies from 3 to 52. The crystal symmetry depends on the number of water molecules, but is frequently cubic. Hydrates with $n \leqslant 5$ are cubic with bimolecular cells. Those with $n = 29$–31 are also cubic, but with larger eight-molecule cells. Structural information on the phosphorus heteropolyacids and their salts is summarized in Table XII.

## Spectra of Orthophosphoric Acid and Phosphates

The ultra-violet absorption spectra of solutions of phosphoric acid, potassium phosphate, hydrogen phosphate and dihydrogen phosphate, and of phosphoric acid vapour have been reported[513, 515] to show absorption maxima in the region 2400–3000 Å.

The Raman spectrum[515] of anhydrous phosphoric acid changes slightly on dilution, some shifts in frequency taking place. Raman spectra have been reported for the primary, secondary and tertiary orthophosphates of the alkali metals,[515, 517–9, 521, 523, 538] for potassium deuterium phosphate,[515] and for single crystals of ammonium dihydrogen phosphate[522] as well as for the acid.[515–20, 523, 538, 609] The spectra are similar to those of phosphoric acid, with some shifts in frequency reflecting changes in symmetry and hydrogen bonding. The Raman spectra of orthophosphates show the four bands expected from tetrahedral symmetry; the $A_1$ breathing frequency gives a strong polarized line in the region 910–980 cm.$^{-1}$, the $F_2$ degenerate stretching vibration gives a weak band around 1000–1080 cm.$^{-1}$, and the $E$ and $F$ bending vibrations give bands in the 360–420 and 490–580 cm.$^{-1}$ regions respectively. In anhydrous phosphoric acid these bands are at 910, 1079, 359 and 496 cm.$^{-1}$.[516] Although no splitting of the triply degenerate stretching vibration because of changes in symmetry has been reported in the Raman spectrum, such splitting is very noticeable in the infra-red spectra of aqueous solutions of orthophosphates, in which this vibration shows up strongly.[878, 1223] Neutral salts show one band at about 1004 cm.$^{-1}$, monoacid salts two bands at about 980 and 1080 cm.$^{-1}$, with the breathing vibration weakly active at 860 cm.$^{-1}$. Diacid salts show three very strong bands at 947, 1072 and 1150 cm.$^{-1}$, as well as a 'breathing' vibration at 878 cm.$^{-1}$. Phosphoric acid itself shows the breathing vibration at 885 cm.$^{-1}$, two very strong bands at 1007 and 1165 cm.$^{-1}$, and a weak band at about 1070 cm.$^{-1}$.[878] The vibrational spectra of phosphoric acid in some non-aqueous solvents have been reported[1224] and some frequency shifts noted. The Raman spectrum of tripotassium orthophosphate shows bands at 1014, 936, 573 and 420 cm.$^{-1}$.[519] Force constants have been calculated for the phosphate ion,[523, 543–4, 879, 1224–5] but because of the variation of the frequencies with concentration and among various salts, and the use of different force fields, widely differing results have been obtained. Valence force constants calculated[1226] from the assignments[878] of aqueous solution spectra are as follows: $F_{\mathrm{PO}} = 6{\cdot}31$, $6{\cdot}97$, $7{\cdot}9$–$8{\cdot}2$, $8{\cdot}88$ millidynes/Å. for $PO_4^{3-}$, $HPO_4^{2-}$, $H_2PO_4^{-}$, $H_3PO_4$ respectively: $F_{\mathrm{PO(H)}} = 5{\cdot}39$, $6{\cdot}02$–$6{\cdot}14$, $7{\cdot}19$ for $HPO_4^{2-}$, $H_2PO_4^{-}$, $H_3PO_4$ respectively. The results were correlated with Cruickshank's[1227] theories of bond orders; it has recently been pointed out[1228] that a correction for the change in average force constant throughout the series is essential for this correlation.

The infra-red spectra of a large number of orthophosphates (Table XIII) have been determined, mainly for frequency correlation purposes.[524–6, 539, 745, 660] The $F_2$-type vibrations of the phosphate ion in the 1000 and 500 cm.$^{-1}$ regions are expected to be strongly active in the infra-red spectra. However, these spectra are normally obtained on the solid, and crystal coupling effects are important. Also, reduction in symmetry by hydrogen bonding may lead to a resolution of the $F_2$ bands into widely spaced components. Tribasic orthophosphates usually show a single strong band in the 1000–1060 cm.$^{-1}$ region,[524–5] with weaker absorption extending over the 1000–1150 cm.$^{-1}$ region, while acid orthophosphates show several strong peaks over the range 850–1400 cm.$^{-1}$,[525] presumably for the reasons given above. Ranges of 1010–1070 cm.$^{-1}$ and 930–990 cm.$^{-1}$ for dibasic phosphates, and 1030–90 and 900–950 cm.$^{-1}$ for monobasic phosphates, have been suggested.[524] The $F_2$-type band in the

## Footnotes to Table IX

[a] May contain up to ½ mol. of zeolitic $H_2O$.

[b] Quartz structure with alternating Al, P atoms replacing Si.

[c] Al–O–P = 145°
P–O 1·56 A.
Al–O 1·70 A.
Cristobalite structure with alternating Al, P atoms replacing Si.

[d] P–O 1·54 A.
B–O 1·44 A.
Cristobalite structure with alternating B, P atoms, replacing Si. Oxygens displaced slightly by presence of unlike atoms.

[e] Cf. $AlPO_4$.

[f] P–O 1·56 A. (assumed).
$Ba_I$–O 6 at 2·80, 6 at 3·23 A.
$Ba_{II}$–O 1 at 2·71, 3 at 2·80, 6 at 2·83 A.

[g] P–O 1·56 A.
O–O (unbonded) 3·1–3·2 A.
O–H····O 2·5 A.
Ba–O (7) 2·6–3·1 A.
(10) 2·6–3·5 A.
Separate tetrahedral $PO_4$ groups linked by H bonding to form continuous chains.
Ba co-ordination: 10 oxygens

[h] Atoms in general positions of $P2_1/n$.

[i] P–O (av.) 1·54 A.
O–O (unbonded) 2·51 A.
Independent $PO_4$ groups. Three different close O····O approaches attributed to hydrogen bonds.

[j] P–O 1·53, 1·54 A.
Corrugated sheets of composition $CaPO_4$. Water in layers between them.

[k] P–O (av.) 1·52 A.
O–O 2·48 A.
Ca–O (av.) 2·52 A.
Corrugated sheets of $CaPO_4$ (as in $CaHPO_4.2H_2O$), separated by $PO_4^{3-}$ ions and water molecules.
Tentative assignment of hydrogen atom positions.

[l] P–O 1·51–1·61 A.
Fe–O 1·99–2·30 A.
$PO_4$ tetrahedra. Octahedral co-ordination of Fe.

[m] P–O 1·57–1·68 A.
Fe–O 2·00–2·02 A.
$PO_4$ tetrahedra. Octahedral co-ordination of Fe.

[n] Ga–O–P = 135°.
Ga–O 1·78 A.
P–O 1·56 A.

[o] P–O 1·57–1·58, 1·52 A.
Trigonal symmetry of $PO_4$ ion. Hydrogen bonds between ions.

[p] P–O 1·56 A.
In–O 4 at 2·19, 2 at 1·98 A.

[q] Complex three-dimensional network, with framework of indium atoms and phosphate groups with one set of water molecules. A second set of water molecules lies in otherwise unoccupied channels of framework.

[r] P–O 1·54 A.
K and $PO_4^{3-}$ ions distributed as Zr and Si ions in zircon. Ferroelectric transition at 123°K.

[s] P–O 1·58, 1·51 A.
K and $PO_4^{3-}$ ions distributed as Zr and Si ions in zircon. Ferroelectric transition at 123°K.

[t] P–O 1·56 A.
O–P–O 110°.
$PO_4$ groups linked by tetrahedrally co-ordinated Li.

[u] P–O 1·54 A.
O–P–O 105°–113°.
Distorted $PO_4$ tetrahedral complexes. Distorted octahedral oxygen co-ordination of $Li^+$ and $Mn^{2+}$.

[v] Double chains of $MoO_6$ octahedra coupled by $PO_4$ groups. $MoO_6$ shares edges with $3PO_4$, $PO_4$ with $3MoO_6$. Chains held together by H bonding.

[w] P–O 1·53 A.
$H_2PO_4^-$ network very similar to $KH_2PO_4$. N–H···O and O–H···O bonding systems confirmed by neutron diffraction. Antiferroelectric transition at −30°C.

[x] P–O 1·59–1·66 Å.
Mn, Na–O 2·17–2·31 Å.
Mn and Na statistically distributed over 2 types of position.

[y] P–O 1·56 Å. (assumed).
$Sr_I$–O 6 at 2·63, 6 at 3·10 Å.
$Sr_{II}$–O 1 at 2·48, 3 at 2·62, 6 at 2·72 Å.

[z] P–O 1·56 Å. (assumed).
Sc–O 4 at 2·09, 4 at 2·37 Å.

[aa] P–O 1·56 Å. (assumed).
Tl–O 2 at 2·02, 4 at 2·28 Å.

[bb] $WO_6$ octahedra joined by $PO_4$ tetrahedra in 3-dimensional arrangement. $WO_6$ linked to 4 $PO_4$ and one $WO_6$, $PO_4$ to 4 $WO_6$.

[cc] Infinite double chain of $[Ga_2OH(H_2O)_2]$ connecting surrounding phosphate groups: formulation $Ga_2OH(H_2O)_2$, $(H_2O)(H)(PO_4)_2$ with $(H_2O)(H)$ disordered.

(a) All the apatites crystallize in the hexagonal system with space group $P6_3/m$ and one formula weight per unit cell.

(b) P–O 1·51–1·54 A.
Ca–O 2·35–2·80 A.
Ca–OH 2·35 A.

(c) A classification of carbonate apatites according to Reference 428 is as follows:

Dahllite—contains an appreciable amount of $CO_2$ and $<1\%$ F, with or without OH.
Dehrite—contains a significant replacement of Ca by Na, and with $CO_2$.
Francolite—as dahllite but $>1\%$ F.
Lewistonite—contains an appreciable amount of K, with or without $CO_2$.

[a] Built up of $UO_2PO_4$ sheets spread normal to *c* axis, held together by Ca atoms between sheets (cf. mica and other platy silicates).

[b] Analogous and partly isomorphous with corresponding Ca compounds (autunites).

[c] See Table IX.

[d] Weak extra lines may be due to twinning or superstructure.

[e] Two parallel sets of infinite chains, one of $MnFeO_4(OH)_2$ octahedra sharing opposite O–O edges, the other of $AlO_2(OH)_2(H_2O)_2$ octahedra sharing opposite $H_2O$ corners; chains alternate sharing OH corners to form parallel sheets held together by $PO_4$ groups.

[f] Metal–oxygen octahedra and $PO_4$ tetrahedra share corners to produce sheets and tie these into a three-dimensional network.

[g] Autunite-like.

[h] P–O 1·49–1·58 in $PO_4$, Fe–O 2·08–2·28, Li–O 2·10–2·26. Sixfold O co-ordination of Fe and Li.

[i] Chains of $BeO_2(OH)_2$ and $PO_4$ tetrahedra linked by Al–O bonds.

500 cm.$^{-1}$ region gives absorption, often with several unresolved bands, in the region 520–620 cm.$^{-1}$ in many phosphates.[660, 745]

The spectra of a number of crystalline phosphates have been studied in considerable detail. Partial assignments have been reported[1229] for dipotassium and diammonium hydrogen phosphates, assuming the potassium salt to have the same space group ($P2_1/a$) as the ammonium salt. Dicalcium phosphate $CaHPO_4$ (monetite)[1231] and its dihydrate (brushite)[1230–1] have been investigated and complete assignments proposed. The factor group splitting in brushite was interpreted[1230] as evidence that the space group was $Ia$ rather than $I2/a$. In synthetic hydroxyapatite and mineral fluorapatite, an infra-red study[1232] and site symmetry analysis suggested that the symmetry of the phosphate ion was lowered to $C_s$ in fluorapatite and $C_1$ in hydroxyapatite, in accordance with the neutron diffraction data.[1181] The infra-red spectrum of octacalcium phosphate indicates[1233] that the symmetry is lowered to $C_1$ for all the phosphate species in the unit cell, in accordance with the crystal structure.[1189] The factor group splitting which causes broad bands in many crystalline phosphates has been eliminated in a number of cases[1234] by diluting the phosphate groups with arsenate groups in a mixed crystal, enabling the site symmetry to be observed directly. In the infra-red spectra of a number of anhydrous phosphates[1287] the selection rules were observed to follow the site symmetry.

Aqueous orthophosphoric acid was at one time used in nuclear magnetic resonance measurements as a standard for $^{31}P$ chemical shift determinations. The shift of 85% orthophosphoric acid was taken as zero, and other orthophosphates then lie between $\pm 5$ p.p.m.[171] The effect of the degree of ionization of phosphates on the chemical shift has been investigated,[532, 739, 1250] enabling orthophosphoric acid to be used as an internal standard in aqueous solutions. The chemical shift changes smoothly from 0 to $-6$ p.p.m. as alkali is added. If the chemical shift is plotted

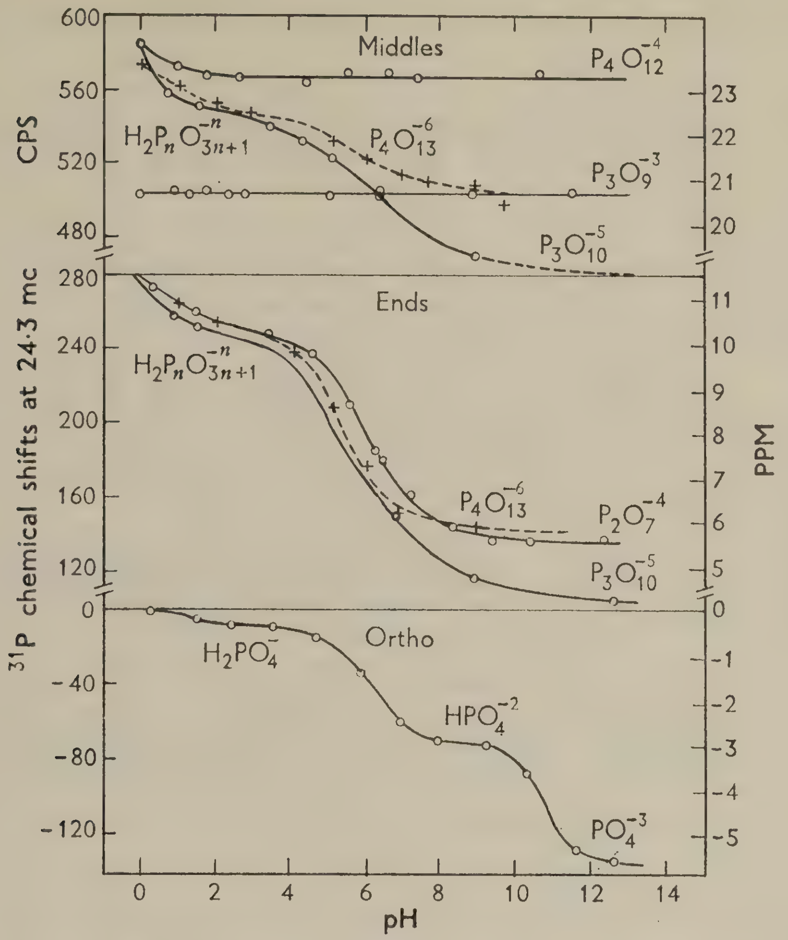

FIG. 12.—Change in $^{31}$P chemical shifts of ortho and condensed phosphates with pH

against pH, inflections appear in the curve (Fig. 12) at positions corresponding to $H_2PO_4^-$ and $HPO_4^=$.[739] The changes in shift are related to the formation of P–O–H bonds of some covalent character.[739]

The effect on the resonance of adding paramagnetic ions has been investigated.[1251] The line width was increased by a different amount by different ions, but no changes in chemical shifts were observed.

Simple crystals of crystalline fluorapatite have been studied by wide-line $^{19}$F and $^{31}$P nuclear magnetic resonance.[1252] The line shapes and second moments were compared with the theoretical calculations based on the crystal structure.

The $^1$H wide-line nuclear magnetic resonance spectrum of phosphomolybdic acid, $H_3PMo_{12}O_{40}$,$29H_2O$, has been studied.[1258] From the dependence of the line shape on temperature and from infra-red data the presence of the oxonium ion was deduced.

## PYROPHOSPHATES

The crystal structure of the isomorphous cubic pyrophosphates of silicon, titanium, zirconium, stannic tin, hafnium and uranium, having the general formula $MP_2O_7$, has been investigated.[547–8] The space group is reported as *Pa*3 and the lattice constants are given in Table XIV. It follows[547] from the choice of space group that the pyrophosphate ion must lie on a threefold axis, giving a P–O–P angle of 180°. It has recently been shown[717] that the linearity of this P–O–P group is not dependent on the choice of space group; the cubic cell and the assumption of a discrete pyrophosphate ion are sufficient to place the ion on a threefold axis. Reasonable agreement[547] between observed and calculated intensities was obtained for zirconium pyrophosphate with P–O (internal) = 1·56 A., P–O (external) = 1·52 A. (Owing to a numerical error in the original paper[547] the results of this work have been wrongly

quoted by some authors[565,716] as leading to a P–O–P angle of 152°.) A high-temperature form of zirconium pyrophosphate, also cubic, has been reported.[554] The linear P–O–P linkages in zirconium pyrophosphate and its isomorphs are unusual; such linkages have also been reported in $\beta$-$Mg_2P_2O_7$[905] and $Mn_2P_2O_7$[903] but other pyrophosphates which have been studied show non-linear P–O–P linkages. The crystal structure of $\beta$-$Mg_2P_2O_7$ has recently been refined[1260] and that of $\beta$-$Zn_2P_2O_7$ determined.[1261-2] In both structures the central oxygen atom of the pyrophosphate ion was found to have enhanced thermal motion in the plane perpendicular to the P–P vector. Evidently the P–O–P bond appears linear only because of the thermal averaging of the central atom position. Bond lengths are for $\beta$-$Mg_2P_2O_7$ P–O(–P) 1·557 (assuming POP = 180°), P–O 1·534, 1·542; for $\beta$-$Zn_2P_2O_7$ P–O(P) 1·569 (for POP = 180°), P–O 1·556, 1·554 A. It is not clear whether the thermal motion is real or due to statistical disorder and, if real, whether it is vibrational or rotational. A single-crystal *X*-ray study[1276] of germanium pyrophosphate has shown that the real cell ($a = 22{\cdot}854$ A.) is twenty-seven times that quoted in the early work.[547-8] Weak lines indicating the larger cell were observed on powder diffractometer traces of Ge, Sn, Pb, Ti, Zr, Hf, Th, U pyrophosphates. Evidently all the cubic pyrophosphates possess the big cell; values in Table XIV refer to the sub-cell. The symmetry requirement that all the P–O–P bonds be linear (or disordered) is relaxed in the larger cell. The crystal structure[1311] of $\alpha$-$Cu_2P_2O_7$ shows the pyrophosphate ion to have a twofold axis and a P–O–P bond angle of 157°. Like the compounds above the high-temperature ($\beta$) phase has a (pseudo) linear P–O–P bond. Diffuse streaks in the *X*-ray scattering pattern in the temperature range of the transition support a positional disordering of pyrophosphate ions.[1311] A preliminary report[549] of a possible linear P–O–P linkage in disodium pyrophosphate hexahydrate, $Na_2H_2P_2O_7,6H_2O$, has since been discounted.[550] In tetrasodium pyrophosphate hexahydrate, $Na_4P_2O_7,10H_2O$,[551] the P–O–P angle is 134°, the internal bonds 1·63 A., and the external bonds an average of 1·47 A. This structure has recently been refined[744] leading to bond lengths of $1{\cdot}61 \pm 0{\cdot}015$ and $1{\cdot}51 \pm 0{\cdot}015$ A., with a P–O–P angle of 133½°, and O–P–O angles of 113° (between external oxygen atoms) and 105° (between internal and external oxygen atoms). When viewed down the P–P vector, the two $-PO_3$ groups are staggered with respect to each other. The space group is stated to be I2/*c*; earlier reports[548,552] gave *C*2/*c*. The crystal structure[1263] of $\beta$-$Ca_2P_2O_7$ shows two independent pyrophosphate groups in an essentially eclipsed configuration. The POP angles are 131° and 138°, and the bond lengths: P–O(P) $1{\cdot}615 \pm 0{\cdot}017$, P–O $1{\cdot}518 \pm 0{\cdot}021$ A. Unit cell data and space groups (Table XIV) have been reported for several other pyrophosphates.[549,553,1211,1264-5] In the structure of tungsten oxypyrophosphate,[648] a P–O–P angle of 142° follows from presumed tetrahedral co-ordination of the phosphorus atoms, after some of the oxygen positions have been calculated from electron-density projections. The structure is built up of layers formed from fairly regular $WO_6$ octahedra, with oxygen atoms shared by coupling pyrophosphate groups. Each tungsten atom is in contact with five pyrophosphate groups, and each pyrophosphate group with five tungsten atoms. Each tungsten atom is also in contact with one oxygen atom which is not bonded to any other group. The layers are held together by Van der Waals forces and the crystals show pronounced layer cleavage.

The configuration of the pyrophosphate ion has also been investigated by spectroscopic means. The infra-red spectra of the $\alpha$ and $\beta$ forms of disodium pyrophosphate, $Na_2H_2P_2O_7$, have been studied in an unsuccessful attempt to determine the ionic symmetry in the crystals.[555] From the infra-red activity, in saturated solutions of tetrasodium and tetrapotassium pyrophosphate in normal and heavy water, of the totally symmetric P=O and P–O–P stretching vibrations of the pyrophosphate ion, which have been assigned[560] to Raman bands at 1018 and 718 cm.$^{-1}$ respectively, it has been concluded that the P–O–P linkage of the pyrophosphate ion is bent in solution.[556-7] In the infra-red (crystal, glass) and Raman (melt) spectra of tetrasodium pyrophosphate POP stretching vibrations were assigned[1267] at 714–730 (s) and 900–915 (as) cm.$^{-1}$, and $PO_3$ stretching vibrations at 1016–1030 (s) and 1100–

1150 (as) cm.$^{-1}$. Approximate force constants have been calculated[1268–9] for the pyrophosphate ion, although one set[1268] is based on the somewhat unlikely assignment of $\nu_s$(POP) at 909 cm.$^{-1}$. The calculations were based on a linear P–O–P bond and the results compared with data on a variety of crystalline phosphates. In the infra-red spectra of the cubic crystalline pyrophosphates, absorptions in the 1060–1125 and 500–675 cm.$^{-1}$ regions were interpreted as arising from stretching vibrations of an M–O–P group and as suggesting covalent bonding between the pyrophosphate groups and the metal atom.[558] It was argued that these compounds could be considered as double oxides, and that this might account for the linearity of the P–O–P group. However, the bands around 500 cm.$^{-1}$ attributed to M–O stretching have been assigned by other workers[1269] to bending motions of the pyrophosphate ion, the double oxide idea being rejected. Several workers[1270–1] have studied the spectra of the cubic pyrophosphates in some detail and shown them to be consistent with a linear P–O–P linkage. A variable-temperature infra-red study of magnesium pyrophosphate[1272] showed that in the low-temperature form the symmetry was not greater than $C_s$ or $C_2$, with a POP angle of not more than 150–160°. In the high temperature form the POP angle appears to be 180°, but the centrosymmetry is thought to be of a statistical nature. It was suggested that the potential energy curve for the POP vibration has two minima, and that the phase transition is explained by the thermal excitation of anionic inversion. Manganese pyrophosphate, also investigated,[1273] shows no such transition to a bent configuration at low temperatures. Other assignments of bands for the pyrophosphate ion are 900–915 cm.$^{-1}$ for the antisymmetrical P–O–P stretching vibration, 966–986 cm.$^{-1}$ for the out-of-phase symmetrical $PO_3$ stretching vibration, and 1122–1150 cm.$^{-1}$ for the unsymmetrical $PO_3$ stretching vibrations.[560] Other workers[559] suggested that a band at 930–950 cm.$^{-1}$ in the infra-red spectra of several pyrophosphates was characteristic of the pyrophosphate grouping and was probably the antisymmetric P–O–P stretching vibration. In another paper[561] on the infra-red spectra of alkali pyrophosphates the assignments of the P–O–P stretching vibrations were inverted, the symmetrical vibrations being placed at 917 cm.$^{-1}$ and the antisymmetrical ones at 700–740 cm.$^{-1}$ Stretching vibrations of the $PO_3$ groups were placed at 1144–1193 cm.$^{-1}$. The infra-red and Raman spectra of the dihydrogen pyrophosphate, $H_2P_2O_7^{2-}$, ion were determined[1320] from the study of aqueous solutions of $Na_2H_2P_2O_7$. Assignments, confirmed by deuterium exchange, included $\nu_{as}PO_2$ 1183, $\nu_sPO_2$ 1110, $\nu_{as}POP$ 910, and $\nu_{as}POP$ 715 cm.$^{-1}$ The broadness of the Raman bands below 750 cm.$^{-1}$ was attributed to rotational isomerism arising from hydroxyl groups on opposite phosphorus atoms. Pyrophosphates of which the spectra have been determined are given in Table XV. The infra-red spectra of large numbers of inorganic and organic pyrophosphates have been correlated, and a band in the 900–980 cm.$^{-1}$ region related to the presence of the pyrophosphate grouping.[215, 525, 559, 661–2, 777–8, 782]

The phosphorus nuclear magnetic resonance spectrum[171, 330, 568–9] of pyrophosphate ions shows a single peak, indicating equivalence of the phosphorus atoms. The chemical shift of tetrasodium pyrophosphate (relative to 85% orthophosphoric acid) is +6 p.p.m.[171, 330] Variation of this shift with pH has been investigated (Fig. 11) and related to the formation of P–O–H bonds of some covalent character.[739] The shifts for sodium and potassium acid pyrophosphates are +10 and +9 p.p.m. respectively.[171] An aqueous solution of pyrophosphoric acid has a shift of +10·6 p.p.m.[226] A rapidly rotating sample of pyrophosphoric acid gives a shift of +12 p.p.m.[971]

## TRIPHOSPHATES

The crystal structures of both forms of sodium triphosphate, $Na_5P_3O_{10}$, have been determined,[550, 574–5] and the results of the determinations on the low temperature phase II have recently been refined.[744] Both forms are monoclinic, space group $C2/c$, with a four-molecule cell, and in each case the triphosphate ions are slightly distorted from a symmetrical *trans* configuration, having axial symmetry and lying on twofold axes in the unit cell. In $Na_5P_3O_{10}$ II the sodium ions are co-ordinated by oxygen in a distorted octahedral arrangement; in $Na_5P_3O_{10}$ I two types of sodium have distorted octahedral co-ordination and a third type has fourfold co-ordination. Parameters of the two structures are given in Table XVI.

Sodium triphosphate hexahydrate, $Na_5P_3O_{10},6H_2O$, was said to be orthorhombic, with $a=7·53$, $b=10·23$, $c=9·83$ A.,[576] but more recent reports[1277–8] indicate it to be triclinic, with $a=9·799$, $b=10·30$, $c=7·652$ A., $\alpha=94·45°$, $\beta=92·20°$, $\gamma=90·99°$, $Z=2$,[1277] space group[1278] $P\bar{1}$. The crystal structure has been determined[1278] and confirms the large difference between the two types of P–O(–P) bond. The POP angle is 123·5°. Details have been published of the use of $X$-ray powder photographs for the

analysis of commercial sodium triphosphates.[570, 748–50] Unit cell data for a series of ammonium triphosphates are listed on p. 1202.

Infra-red spectra have been reported[525, 560, 567, 577, 665] for sodium triphosphate phase I, phase II, and hexahydrate, and the spectra have been used for analytical purposes.[665] The infra-red spectrum of sodium triphosphate glass, and the Raman spectra of the melt[560] and solution,[760] have been determined. Assignments were made of a $PO_3$ symmetrical stretching vibration at 998 (Raman, very strong), or 1017 (infra-red, weak) $cm.^{-1}$, $PO_3$ antisymmetrical stretching vibrations at 1150 and 1085 $cm.^{-1}$ (Raman) or 1126, 1150, and 1215 $cm.^{-1}$ (infra-red, very strong), $PO_2$ antisymmetrical stretching vibration at 1215 $cm.^{-1}$ (infra-red), $PO_2$ symmetrical stretching vibration at 1112 $cm.^{-1}$ (Raman, strong), POP symmetrical stretching vibrations at 692–712 $cm.^{-1}$ (Raman and infra-red) and 760 $cm.^{-1}$ (infra-red only), and POP antisymmetrical stretching vibrations at 886 (Raman, weak), 888 (infra-red) $cm.^{-1}$ and 953 $cm.^{-1}$ (infra-red).[560] The infra-red spectra of potassium triphosphate,[525] silver triphosphate,[525–6] dizinc sodium triphosphate,[526] dizinc sodium triphosphate nonahydrate[525] and nickel trisodium triphosphate dodecahydrate[525, 1245] have been reported.

The phosphorus nuclear magnetic resonance spectrum of triphosphate ions[171, 330, 568–9, 663] shows separate peaks, corresponding to the end and middle groups, with relative intensities of two to one, and a doublet and triplet spin-spin splitting respectively, confirming the chain structure of the ion. The chemical shifts[171] are +4 p.p.m. for the end groups and +18 p.p.m. for the middle groups. The spin-spin splitting between the non-equivalent phosphorus nuclei is 16 cycles/sec.[171, 663] Changes in chemical shift with pH have recently[739] been observed for both end and middle groups (Fig. 11). These changes are attributed to the formation of P–O–H bonds of some covalent character. The change of shift with pH for middle groups is about half that for end groups, and this is taken as an indication that the hydrogen atoms spend some time on the middle groups as well as on the end groups. The lack of any P–O–H spin-spin coupling and the appearance of single phosphorus resonances are strong evidence for a rapid exchange of hydrogen atoms, so that only information on time-average location of these may be obtained.[739]

## LONGER-CHAIN PHOSPHATES

The infra-red spectrum of sodium tetraphosphate, $Na_6P_4O_{13}$, and the Raman spectrum of the melt have been determined.[560] The assignments made were very similar to those given above for the triphosphate.

The phosphorus nuclear magnetic resonance spectrum of tetraphosphate ions shows two peaks of equal intensity, one from the end groups at a chemical shift of +5 p.p.m., and one from the middle groups at a chemical shift of +18 p.p.m.[330] This distinction between end and middle group peaks is maintained throughout the whole range of polyphosphate chain lengths.[171, 330, 568–9] End group chemical shifts are between +6 and +9 p.p.m. Middle group shifts range from +18 p.p.m. in short chains to +21 p.p.m. in long chains. The intensity ratio of the two peaks provides a measure of the average chain length, and the method has been used for the analysis of polyphosphates.[787] The spectrum of tetraphosphate ions has recently[739] been analysed to give values of the spin-spin coupling constants of 19·7 c/s between inner and outer phosphorus nuclei, and 16·5 c/s between the inner nuclei. As with triphosphate ions, changes in pH cause changes in chemical shift, related to the formation of P–O–H bonds having some covalent character (Fig. 10). The changes for middle groups are smaller than with triphosphate ions.[739]

### Metaphosphates

The sparingly soluble crystalline alkali metal ‘metaphosphates’ of general formula $(MPO_3)_n$, typified by the varieties of Maddrell's salt, $(NaPO_3)_n$, and the sodium and potassium Kurrol salts, form fibrous crystals similar to those of asbestos. They are generally considered to contain long chains of $PO_3^-$ groups, and hence to be linear polyphosphates of high molecular weight, rather than true cyclic metaphosphates. The long chain structure has been confirmed for Maddrell's salt,[578] $(NaPO_3)_n$, and in detail for rubidium metaphosphate Kurrol salt,[579] $(RbPO_3)_n$, silver metaphosphate[906] $(AgPO_3)_n$, and sodium Kurrol salt type $\alpha$.[907] The unit cell of rubidium metaphosphate contains a portion of two different chains which spiral in opposite ways about the screw axes. The pattern repeats after two $PO_3$ units. The four-molecule cell is monoclinic, with $a = 12{\cdot}123$, $b = 4{\cdot}228$, $c = 6{\cdot}479$ A., $\beta = 96{\cdot}3°$, space group $P2_1/n$. Bond lengths were given as P–O (chain) 1·62 A., P–O (external) 1·47 and 1·45 A. This structure has more recently been refined[744]; the latest bond lengths are P–O (chain) $= 1{\cdot}616 \pm 0{\cdot}010$ A., P–O (external) $= 1{\cdot}488 \pm 0{\cdot}010$ A., with bond angles of O–P–O (chain) = 103°, O–P–O (external) = 120°, and P–O–P = 129°. The crystal structure of Maddrell's salt, $(NaPO_3)_n$ (II) is somewhat similar to that of rubidium metaphosphate, but is disordered.[1281] The pattern is repeated every three $PO_3$ units, being similar to $\beta$-wollastonite in this respect.[578] Silver metaphosphate, $(AgPO_3)_n$, and sodium Kurrol salt type $\alpha$ have similar structures with helically arranged chains of $PO_4$ tetrahedra parallel to the $b$ axis with four tetrahedra per repeat unit.[906–7] Each silver or sodium atom has five oxygen atom neighbours. Unit cell data (Table XVII) have been reported for several other sparingly soluble metaphosphates.

The Raman[584–5, 760] and infra-red[525, 567, 584] spectra of sodium and potassium Kurrol salts have been reported and assignments given.[584] Antisymmetrical $PO_2$ stretching vibrations were assigned in the infra-red at 1285 cm.$^{-1}$, and in Raman and infra-red at 1255–1270 cm.$^{-1}$, symmetrical $PO_2$ stretching vibrations in Raman and infra-red at 1140–1150 cm.$^{-1}$ and 1087–1108 cm.$^{-1}$, anti-symmetrical POP stretching vibrations in the infra-red at 980–1020 cm.$^{-1}$ and 860 cm.$^{-1}$, and symmetric P–O–P stretching vibrations at 677–730 cm.$^{-1}$ in the infra-red. Bending and rocking motions of the $PO_2$ groups were assigned to Raman bands at 514–534, 425–437, and 364–375 cm.$^{-1}$. Infra-red spectra of the two forms of Maddrell's salt, $[NaPO_3]_n$ II and III, have also been reported.[525, 567, 665] The infra-red spectrum (polarized radiation)[1291] of $(KPO_3)_x,K_2O$ showed fourteen bands between 650 and 1400 cm.$^{-1}$, indicating that interactions between $PO_3$ groups of different chains in the unit cell, as well as between neighbouring groups in the same chain, were important.

*Table XVII.—Unit Cell Data for Sparingly Soluble Metaphosphates*

| Salt | Unit cell data (A or degrees) | | | | | Space group | References |
|---|---|---|---|---|---|---|---|
| | *a* | *b* | *c* | *β* | *Z* | | |
| $(AgPO_3)_n$ | 11·86 | 6·06 | 7·31 | 93·5 | 8 | $P2_1/n$ | 907 |

### PHOSPHATE GLASSES

The Raman[584–5, 760] and infra-red[525, 567, 584] spectra of vitreous sodium polyphosphate (Graham's salt) have been reported. Assignments[584] are similar to those given for the Kurrol salts (above). The infra-red spectra of a wide range of phosphate and phosphate–fluoride glasses have been determined[647] over the region 2–15 microns. The cations present were sodium, potassium, calcium and lithium, and the composition of the glasses ranged from metaphosphate to pyrophosphate. The metaphosphate glasses of sodium, calcium and lithium show very similar spectra, suggesting structural similarities. The spectrum of potassium metaphosphate glass is very different, suggesting a different symmetry for the polyphosphate chain in the solid state. The addition of sodium fluoride or metallic oxides to the glasses causes radical changes in the spectra. The Raman spectrum of a glassy polyphosphoric acid obtained from the thermal dehydration of phosphoric acid or ammonium dihydrogen phosphate has been reported.[1280] Fourteen lines were reported, with three strong polarized lines at 686, 1151 and 1341 cm.$^{-1}$. Approximate stretching force constants were calculated.[1280] The cylindrical distribution function in oriented sodium metaphosphate glass fibres has been studied.[1283] In-chain and out-of-chain PO bond lengths of 1·62 and 1·46 A. respectively were found. It was suggested that long chains of $PO_4$ tetrahedra, along the fibre axis, were similar to those in $Rb(PO_3)_n$.

## CYCLIC PHOSPHATES

The phosphorus nuclear magnetic resonance spectra of tri- and tetrametaphosphates[171] show a single peak at about the same position as the middle group peak in chain phosphates, thereby confirming the cyclic structure. The shift range for different cyclic phosphates (sodium salts) has been quoted as 20·9 p.p.m. for the trimetaphosphate,[1192, 1322] 22·9 p.p.m. for the tetrametaphosphate,[1192] and 21·9 for the hexametaphosphate, all relative to 85% $H_3PO_4$.

The crystal structures of ammonium tetrametaphosphate, $(NH_4)_4P_4O_{12}$,[587–9, 744, 908] and of the monoclinic form of sodium tetrametaphosphate tetrahydrate, $Na_4P_4O_{12},4H_2O$,[590, 596, 751] have been determined. Ammonium tetrametaphosphate is orthorhombic, with $a=10\cdot42$, $b=10\cdot82$, $c=12\cdot78$ A. The unit cell contains four molecules, and has space group *Cmca*. Tetrametaphosphate ions, $P_4O_{12}{}^{4-}$, are stacked in a face-centered array, interleaved with layers of $NH_4$ cations. The tetrametaphosphate rings are nearly flat, with $C_{2h}$ symmetry. This structure has more recently been refined[744]; the latest bond lengths and angles are given in Fig. 13. Monoclinic sodium tetrametaphosphate tetrahydrate[751] has a bimolecular cell of dimensions $a=9\cdot667$, $b=12\cdot358$, $c=6\cdot170$ A., $\beta=92°\ 16'$, with space group $P2_1/a$. Sodium ions are co-ordinated by six oxygen atoms in an approximately octahedral configuration, and the tetrametaphosphate rings lie on centres of symmetry, also showing strong pseudo-$C_{2h}$ point symmetry, as in the ammonium salt. Bond lengths and angles are given in Fig. 13.

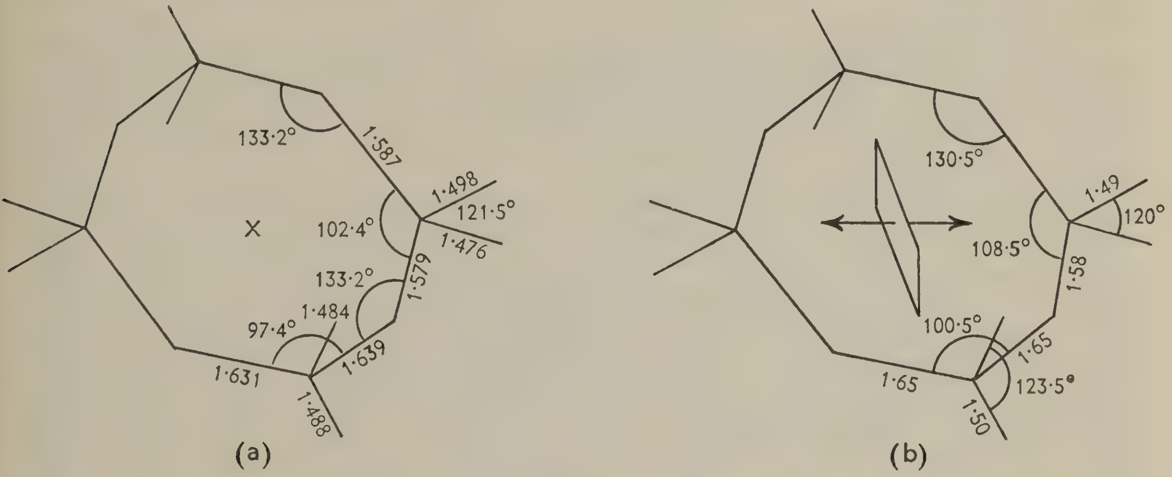

FIG. 13.—Bond lengths and angles of the tetrametaphosphate ions in (*a*) monoclinic sodium tetrametaphosphate tetrahydrate[751] (*b*) ammonium tetrametaphosphate[587–9, 744]

Recently the structures of triclinic sodium tetrametaphosphate tetrahydrate,[1293] sodium trimetaphosphate and its monohydrate[1294] have been determined. Triclinic $Na_4P_4O_{12},4H_2O$ has cell dimensions[1293] $a=6\cdot652$, $b=9\cdot579$, $c=6\cdot320$ A., $\alpha=103°\ 24'$, $\beta=106°\ 59'$, $\gamma=93°\ 17'$, space group $P\bar{1}$, $Z=1$. The tetrametaphosphate ring is on a centre of symmetry; there are some similarities between the monoclinic and triclinic structures, but the differences are too great to permit a transition between the two forms in the solid state.

Sodium trimetaphosphate and its monohydrate[668, 1294] have very similar structures. The anhydrous structure contains a hole which is large enough to accommodate the water molecule (but it cannot get in or out). In the hydrate the water fills this hole and there are some slight changes in the cell dimensions; this situation is thought to be unique. Both structures are orthorhombic with space group *Pmcn*, $Z=4$. The anhydrous salt has $a=7\cdot928$, $b=13\cdot214$, $c=7\cdot708$ A., and the monohydrate $a=8\cdot500$, $b=13\cdot189$, $c=7\cdot558$ A. Earlier cell data[591] on the anhydrous salt were not confirmed. The trimetaphosphate ions have a chair configuration lying on a mirror plane. The average ring angles are: O–P–O 101°, P–O–P 127°; the largest change on hydration is at the oxygen atom on the mirror plane, where the P–O–P angle changes from 128 to 122°. Bond lengths are as follows (values for the monohydrate in brackets): ring bonds 1·60 (1·61), 1·63 (1·63), 1·61 (1·63) A., exocyclic bonds 1·49 (1·51), 1·48 (1·47), 1·48 (1·49), 1·48 (1·47) A. Cell dimensions have also been reported[668] for the sesquihydrate, $Na_3P_3O_9,1{\cdot}5H_2O$ (orthorhombic, $a=11{\cdot}05$, $b=20{\cdot}70$, $c=8{\cdot}01$ A., $Z=8$, space group $A2_122$), and the trihydrate (tetragonal, $a=12{\cdot}86$, $c=12{\cdot}63$ A.). A second form of the monohydrate has been reported; it is tetragonal with a tetramolecular cell and $a=7{\cdot}99$, $c=13{\cdot}14$ A.[592]

The crystal structure of lithium dipotassium trimetaphosphate monohydrate has been determined.[1301] The cell is monoclinic, with $a=8{\cdot}669$, $b=14{\cdot}497$, $c=7{\cdot}634$ A., $\beta=99°\ 53'$, space group $P2_1/c$, $Z=4$. The trimetaphosphate ring has a chair form of pseudo-$C_{3v}$ symmetry. Average bond lengths are 1·61 A. for ring bonds, 1·49 A. for exocylic bonds, and average ring angles are 100·15° (O–P–O) and 128·9° (P–O–P).

Crystallographic data for some trimeta-arsenatophosphates, $Na_3(As,P)_3O_9$ have been reported.[1295] For As:P = 1:6, the unit cell is orthorhombic with $a=8{\cdot}04$, $b=13{\cdot}35$, $c=7{\cdot}82$ A., space group $P2_1cn$. For As:P = 1:12, it has $a=11{\cdot}31$, $b=20{\cdot}16$, $c=6{\cdot}94$ A., space group $Pmmb$ or $Pm2_1b$. For a ratio of As:P = 1:2·7, the cell is triclinic with $a=7{\cdot}97$, $b=7{\cdot}10$, $c=7{\cdot}14$ A., $\alpha=90{\cdot}1°$, $\beta=93{\cdot}2°$, $\gamma=103{\cdot}7°$, and the structure was determined.

The structure of sodium hexametaphosphate hexahydrate, $Na_6P_6O_{18},6H_2O$, has been determined.[1296] The structure is orthorhombic, space group $Ccma$, with $a=10{\cdot}58$, $b=18{\cdot}54$, $c=10{\cdot}48$ A. The anion $P_6O_{18}{}^{6-}$ has a cyclic chair-form structure, symmetry $C_{2h}$. Bond lengths are 1·60, 1·61, 1·62 A. in the ring, and 1·50, 1·48, 1·49, 1·49 A. exocyclic.

An approximate structure has been proposed for aluminium tetrametaphosphate.[586] The complicated cubic structure has a tetramolecular cell of side 13·63 A., and the space group is $I\bar{4}3d$. The tetrametaphosphate rings are puckered, with $S_4$ symmetry, and their outer oxygen atoms provide octahedral co-ordination for the aluminium ions.

A compound described as a sodium metaphosphate, $Na_2H_2P_4O_{12}$,[593] with a fibrous crystal habit, has been claimed to be an ultraphosphate, $Na_2P_4O_{11}$, on the basis of an *X*-ray investigation,[594] but more recent work[595] has cast doubt on this interpretation. One molecule was removed from the original formula to obtain agreement between calculated and observed densities, and the structure was said to comprise partly disordered chains, composed of tetrametaphosphate rings linked by the sharing of an oxygen atom between adjacent rings. Two forms are described; form I is monoclinic, $a=30{\cdot}7$, $b=6{\cdot}77$, $c=7{\cdot}12$ A., $\beta=94{\cdot}1°$, space group $P2_1/a$, while form II is monoclinic and pseudo-orthorhombic, with $a=18{\cdot}74$, $b=14{\cdot}79$, $c=7{\cdot}03$ A., $\beta=90{\cdot}0°$, space group $B2/a$ or $Ba$. The latest work[297–8] on the orthorhombic modification shows that the structure consists of $P_4O_{12}$ rings linked to chains, probably by hydrogen bonds. Each chain has two possible positions differing by $C/2$, producing the observed disorder.

It was concluded[602] from the Raman spectra of solutions of sodium, potassium and ammonium tetrametaphosphates that the tetrametaphosphate ion in solution has a puckered *trans*-configuration of $C_{2h}$ symmetry. Tentative assignments were made of antisymmetrical $PO_2$ stretching vibrations to bands at 1365 and 1248 cm.$^{-1}$; of symmetrical $PO_2$ stretching vibrations to bands at 1158 and 1114 cm.$^{-1}$; and of ring vibrations to bands at 1074, 1015, 897 and 813 cm.$^{-1}$. The Raman and infra-red spectra of crystalline tetrametaphosphates[603–4] have been interpreted as showing different symmetry for the anions; $S_4$ symmetry in aluminium tetrametaphosphate and $C_{2h}$ symmetry in ammonium tetrametaphosphate were suggested, confirming the *X*-ray results. The spectra of cupric tetrametaphosphate and magnesium tetrametaphosphate suggest different structures, the anion having $D_{2d}$ symmetry in each case. Suggested assignments were 1235–1314 cm.$^{-1}$ for $PO_2$ antisymmetrical stretching vibrations, 1093–1182 cm.$^{-1}$ for the symmetrical vibrations, and 880–1060 and 693–882 cm.$^{-1}$ for ring vibrations. Later work[1299] on the Raman (solution and solid) and infra-red (solid) spectra of sodium tetrametaphosphate suggested that the ring has a *trans*-$C_{2h}$ configuration in the solid as well as in solution.

The Raman spectra of solutions of sodium and potassium trimetaphosphate and trimetaphosphoric acid,[521, 565, 597–8, 600] and the infra-red spectra of sodium, potassium, silver and lead trimetaphosphate powders[525, 567, 584, 599, 665] have been determined. The Raman spectra were interpreted[598] as indicating a flat ring, with $D_{3h}$ symmetry for the trimetaphosphate ion in solution. Bands at 1158, 665, 634 and 398 or 356 cm.$^{-1}$ were assigned to $A_1'$-type vibrations, and bands at 1119, 1000 and 763 cm.$^{-1}$ to $E'$-type vibrations. Some of the more detailed assignments given in this paper have since been revised.[584, 601] From the infra-red spectrum of solid anhydrous sodium trimetaphosphate[584] it was concluded that the ion has $C_{3v}$ symmetry in this crystal. The $D_{3h}$ symmetry of the ion in solution was supported by the infra-red spectra of trimetaphosphate ions in solution in normal and heavy water[601]; in this paper the antisymmetrical $PO_2$ stretching vibrations were assigned at 1277 cm.$^{-1}$ (infra-red, $A_2''$) and 1243 cm.$^{-1}$ (Raman, $E''$), the corresponding symmetrical vibrations at 1158 cm.$^{-1}$ (Raman, $A_1'$) and 1098–1119 cm.$^{-1}$ (Raman and infra-red, $E'$), while ring vibrations were assigned at 1000–1015 cm.$^{-1}$ (Raman, infra-red), 763–783 cm.$^{-1}$ (Raman, infra-red), and 634 cm.$^{-1}$ (Raman). These assignments, particularly those for the ring vibrations, cannot be regarded as definitely established. In the same paper[601] the infra-red spectrum of crystalline sodium trimetaphosphate hexahydrate was given, and it was concluded that the ion in this crystal has $C_{3v}$ symmetry, as in the corresponding anhydrous salt. Later work,[1299] however, including polarization data on the solution, rejected the $D_{3h}$ symmetry in solution because of polarized bands (5 or 6) and the similarity to the crystal spectra. It was concluded that the symmetry was $C_{3v}$ both in the solid and in solution.

In addition to spectra contained in papers quoted above, the following infra-red spectra have been reported: sodium trimetaphosphate (anhydrous, monohydrate, hexahydrate), magnesium trimetaphosphate decahydrate, calcium sodium trimetaphosphate trihydrate, strontium trimetaphosphate heptahydrate, barium trimetaphosphate tetrahydrate, manganese trimetaphosphate undecahydrate, nickel trimetaphosphate,[1245] sodium tetrametaphosphate (normal and metastable forms, and monohydrate), silver tetrametaphosphate dihydrate,[525] silver trimetaphosphate,[525–6] silver tetrametaphosphate,[526] and magnesium tetrametaphosphate octahydrate, calcium tetrametaphosphate pentahydrate, strontium tetrametaphosphate pentahydrate, barium tetrametaphosphate tetrahydrate, lead tetrametaphosphate tetrahydrate, manganese tetrametaphosphate monohydrate, cupric tetrametaphosphate octahydrate, aluminium tetrametaphosphate[525] and nickel tetrametaphosphate.[1245] Both types of salt are generally characterized by strong absorption in the 510–580, 990–1020 and 1200–1280 cm.$^{-1}$ regions, with weaker absorptions around 750–820 cm.$^{-1}$, 1110 cm.$^{-1}$ and 1150 cm.$^{-1}$ [525, 660]

#### BRANCHED PHOSPHATES

The phosphorus nuclear magnetic resonance spectra of highly branched ultraphosphates heated to their softening point[171] show a broad peak at a chemical shift of +30–31 p.p.m. which is absent from unbranched material and may be assigned to the phosphorus atoms at branch points. Azeotropic phosphoric acid shows a similar peak at +34 p.p.m.[171]

## LOWER PHOSPHORUS OXYACIDS AND SALTS

### Phosphorous acid and phosphites

The crystal structure of phosphorous acid has been determined.[909] The unit cell is orthorhombic, with $a = 7{\cdot}27$, $b = 12{\cdot}06$, $c = 6{\cdot}85$ A., and eight molecules per cell, with space group $Pna2_1$. The $PO_3$ group has two P–O bonds of length 1·54 A. and one of length 1·47 A., supporting the expected structure $H_2(HPO_3)$. The molecules appear to be linked by two hydrogen bonds per molecule, as expected. The O–P–O angle between the two hydroxyl groups is 102 ± 3°, and the other two O–P–O angles are 113 ± 5° and 116 ± 3°.

The crystal structure of magnesium phosphite hexahydrate, $MgHPO_3,6H_2O$, has been determined.[605] The lattice is rhombohedral, with $a = 5{\cdot}96$ A. and $\alpha = 96° 24'$, space group *R*3. The structure is built up from discrete tetrahedral $[HPO_3]^{2-}$ and octahedral $Mg^{2+}(H_2O)_6$ groups, which are bound together by a continuous 3-dimensional system of hydrogen bonds. The phosphite ion has threefold symmetry and lies on a threefold axis of the unit cell. The P–H distance is 1·47 A., P–O = 1·51 A., and the angles H–P–O = 109°, O–P–O = 110°. The crystal structure of phosphorous acid has been reported.[658] The cell is orthorhombic, with $a = 7{\cdot}257$, $b = 12{\cdot}044$, $c = 6{\cdot}845$ A., space group $Pna2_1$, and eight molecules per cell. The P–H distance is close to 1·39 A.

Disodium phosphite pentahydrate, $Na_2HPO_3,5H_2O$, has an orthorhombic cell with $a = 6{\cdot}4$, $b = 7{\cdot}6$, $c = 9{\cdot}4$ A., and two molecules per cell.[910] The electron spin resonance spectrum of the $\gamma$-irradiated compound has been investigated[910] and shown to arise from the ionic radical $\cdot PO_3^{=}$. Strong hyperfine coupling with the phosphorus nucleus was observed, and the dependence of line splittings on the field direction indicated two magnetically distinct sites. This shows that the $HPO_3^{=}$ ion has a plane of symmetry perpendicular to the *b* axis. The spectrum of $\cdot PO_3^{=}$ is consistent with a pyramidal ion having O–P–O angles of 110°. This radical has also been observed in magnesium phosphite hexahydrate,[911] and in ammonium phosphorofluoridate,[1333] in which the principal values of the $^{31}P$ hyperfine interaction tensor for the radical were determined as 1822·3, 1419·7, 1408·6 Mc/s, in reasonable agreement with theoretical predictions.[1333]

The crystal structure of cupric phosphite dihydrate, $CuHPO_3,2H_2O$, has been determined.[1302] The structure is orthorhombic with $a = 6{\cdot}71$, $b = 9{\cdot}00$, $c = 7{\cdot}40$ A., $Z = 4$, space group $P2_12_12_1$. Zigzag chains of deformed octahedral $CuO_3(H_2O)_3$ groups are bound together by phosphite groups. Tin (II) phosphite, $SnHPO_3$, is orthorhombic,[1303] with $a = 4{\cdot}60$, $b = 6{\cdot}18$, $c = 12{\cdot}34$ A., $Z = 4$, space group *Pnnm* or *Pnn*2. Lead (II) nitrophosphite, $PbHPO_3,Pb(NO_3)_2$, is orthorhombic,[1304] with $a = 7{\cdot}22$, $b = 10{\cdot}46$, $c = 5{\cdot}42$ A., $Z = 2$, space group probably $Pmn2_1$.

The Raman spectra[518, 538, 597, 606–9] of phosphite ions in $H_3PO_3$, $KH_2PO_3$, $K_2HPO_3$, $Na_2HPO_3$, $NaH_2PO_3$ solutions and crystalline $H_3PO_3$ and $Na_2HPO_3$[606] have been obtained. Recent work on the Raman spectrum of $NaH_2PO_3$[916] has cast doubt on the published spectra of this and the monopotassium salt.[518, 597] Infra-red spectra have been reported for aqueous solutions of $Na_2HPO_3$ and $K_2HPO_3$,[566] for crystalline $Na_2HPO_3$, $BaHPO_3$, $CaHPO_3,H_2O$,[525, 610, 1306] $H_3PO_3$, $(NH_4)_2HPO_3$,[1306] $Na_2HPO_3,5H_2O$,[525, 610, 1307] $Li_2HPO_3,H_2O$, $SrHPO_3,H_2O$, $PbHPO_3$, $NiHPO_3,H_2O$,[525, 610] $NaH(HPO_3),2{\cdot}5H_2O$, $Na_2H_4(HPO_3)_3$, $NaH_3(HPO_3)_2$,[1307] and have also been observed in aqueous solutions of $NaH_2PO_3$.[878] The dibasic nature of the acid is confirmed by the general appearance of bands in the 2280–2430 cm.$^{-1}$ region, arising from P–H linkages. The Raman and infra-red spectra of mono- and disodium phosphite solutions[538, 878, 916] show clearly that the symmetry of the $HPO_3^{2-}$ ion is reduced in the former salt by the addition of a hydrogen atom to form $H_2PO_3^-$ ions. A symmetry of $C_{2v}$ has been suggested[610] from infra-red spectra for phosphite ions in various metallic salts, but it is not clear from the paper whether this refers to $HPO_3^{2-}$ or to $H_2PO_3^-$ ions. For the $HPO_3^{2-}$ ion in solution symmetry $C_{3v}$ has been suggested[538] and the latest infra-red work,[566] based on the spectra of crystalline barium phosphite and aqueous sodium and potassium phosphites, with earlier Raman work[538] confirms this and enables a full assignment of the spectra (Table XVIII) to be made. A normal co-ordinate calculation based on complete assignments of normal and deuterated compounds has been made[1306] using a simple valence force field. Results were $F_{PH} = 3{\cdot}331$, $F_{PO} = 6{\cdot}418$ millidynes/A. $C_s$ or $C_1$ symmetry was proposed for the phosphite groups in crystalline phosphorous acid.[1306] Figures of 3·0–3·5 millidynes/A. have also been suggested[1088] for $F_{PH}$ in phosphorous acid and different salts.

A band at 1744 cm.$^{-1}$ due to P–D stretching has been reported in the Raman spectrum of a strong solution of phosphorous acid in deuterium oxide. It is suggested that the deuterium exchange is evidence for the presence of small amounts of the tautomeric form $P(OH)_3$.[608] A similar band has been observed in the infra-red spectrum.[878]

*Table XVIII.—Spectra and Assignments*[566] *for Phosphite Ion,* $(HPO_3)^{2-}$

| Raman cm.$^{-1}$ ($Na_2HPO_3$ solution) | Infra-red cm.$^{-1}$ $K_2HPO_3$ solution | Infra-red cm.$^{-1}$ $BaHPO_3$ mull | Assignment |

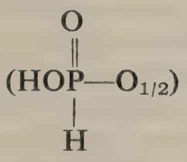
The far ultra-violet spectrum of phosphite ions in aqueous solution has been reported.[1318] The spectrum shows weak absorption above 200 mμ and a steeply rising absorption edge, attributed to a charge-transfer-to solvent transition, below 200 mμ.

The molar magnetic rotatory power (defined as $\rho M/d$, where $\rho$ is Verdet's constant, $M$ the molecular weight, and $d$ the density) of phosphite ions is $100 \times 10^{-2}$ min. of arc.[607, 611]

The phosphorus[110, 171, 225, 569, 634, 1308] and proton[225, 634, 1308] nuclear magnetic resonance spectra of phosphite ions are in agreement with the $HPO_3^{2-}$ structure. Strong phosphorus–proton spin-spin coupling is observed[171, 225, 634] indicating that the proton is directly bonded to the phosphorus. The phosphorus chemical shift lies between $-4$ and $-8$ p.p.m.[110, 171, 225] The spin-spin coupling constant $J_{P-H}$ was reported to be 707 c/s.[225, 634]

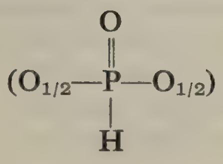
The effects of concentration, and of neutralization, on the NMR parameters of aqueous phosphorous acid have been investigated.[1250] The $^{31}P$ shift and the coupling constant varied from $-3{\cdot}9$ p.p.m. (relative to 85% $H_3PO_4$) and 664 c/s respectively at zero concentration to $-5{\cdot}8$ p.p.m. and 690 c/s at 10 molar. The effect of neutralization at constant phosphorus concentration was an increase in shift of about 1 p.p.m., to $-3{\cdot}3$ p.p.m., and a change in $J_{PH}$ from about 670 c/s to about 570 c/s. These changes were attributed to the association of protons with the anions. The effect of protonation of phosphorous acid has also been studied[1305] and followed by means of $J_{PH}$, which changes from 683 c/s to 806 c/s as the acid is protonated.

The $^{31}P$ NMR spectra of a series of polyphosphorous acids have been reported.[1309] Shift and coupling data were for end groups



$$(\mathrm{HO}\underset{\displaystyle\mathrm{H}}{\overset{\displaystyle\mathrm{O}}{\overset{\|}{\underset{|}{\mathrm{P}}}}}\text{—}\mathrm{O}_{1/2}) \quad \delta = +7{\cdot}4 \text{ p.p.m.}, \quad J_{PH} = 710 \text{ c/s}$$

for middle groups



$$(\mathrm{O}_{1/2}\text{—}\underset{\displaystyle\mathrm{H}}{\overset{\displaystyle\mathrm{O}}{\overset{\|}{\underset{|}{\mathrm{P}}}}}\text{—}\mathrm{O}_{1/2}) \quad \delta = +14, \quad J_{PH} = 760 \text{ c/s}$$

Data for the 'neso' group (orthophosphorous acid) $H_2.HPO_3$ were reported as $\delta = 3{\cdot}2$ p.p.m., $J_{PH} = 670$ c/s.

### Hypophosphites

The crystal structures of ammonium hypophosphite, $NH_4H_2PO_2$,[613] magnesium hypophosphite hexahydrate, $Mg(H_2PO_2)_2,6H_2O$,[614] and calcium hypophosphite, $Ca(H_2PO_2)_2$,[658] have been determined. Ammonium hypophosphite is orthorhombic, with $a = 7{\cdot}57$, $b = 11{\cdot}47$, $c = 3{\cdot}98$ A. The unit cell contains four molecules and the space group is *Cmna*. The structure is a distortion of the cæsium chloride arrangement. The hypophosphite ion was considered[613] as a distorted tetrahedron of $H_2PO_2^-$, with P–O = 1·52 A., and O–P–O = 121°. The position of the hydrogen atoms was not determined. Magnesium hypophosphite hexahydrate has a tetragonal cell, with $a = 10{\cdot}36$, $c = 20{\cdot}46$ A., containing eight molecules; a cell of half this size was reported earlier.[615] The space group is *I4/acd*. The P–O distance in the hypophosphite ion is 1·52 A., and the O–P–O angle 109°. Unit cell data have also been published[615] for cobaltous hypophosphite hexahydrate and the corresponding nickel salt, which are both isomorphous with magnesium hypophosphite hexahydrate. The tetragonal pseudo-cubic cells quoted, like that of the magnesium salt, may be half the true cells. The dimensions given are $a = c = 10{\cdot}22$ A. and 10·30 A. respectively for the cobalt and nickel salts. Calcium hypophosphite, which has been studied by both *X*-ray and neutron diffraction,[658] is monoclinic, with $a = 15{\cdot}08$, $b = 5{\cdot}66$, $c = 6{\cdot}73$ A., $\beta = 102{\cdot}8°$, space group *C*2/*c*. The P–O and P–H bond lengths are 1·505 A. and 1·39 A. respectively.

The electron spin resonance spectrum of $\gamma$-irradiated ammonium hypophosphite has been investigated.[912] The spectrum indicates that the ionic radical $H\dot{P}O_2^-$ is initially formed. There is strong hyperfine coupling to the phosphorus nucleus, and weaker isotropic coupling to the proton. The radical is irregular tetrahedral in shape with the unpaired electron occupying an $sp^3$ hybrid $\sigma$-orbital which is estimated to be 117 ± 5° from the direction of the P–H bond. There is evidence that the radical $H\dot{P}O_2^-$ reacts with an $H_2PO_2^-$ ion in an adjacent site along the *b* axis to form the species $O_2\dot{P}{-}PHO_2^{=}$. The angle between the P–P bond and the orbital of the unpaired electron is estimated to be 108 ± 5°.

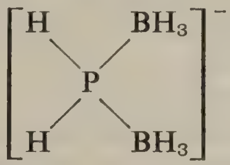
The Raman[518-9, 538, 565, 597, 609, 616, 912] spectra of hypophosphite ions in sodium and potassium hypophosphite solutions have been published. The infra-red spectra[525, 610, 912] of crystalline lithium, sodium, potassium, calcium, strontium, barium, lead and manganese hypophosphites, as well as of sodium hypophosphite monohydrate and magnesium hypophosphite hexahydrate, have been reported. The symmetry of hypophosphite ions in solution was suggested as $C_{2v}$ from an investigation of Raman spectra.[538] Later work[566] on the Raman and infra-red spectra of solutions of potassium hypophosphite, and the infra-red spectrum of an oriented film of potassium hypophosphite, using polarized radiation, has confirmed this. An assignment of the spectra was made, and the results with polarized radiation suggested that the crystal structure of potassium hypophosphite is similar to that of ammonium hypophosphite. A normal co-ordinate analysis has been carried out[617, 912, 1088] on the hypophosphite and deuterohypophosphite ions, using data from the normal and deuterated sodium, potassium and barium salts. The results confirm the conclusions of Reference 566. In another recent investigation[659] the infra-red spectra of thin films of hypophosphorous acid and the sodium, potassium, ammonium and calcium salts were obtained in a low-temperature cell. The infra-red spectra of the deuterated acid and salts, and the Raman spectrum of liquid hypophosphorous acid, were also obtained. From these data, complete and well-established assignments of the spectra of the hypophosphite and deuterohypophosphite ions were made on the basis of $C_{2v}$ symmetry. In solid potassium hypophosphite, $PH_2$ symmetric and antisymmetric stretching vibrations are at 2345 and 2320 cm.$^{-1}$ respectively, $PH_2$ deformation, wagging, twisting and rocking vibrations at 1172, 1082, 926 and

812 cm.$^{-1}$ respectively, and $PO_2$ antisymmetric stretching, symmetric stretching, and deformation vibrations at 1194, 1054 and 474 cm.$^{-1}$ respectively. The antisymmetric $PO_2$ stretching, symmetric $PO_2$ stretching, $PH_2$ rocking, and antisymmetric $PH_2$ stretching are, in order of decreasing strength, the strongest bands in the infra-red spectrum. The assignments were checked by the Teller–Redlich product rule. The infra-red spectrum of the calcium salt suggested $C_1$ or $C_2$ site symmetry for the hypophosphite ion in the crystal. The crystal structure[658] shows that the symmetry is actually $C_1$. A normal co-ordinate analysis of the hypophosphite ion was carried out, using a simple valence force field. Calculated and observed frequencies agreed to within 1·4%. The main force constants obtained were $F_{P-H} = 3{\cdot}077$ millidynes/Å., $F_{P-O} = 8{\cdot}133$ millidynes/Å.

In recent work the infra-red spectra of the hypophosphites of uranyl $[(UO_2)_2(H_2PO_2)_2,2H_2O]$, thorium $[Th(H_2PO_2)_4]$, ytterbium $[Yb(H_2PO_2)_3]$, thulium $[Tm(H_2PO_2)_3]$, samarium $[Sm(H_2PO_2)_3]$,[1316] lanthanum $[La(H_2PO_2)_3]$,[1316,1317] yttrium $[Y(H_2PO_2)_3]$ and scandium $[Sc(H_2PO_2)_3]$[1317] are reported. The Raman spectra of the first six compounds above are also reported.[1316] The spectra were similar to those of hypophosphites of monovalent cations.

The far ultra-violet spectrum of hypophosphite ions in aqueous solution has been reported.[1318] The spectrum shows weak absorption above 200 mμ and a steeply rising absorption edge, attributed to a charge-transfer-to solvent transition, below 200 mμ.

Some infra-red and spectral data for the ion:



analogous to hypophosphite, have been determined.[1319]

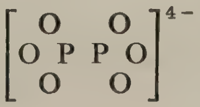
The phosphorus[110,171,225,569,612] and proton[225,634] nuclear magnetic resonance spectra of hypophosphite ions show spin-spin splitting of the phosphorus resonance into a triplet, confirming the $H_2PO_2^-$ structure. The phosphorus chemical shift is between −6 and −13 p.p.m.[171,225]; the spin-spin coupling constant $J_{P-H}$ has been reported as 593 cycles/sec.[225,634] and 561 cycles/sec.[612] The effects attributed to proton association of concentration and of neutralization on the NMR parameters of hypophosphorous acid have been investigated.[1250] The shift relative to 85% $H_3PO_4$ and the coupling constant changed from −10·5 p.p.m. and 547 c/s respectively at zero concentration to −12·2 p.p.m. and 566 c/s at 10 molar. The effect of neutralization at constant phosphorus concentration was an increase in shift of about 4 p.p.m., to −7·3 p.p.m., and a change in $J_{PH}$ from about 570 to 520 cycles. The effect of protonation of hypophosphorous acid in sulphuric acid has also been studied[1305]; the coupling constant increases from about 572 to about 674 c/s.

The possibility of a tautomeric form of hypophosphorous acid, containing trivalent phosphorus, has been suggested at various times and evidence for its existence has been claimed.[618] The concentration of any such form is evidently too low to be detected spectroscopically.

## OTHER OXYACIDS CONTAINING TWO PHOSPHORUS ATOMS

### Hypophosphates

Early work[620–1] on diammonium dihydrogen hypophosphate, $(NH_4)_2H_2P_2O_6$, used unit cell and space group considerations to show that the hypophosphate ion must have the symmetrical



$$\left[\begin{matrix} & O & & O & \\ O & P & & P & O \\ & O & & O & \end{matrix}\right]^{4-}$$

structure. A detailed structure determination[913] confirms this. The cell is orthorhombic, space group *Pccn*, with $a=7{\cdot}24$, $b=9{\cdot}36$, $c=11{\cdot}44$, $Z=4$. The hypophosphate ions lie on sites of twofold symmetry, but approximate to the symmetrical staggered ($D_{3d}$) configuration. The ammonium ions have fourfold co-ordination to the oxygen atoms of the hypophosphate ions. The bond lengths are P–P 2·17 A., P–O 1·50 A., P–O(H) 1·57 A., angles PPO = 106·7° (av.), OPO = 113·3°, 116·7°, 106·2°.

The electron spin resonance spectrum of $\gamma$-irradiated diammonium dihydrogen hypophosphate has been investigated[914] and shown to arise from the ionic radical $(O_2\dot{P}–PO_3)^{3-}$. On heating the crystal to about 120°C. the P–P bond of the trapped species breaks, the products being $PO_3^{=}$ and (presumably) $PO_2^{-}$.

The Raman spectra of solutions of dipotassium and monoammonium hypophosphate and of hypophosphoric acid have been reported.[622–3] In the earlier work,[622] the value of the P–P bond force constant of 2·34 millidynes/A. was obtained from the dipotassium salt, but the ion was regarded as $P_2O_6^{4-}$ instead of the more likely $H_2P_2O_6^{2-}$, and the agreement between calculated and observed frequencies was poor. In the later work[623] the ion was also regarded as $P_2O_6^{4-}$; the spectrum was said to be consistent with a staggered configuration, but there were discrepancies. Both studies, however, confirm the symmetrical $O_3PPO_3$ structure by the absence of a PH band. A recent investigation[915] gives three bands in the Raman spectrum of a solution of tetrapotassium hypophosphate, as well as the infra-red spectra of the aqueous and solid salt and of several other solid salts, mentioned below. The observed fundamentals were assigned, and assignments were also proposed for several of the unobserved fundamentals on the basis of combination bands. The spectra are regarded as supporting the staggered $D_{3d}$ configuration for the $P_2O_6^{4-}$ ion. The main assignments are as follow: 1064 (infra-red, $E_u$, degenerate P–O stretch), 1023 (Raman, $A_{1g}$, P–O breathing), 909 (infra-red, $A_{2u}$, symmetrical out of phase P–O stretch), 666 (Raman, $A_{1g}$, symmetrical $PO_3$ deformation, in phase), 568 (infra-red, $A_{2u}$, $PO_3$ symmetrical $PO_3$ deformation, out of phase) and 493 cm.$^{-1}$ (infra-red, $E_u$, $PO_3$ degenerate deformation).

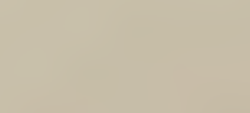
Infra-red spectra (of the solids) have been reported for tetrasodium hypophosphate, tetralithium hypophosphate mono- and heptahydrates, magnesium hypophosphate monohydrate, cerium hypophosphate monohydrate, sodium hexamminecobaltic hypophosphate tetrahydrate, thallous and silver hypophosphates,[915] barium and lead hypophosphates,[656, 915] sodium hypophosphate decahydrate, calcium hypophosphate dihydrate, strontium hypophosphate dihydrate, diammonium dihydrogen hypophosphate, disodium dihydrogen hypophosphate hydrate and dirubidium dihydrogen hypophosphate hydrate.[656] All show strong absorption in the 890–940 cm.$^{-1}$ and 1030–1135 cm.$^{-1}$ regions.[660]

The phosphorus nuclear magnetic resonance spectrum[171, 330, 569] of the hypophosphate ion shows a single peak, confirming the symmetrical structure. The chemical shift is $-9$ p.p.m.[171]

The far ultra-violet spectrum of hypophosphate ions in aqueous solution has been reported.[1318] The spectrum shows weak absorption above 200 m$\mu$ and a steeply rising absorption edge, attributed to a charge-transfer-to solvent transition, below 200 m$\mu$.

### Pyrophosphites

The Raman spectrum of sodium pyrophosphite,[609] $Na_2H_2P_2O_5$,[624–5] is as follows[625]: 335 (3), 449 (2), 469 (2), 529 (2), 559 (2), 720 (3), 917 (2), 1009 (6), 1033 (7), 1068 (3), 1107 (10), 1212 (3), 2417 (8). There is poor agreement between the data of Reference 625 and those of References 609 and 624. More recent work[916] supports the data given above. The spectrum of pyrophosphorous acid[625] has also been reported. The spectra are similar, and have been interpreted[625] as arising from a symmetrical anion

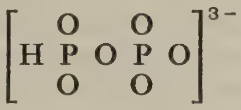


$$\left[\begin{array}{ccccc} & H & & H & \\ O & P & O & P & O \\ & O & & O & \end{array}\right]^{2-}$$

The phosphorus nuclear magnetic resonance spectra of sodium pyrophosphite[171, 569] and pyrophosphorous acid[626, 1321] have been determined. They show a symmetrical doublet arising from spin-spin splitting (by the protons) of the resonance from two chemically equivalent phosphorus atoms, confirming the above structure. The chemical shift is between +2·6 and +5 p.p.m., and the indirect spin-spin coupling constant $J_{P-H}$ is 685–780 c/s. The proton resonance also shows a doublet.[1308]

## Isohypophosphates

Although the Raman spectrum of sodium isohypophosphate, $Na_3HP_2O_6$, has been reported,[627] the main spectroscopic evidence for the structure of this anion comes from the phosphorus nuclear magnetic resonance spectrum.[171, 330] This shows resonances from two chemically non-equivalent phosphorus nuclei, one of which is split into a doublet by spin-spin interaction with the proton, while both phosphorus resonances are further split by spin-spin interaction between the two non-equivalent phosphorus nuclei. The P–H spin-spin splitting is 620 c/s, similar to that in phosphites; the P–P splitting (17 c/s) is similar to that across a P–O–P link in polyphosphates. The structure is therefore:

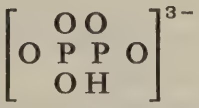


$$\left[\mathrm{H}\,\overset{\mathrm{O}}{\underset{\mathrm{O}}{\mathrm{P}}}\,\mathrm{O}\,\overset{\mathrm{O}}{\underset{\mathrm{O}}{\mathrm{P}}}\,\mathrm{O}\right]^{3-}$$

The chemical shifts are +1 p.p.m. ($PO_2H$ group) and +3 p.p.m. ($PO_3$ group), (relative to 85% orthophosphoric acid).

## Diphosphites

The Raman spectrum of molten sodium diphosphite dodecahydrate, $Na_3HP_2O_5$, $12H_2O$, has been determined.[628] Strong bands were assigned to PH and PP stretching vibrations at 2271 and 312 cm.$^{-1}$ respectively, and it was concluded that the anion has the structure:



$$\left[\mathrm{O}\,\overset{\mathrm{O}}{\underset{\mathrm{O}}{\mathrm{P}}}\,\overset{\mathrm{O}}{\underset{\mathrm{H}}{\mathrm{P}}}\,\mathrm{O}\right]^{3-}$$

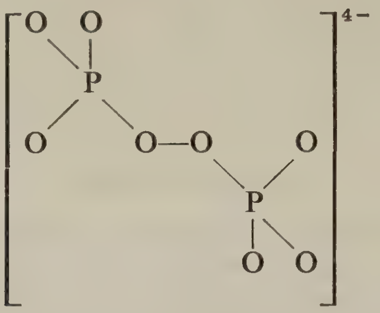
Weaker bands were observed at 427, 480, 504, 586, 615, 919, 950, 983, 1022, 1052, 1098 and 1114 cm.$^{-1}$

The phosphorus and hydrogen nuclear magnetic resonance spectra of the diphosphite ion[330] have established that the above structure is correct. The spectrum is that of two chemically non-equivalent phosphorus nuclei, both coupled by spin-spin interactions to a proton (an ABX system[629]). Analysis of the spectrum yielded the chemical shifts of +7·0 p.p.m. ($PO_3$ group), −22·8 ($PO_2H$ group), and the spin-spin couplings $J_{P_1P_2}=480$ c·s, $J_{P_1H}=444$ c/s, $J_{P_2H}=94$ c/s.

## OTHER OXYACIDS OF PHOSPHORUS

The crystal structure of the compound $Cs_6(PO_2)_6$ has been determined.[630] The structure is monoclinic, space group $P2_1/c$, with a two-molecule cell having $a=9{\cdot}47$, $b=9{\cdot}49$, $c=16{\cdot}05$ A., $\beta=110{\cdot}5°$. The oxygen positions were not determined accurately, but the phosphorus positions were determined sufficiently accurately to indicate that the anion is a puckered six-membered ring of phosphorus atoms, with attached oxygen atoms. The salt is hydrated, but the water molecules were not located. The ring lies on a twofold axis and has a chair configuration. Bond lengths are P–P = 2·18, 2·26, 2·16 A. (average 2·20 A.). Angles in the ring are 101·8, 104·5, 101·8°

The infra-red and Raman spectra of the alkali metal salts of peroxydiphosphoric acid, $H_4P_2O_8$, have been investigated.[557, 631] From considerations of the numbers of bands and their activity, structures with a linear P–O–O–P link were excluded, and it was concluded that the anion had the symmetrical *trans*-configuration:



with symmetry probably $C_2$ or $C_{2h}$. Suggested assignments were as follows: antisymmetric $PO_3$ stretching vibrations at 1132, 1159 and 1196 cm.$^{-1}$ in the infra-red, symmetric $PO_3$ stretching vibrations at 1008, 1101, 1125 cm.$^{-1}$ in the Raman, antisymmetric P–O–O–P stretching at 980–1005 cm.$^{-1}$ in the infra-red, symmetric P–O–O–P stretching at 784 cm.$^{-1}$ in the Raman, and symmetric O–O stretching at 890 cm.$^{-1}$ in the Raman spectrum. The infra-red spectra (as powders) of lithium, sodium, potassium, calcium, strontium and barium peroxydiphosphates, all with unknown amounts of water of crystallization, have been reported.[656,660] They show strong absorption in the 970–1000 and 1070–1200 cm.$^{-1}$ regions.

## Phosphorothioates

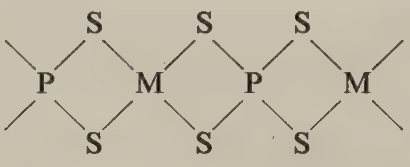
Cuprous phosphorotetrathioate, $Cu_3PS_4$, is orthorhombic, space group $Pmn2_1$, with $a = 6{\cdot}46$, $b = 7{\cdot}43$, $c = 6{\cdot}18$ A., $Z = 2$.[632] The data indicate the presence of tetrahedral $PS_4^{3-}$ ions.

Unit cell data for some sodium and potassium phosphorothioates have been reported[633,1324–5] and are given in Table XIX.

The average P–S bond length in potassium phosphorotetrathioate is 2·045 A.[1325]

The space-group possibilities for trisodium phosphorothioate require the anion to have at least threefold symmetry. In the remaining salts special symmetry is not imposed by space group considerations.

Aluminium[1326] and boron[1327] phosphorotetrathioates both have structures consisting of infinite chains of the form:



The aluminium salt[1326] is isostructural with silicon disulphide, and has an orthorhombic cell, with $a = 5{\cdot}61$, $b = 5{\cdot}67$, $c = 9{\cdot}05$ A., space group $P_{222}$. The boron salt has a high-temperature monoclinic form, with $a = 10{\cdot}38$, $b = 6{\cdot}05$, $c = 6{\cdot}69$ A., $\beta = 75°$, and a low-temperature orthorhombic form, with $a = 5{\cdot}60$, $b = 5{\cdot}25$, $c = 9{\cdot}04$. Average bond lengths were Al–S and P–S = 2·1 A. in the aluminium salt, and B–S = 1·89, P–S = 2·16 in the orthorhombic boron salt.

The Raman spectrum of trisodium phosphoromonothioate in aqueous solution and as the crystalline dodecahydrate, and the Raman[918] and infra-red[918,1328] spectra of the dodecahydrate and the anhydrous salt, have been reported. Symmetrical and degenerate stretching vibrations of the $PO_3$ group were assigned at 961 and 1037 cm.$^{-1}$ respectively, with bending modes of this group at 519 ($E$) and 610 ($A_1$) cm.$^{-1}$ The P–S stretching vibration was assigned at 436 cm.$^{-1}$ A normal co-ordinate analysis was carried out and stretching force constants $F_{P-O} = 5{\cdot}91$ millidynes/A. and $F_{P-S} = 2{\cdot}86$ millidynes/A. were obtained.[918] Spectra have also been reported for

*Table XIX.—Unit Cell Data for Phosphorothioates*

| Compound | Crystal system | Space group | Unit cell data (dimensions in A.) | | | | References |

disodium phosphoromonothioate pentahydrate,[1328-9] diammonium phosphoromonothioate[1329] (infra-red) and disodium phosphoromonothioate in aqueous solution (Raman).

The infra-red spectra of phosphorotetrathioates show strong absorption in the 520–575 cm.$^{-1}$ region.[660] The infra-red spectra (as powders) of sodium phosphoromonothioate decahydrate, $Na_3PSO_3,10H_2O$, sodium calcium phosphoromonothioate octahydrate, sodium strontium phosphoromonothioate octahydrate, sodium barium phosphoromonothioate octahydrate and cobaltous, nickel and lead phosphoromonothioates, have been reported.[656] These salts show strong absorption in the 540–580 and 1010–1120 cm.$^{-1}$ regions.[656, 660]

The phosphorus nuclear magnetic resonance spectra of solutions of the various trisodium phosphorothioates in 3% sodium sulphide solution have been reported.[832, 917] The phosphorus chemical shifts, relative to 85% orthophosphoric acid, are as follow: $Na_3PS_4$, −87·5 p.p.m.; $Na_3POS_3$, −86·5 p.p.m.; $Na_3PO_2S_2$, −61·9 p.p.m.; $Na_3PO_3S$, −33·8 p.p.m.

## Phosphorofluoridates

The crystal structure of potassium phosphorodifluoridate, $KPO_2F_2$, has been determined.[1330] The cell is orthorhombic, with $a = 8{\cdot}03_9$, $b = 6{\cdot}20_5$, $c = 7{\cdot}63_5$ A., $Z = 4$, space group *Pnma*. Dimensions of the $PO_2F_2^-$ ion are as follow: P–O 1·470 A., P–F 1·575 A., FPF 97·1°, OPO 122·4°. Lead phosphorofluoridate, $PbPO_3F$, is orthorhombic,[1389] with $a = 6{\cdot}951$, $b = 8{\cdot}521$, $c = 5{\cdot}470$ A., $Z = 4$, space group *Pbnm* or *Pna*$2_1$, and is probably isostructural with lead sulphate.

The fluorine nuclear magnetic resonance spectra of phosphorofluoridic acid, $FPO(OH)_2$, phosphorodifluoridic acid, $F_2PO(OH)$[225, 634-5] and aqueous sodium phosphorofluoridate, $Na_2PO_3F$,[225] with the phosphorus spectra of phosphorodifluoridic acid,[110, 225] have been reported. Data have also been given[635] for a new phosphorus- and fluorine-containing species believed to be a phosphorofluoridate end group, $HO(O)P(F)O\frac{1}{2}$–. Chemical shift and spin-spin coupling data are given below:

| Compound | Phosphorus chemical shift (rel. to 85% $H_3PO_4$) p.p.m. | Fluorine chemical shift (rel. to $CF_3.COOH$) p.p.m. | $J_{P-F}$ c/s |
|---|---|---|---|
| $FPO(OH)_2$ | — | −2·5 | 954 |
| $F_2PO(OH)$ | 20·1 | 9·0 | 981 |
| $Na_2PO_3F$ aq. | — | 26·8 | 781 |
| $HO(O)P(F)O\frac{1}{2}$– (?) | 25·0 | −5·0 | 944 |

$^{31}P$ NMR data have also been reported[1331] for ammonium phosphorothiofluoridate, $(NH_4)_2PO_2SF$, and ammonium phosphorothiodifluoridate, $NH_4POSF_2$. Data (85% $H_3PO_4$ as standard) were as follows: $(NH_4)_2PO_2SF$ (aq.), $\delta_P = -43{\cdot}9$ p.p.m., $J_{PF} = 980$ c/s; $NH_4POSF_2$, $\delta_P = -47{\cdot}1$ p.p.m., $J_{PF} = 1120$ c/s. Spectra (NMR and infra-red) have been determined[1332] for various salts containing phosphorodithiodifluoridate $PS_2F_2^-$, pyrophosphoropentathiodifluoridate $S_2FPSPS_2F^{2-}$, and bis-phosphorotrithiofluoridate $FS_2PSSPS_2F^{2-}$, but the only data to have been reported[1332] are as follow: (ref. $CFCl_3$, $H_3PO_4$) $PS_2F_2^-$, $\delta_F = +2{\cdot}3$, $\delta_P = -118$ p.p.m., $J_{PF} = 1149$ c/s. $S_2FPSPS_2F^{2-}$, $J_{PF} = 1160$ c/s, $S_2FPSSPFS_2^{2-}$, $\delta_F = -7{\cdot}4$ p.p.m., $J_{PF} = 1170$ c/s.

The Raman spectra of molten potassium phosphorodifluoridate and a mixed sodium potassium phosphoromonofluoridate, as well as the infra-red spectra of crystalline potassium phosphoromono- and difluoridates, have been reported.[838] In the phosphoromonofluoridate, symmetrical and degenerate stretching vibrations of the $PO_3$ group were assigned at 998–1008 and 1120–1170 cm.$^{-1}$ respectively, with the P–F stretching vibration at 698–705 cm.$^{-1}$ and deformations of the $PO_3$ group in the 500 cm.$^{-1}$ region. In the phosphorodifluoridate, symmetric and antisymmetric vibrations of the $PO_2$ group were assigned at 1145 and 1290–1311 cm.$^{-1}$ respectively, with the corresponding vibrations of the $PF_2$ group at 824–834 and 857 cm.$^{-1}$ Stretching force constants of the PF and PO bonds were estimated as 3·8 and 7·3 millidynes/A. respectively in the phosphoromonofluoridate and 4·9 and 9·4 millidynes/A. in the phosphorodifluoridate.[838]

In a series of phosphorofluoridates including sodium and potassium phosphorodifluoridates and pyrophosphorodifluoridates, the symmetrical and antisymmetrical $PO_2$ stretching vibrations were assigned[1334] (inorganic derivatives only) in the ranges 1107–1166 and 1298–1323 cm.$^{-1}$ respectively. In phosphorodifluoridic acid, $F_2POOH$, the infra-red spectrum of the monomeric species has been determined[1335] from the spectrum of the superheated vapour. The PO frequencies are 1332 (assoc.), 1393 (free) cm.$^{-1}$ and the symmetric and asymmetric $PF_2$ stretching frequencies 881 (assoc.), 865/873 (free) cm.$^{-1}$, and 983 (assoc.), 956/967 (free) cm.$^{-1}$ respectively.[1335]

The infra-red spectra of ammonium phosphorodifluoridate, ammonium phosphoromonofluoridate monohydrate, calcium and strontium phosphoromonofluoridates (both with unknown water of crystallization), barium and lead phosphoromonofluoridates,[656] and sodium, potassium and silver phosphoromonofluoridates[526, 656] have been reported. The characteristic absorptions due to P–F stretching vibrations occur in the 720–835 cm.$^{-1}$ region.[656] Other strong absorptions occur in the 1090–1175 cm.$^{-1}$ region.[660] Infra-red spectra have also been reported for a series of phosphoromonofluoridate hydrates, as follows: $CdPO_3F,8H_2O$, $MnPO_3F,4H_2O$, $NiPO_3F,7H_2O$, $Cr_2(PO_3F)_3,18H_2O$, $Fe_2(PO_3F)_3,12H_2O$[1336] (all these hydrates were stated[1336] to be isomorphous with the corresponding sulphates), and for series of $NaPO_3$–NaF glasses of Na:P ratios between 1·28 and 1·5.[1337]

In the infra-red spectrum of phosphorothiodifluoridate ion, $SOPF_2^-$ (tetraethylammonium salt) the PO and PS stretching vibrations were assigned[1334] at 1218 and 658 cm.$^{-1}$ respectively. In a series of alkyl ammonium, phosphonium, and arsenium salts in this anion, the PO vibration was assigned[1338] in the range 1240–1247 cm.$^{-1}$ with the PS vibration at 645 cm.$^{-1}$, and $PF_2$ vibrations at 814–822 cm.$^{-1}$ (as) and 797–807 cm.$^{-1}$ (s).

## Phosphorochloridates

The phosphorus nuclear magnetic resonance spectrum of a system of phosphorochloridic acids has been investigated.[919] Phosphorodichloridic acid, $(HO)Cl_2PO$, has a chemical shift of $-9{\cdot}5$ to $-10{\cdot}5$ p.p.m. (relative to 85% orthophosphoric acid). Peaks at chemical shifts of $-18{\cdot}2$ p.p.m. and $-13{\cdot}0$ p.p.m. were tentatively assigned to phosphoromonochloridic acid, $(HO)_2ClPO$, and to the monochlorphosphate end group, $(HO)ClP(O)O_{\frac{1}{2}}$–, respectively.

NMR data have been reported[1339] for the phosphorothiochlorofluoridate ion $SPOClF^-$ (tetraphenylphosphonium salt). The $^{19}F$ chemical shift ($CCl_3F$ ref.) was $+43{\cdot}6$ p.p.m., and the coupling constant $J_{PF}$ was 1056 c/s.

The Raman spectrum of phosphorodichloridic acid, $(HO)Cl_2PO$, has been reported.[1340] Assignments included 1249 ($\nu$PO), 595 ($\nu_{as}PCl_2$) and 554 cm.$^{-1}$ ($\nu_s PCl_2$). In the infra-red spectra of a series of phosphorodichloridate salts, vibrations were assigned[1341] as follows: $\nu_{as}PO_2$, 1205–1259; $\nu_s PO_2$ 1082–1147, $\nu_{as}PCl_2$ 608–708, $\nu_s PCl_2$ 569–590 cm.$^{-1}$ In the salts $M(O_2PCl_2)_3$ (M = Al, Ga, In, Fe) polymeric structures with oxygen bridges were proposed on the basis of the infra-red spectra, with bands at 481–542 and 190–337 cm.$^{-1}$ attributed to vibrations of the $MO_6$ octahedra. In the beryllium salt, $Be(O_2PCl_2)_2$, these bands are absent, evidently because of the ionic nature of the salt.

The infra-red spectra of a series of phosphonium and arsenium phosphorothiodichloridates, $X^+Cl_2POS^-$, and phosphorothiochlorofluoridates, $X^+FClPOS^-$, have been reported.[1339] Assignments included the following: $\nu$PO 1210–1215 ($Cl_2POS^-$), 1228–30 ($FClPOS^-$); $\nu$PS 645–7 ($Cl_2POS^-$), 638–640 ($FClPOS^-$); $\nu_{as}PCl_2$ 462–5, $\nu_s PCl_2$ 437–8 ($Cl_2POS^-$); $\nu$PF 792–5, $\nu$PCl 477–483 ($FClPOS^-$) cm.$^{-1}$

## PHOSPHORUS–NITROGEN COMPOUNDS

### Ionized Phosphorus–Nitrogen Compounds

The crystal structure of sodium monoamidophosphate, $NaHPO_3.NH_2$, has been determined.[657] The structure is hexagonal, with $a = 5{\cdot}773$ and $c = 6{\cdot}031$ A., $Z = 2$, space group $Pb_3$. The amidophosphate anion is a zwitterion similar to the sulphamate ion, and the formula can be written $Na^+[NH_3{}^+PO_3{}^-]^-$. Each nitrogen atom of the anion is linked by three equivalent hydrogen bonds to the oxygen atoms of three other anions, as shown in Fig. 14.

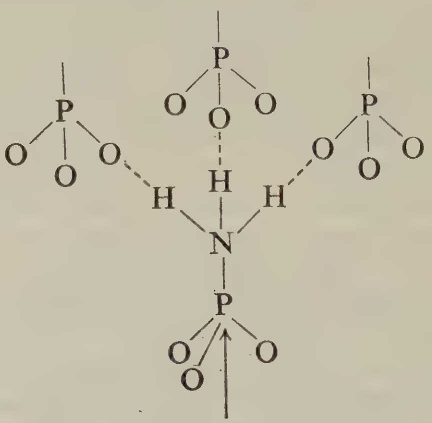

FIG. 14.—Detail of structure of sodium monoamidophosphate

The P–N bond lies on a threefold axis. Each sodium atom is surrounded by a distorted octahedron of oxygen atoms at distances of 2·39 or 2·43 A. This structure has recently been refined[744]; the bond lengths from this refinement are P–N = 1·769 ± 0·019 A., P–O = 1·522 ± ·011 A., and the angles, O–P–O = 114°, N–P–O = 103°. The N–H–O distance is 2·84 A.[657]

The infra-red spectra of dipotassium monoamidophosphate and barium diamidophosphate have been reported, as have the spectra of the thermal decomposition products of these salts, of empirical composition approximately $K_4P_2O_6NH$, $K_6P_3O_9N$ and $Ba(PO_2NH)_2$.[1343]

The infra-red spectra of a number of diamidophosphoromonothioates, $M^+POS(NH_2)^-$, have been reported.[1344] These included the sodium salt, sodium salt dihydrate (Raman spectrum also), calcium and strontium salts (aq. solution), and barium salt dihydrate (Raman also). Assignments made included $\nu$PO 1105–1160, $\nu_{as}PN_2$ 770–845, $\nu_s PN_2$ 778–825, $\nu$PS 480–533 cm.$^{-1}$

The infra-red spectra (KBr discs, aqueous solutions) of monoamidophosphoric acid and its monosodium,[920, 1342] monopotassium, monosilver and monobarium salts, as well as the disodium salt, have been reported, and assignments proposed[920] which differ from earlier assignments[667] by the same author. The $A_1$ and $E$ bending vibrations and the rocking vibration of the $NH_3{}^+$ groups in the zwitterions $[PO_3{}^-NH_3{}^+]^-$ are assigned around 1480, 1610 and 1020 cm.$^{-1}$ respectively, with the $A_1$ and $E$ stretching vibrations of the $PO_3{}^-$ group around 993 and 1165 cm.$^{-1}$ [920] and the P–N stretching vibration around 710 cm.$^{-1}$ [667, 920] In the disodium salt, $[Na^+]_2[PO_3NH_2]^{2-}$, the $NH_2$ bending and rocking vibrations are assigned at 1610 and 1078 cm.$^{-1}$ respectively, the symmetric and antisymmetric $PO_3$ stretching vibrations at 980 and 1141/1188 cm.$^{-1}$,[920] and the PN stretching vibration at 810 cm.$^{-1}$ [667, 920] The difference between the P–N stretching frequencies is regarded[920] as indicating stronger P–N bonds in the $PNH_3{}^+$ group than in the $PNH_2$ group. Other workers have suggested[660–2] that the P–N group absorbs in the region 680–750 cm.$^{-1}$; however, some authors[526] regard the major part of the absorption in the 650–900 cm.$^{-1}$ region as arising from motions of the $NH_2$ group.

Other infra-red spectra of amido- and imido-phosphates have been reported, as follow: monopotassium, monoammonium monoamidophosphates,[525] disilver monoamidophosphate,[525-6] disodium monoamidophosphate,[526, 667] monosodium monoamidophosphate,[525, 667] monobarium monoamidophosphate and barium monoamidophosphate monohydrate, monomagnesium monoamidophosphate and magnesium monoamidophosphate heptahydrate, monoamidophosphoric acid,[667] zinc and thallous monoamidophosphate,[526] zinc diamidophosphate,[526] tetrasodium, dipotassium dihydrogen (and deuterated salt), tetrapotassium, zinc, silver and thallous imidodiphosphates,[526] ($Ag_4P_2O_6NAg$),[526] sodium, sodium dizinc and thallous di-imidotriphosphates, silver and thallous di-imidotrimetaphosphates and thallous di-imidotrimetaphosphate-thallous hydroxide, ($Tl_3P_3O_7(NH)_2.TlOH$).[526]

The crystal structure of potassium amidotriphosphate tetrahydrate, $K_4P_3O_9NH_2, 4H_2O$, has been determined.[1345] The cell is triclinic, with $a = 6{\cdot}08$, $b = 10{\cdot}06$, $c = 12{\cdot}72$ A., $\alpha = 95{\cdot}9°$, $\beta = 91{\cdot}7°$, $\gamma = 107{\cdot}1°$, $Z = 2$, space group $P\bar{1}$. The amidotriphosphate anion is similar to that of triphosphate with one terminal oxygen replaced by an amido group. The anion has a less extended configuration than the anion of sodium triphosphate. The structure consists of layers of amidotriphosphate anions and potassium atoms alternating with layers of water molecules.

The phosphorus nuclear magnetic resonance spectrum of the amidotriphosphate ion, $(PO_3.O.PO_2.O.PO_2NH_2)^{4-}$, has been reported.[663] The amidophosphate end group has a chemical shift of +0·2 p.p.m., and the spin-spin splitting between the amidophosphate end group and the middle group is 18 c/s. The phosphorus nuclear magnetic resonance spectra of monosodium monoamidophosphate and of diamidophosphoric acid have been determined.[171] The chemical shifts are −3 and +3·5 p.p.m. respectively, the latter figure being regarded[171] as doubtful.

NMR data for a series of amido and imido phosphates have been reported[1346-7] and are tabulated below. The substitution of –NH– for –O– in chain and ring compounds generally results in negative displacement of the phosphorus shift.[1346]

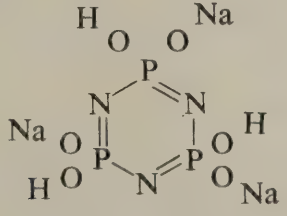
| Compound | $^{31}P$ chemical shift (ref. $H_3PO_4$) p.p.m. | Reference |
|---|---|---|
| $HPO_2(NH_2)_2$ | +0·2 | 1347 |
| $Na_2PO_3NH_2$ | −8·9 | 1348 |
| $NaPO_2(NH_2)_2$ | −14·5 | 1347–8 |
| $NaPOS(NH_2)_2$ | −54·2 | 1347–8 |
| $Na_4O_3PNHPO_3$ | −2·7 | 1347–8 |
| $Na_5O_3PNHPO_2NHPO_3$ | −1·6 | 1347–8 |

The infra-red spectra of some (tetraphenyl phosphonium) diazophosphoromonothioates, $PSO(N_3)_2^-$, and azophosphorothiofluoridates, $PSON_3F^-$, have been reported[1348] and some assignments made, including the following: $PSO(N_3)_2^-$, $\nu_{as}N_3$ 2125/2155, $\nu_sN_3$ 1270/1290, $\nu$PO 1215/1230, $\nu$PS 610 cm.$^{-1}$; $PSON_3F^-$, $\nu_{as}N_3$ 2150, $\nu_sN_3$ 1272, $\nu$PO 1210/1230, $\nu$PF 798, $\nu$PS 630.

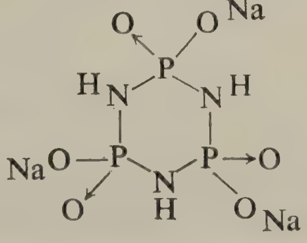
### TRIMETAPHOSPHIMATES

The acids and salts obtained from the hydrolysis of phosphonitrilic chlorides have been described as phosphonitrilates (I) and as trimetaphosphimates (II), depending on the situation of the hydrogen atoms.

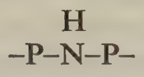
I



II



The first report[656] of the infra-red spectra of this class of compounds described them as of type I, on the basis of the assignment of P–O–H bands at 2700 cm.$^{-1}$ and 1400–1220 cm.$^{-1}$, and P=N bands at 1200–900 cm.$^{-1}$ Later work[526] using anhydrous samples and mulling techniques, showed that the bands around 2700 cm.$^{-1}$ were absent. The bands in the 1400–1200 cm.$^{-1}$ region were related to the



$$-P-\overset{H}{N}-P-$$

grouping, and those in the 1200–900 cm.$^{-1}$ region to P(O)–O$^-$ rather than to P=N. The Raman spectrum of sodium trimetaphosphimate[598] shows strong similarities to that of sodium trimetaphosphate, providing further support for the trimetaphosphimate structure. It appears from this evidence that the salts are most likely to be in the trimetaphosphimate form (II), and this conclusion is supported by chemical evidence (see page 221). Detailed assignments of the infra-red spectra of the normal and deuterated tetrametaphosphimic acids, both anhydrous and dihydrated, have been proposed on this basis.[921–2] Stretching vibrations of the $PO_2H$ groups were assigned in the regions 793$^{-}$945 cm.$^{-1}$ (symmetrical) and 1068–1207 cm.$^{-1}$ (antisymmetrical). Ring stretching vibrations were assigned at 524–624 cm.$^{-1}$ (breathing) and 840–1040 cm.$^{-1}$ (antisymmetrical). NH and ND bending vibrations were assigned at 758–813 and 583–611 cm.$^{-1}$ respectively. The salts of which the infra-red spectra have been reported are the trimetaphosphimates of sodium magnesium (hexahydrate), sodium calcium (tetrahydrate), sodium strontium (tetrahydrate) and sodium barium ($NaBa(PO_2NH)_3,1{\cdot}5H_2O$), the tetrametaphosphimates of dipotassium dihydrogen, dirubidium dihydrogen, sodium (2·5-hydrate), calcium (tetrahydrate), barium (dihydrate), copper (-ic, tetrahydrate), nickel (2·5-hydrate) and lead (hydrate),[656] trimetaphosphimic acid,[526] the trimetaphosphimates of sodium dihydrogen (dihydrate), potassium (and deuterated salt), thallium (ous) and thallium-thallous hydroxide [$Tl_3(PO_2NH)_3.TlOH$], the tetrametaphosphimates of ammonium (tetrahydrate), disodium dihydrogen, sodium (trihydrate), potassium and thallium (ous),[526] the trimetaphosphimates of sodium (tetrahydrate) and silver, and the tetrametaphosphimates of diammonium dihydrogen and silver.[525–6]

The infra-red and Raman spectra of potassium trimetaphosphimate, $K_3(PO_2NH)_3$, and its deuterated analogue have recently been determined,[1351] both in the crystal and in solution. It was concluded that the anion had $C_{3v}$ symmetry both in the crystal and in solution. Assignment (for the solution) included the following: $\nu_{as}PO_2$ 1207($A_1$), 1170($E$); $\nu_sPO_2$ 1107($A_1$), 1053($E$); $\nu$P–NH–P 953, 830($E$); $\nu_s$P–NH–P 755($A_1$). Assignments in the crystal were similar.

The phosphorus nuclear magnetic resonance spectrum of sodium trimetaphosphimate has been determined.[171] There is a single peak at a chemical shift of +1 p.p.m., confirming the ring structure. The shift for potassium tetrametaphosphimate has been reported[1347] as +3·7 p.p.m. $^{31}$P NMR data for sodium mon-, di and tri-imidotrimetaphosphate have been reported[1346] as follows: mono +10·4($\alpha$), +20·2($\beta$) p.p.m.; di +4·2($\alpha$), +7·9($\beta$) p.p.m., $J\alpha\beta=7$ c/s; tri(trimetaphosphate) +1·5 p.p.m.

Preliminary *X*-ray structure data have been reported for tetrametaphosphimic acid and some of its salts.[666] Dipotassium dihydrogen tetrametaphosphimate is orthorhombic, with $a=13{\cdot}89$, $b=8{\cdot}07$, $c=5{\cdot}03$ A. and a bimolecular cell. The corresponding rubidium salt is also orthorhombic with a bimolecular cell, of dimensions $a=14{\cdot}03$, $b=8{\cdot}34$, $c=5{\cdot}06$ A., and is isomorphous with the potassium salt. The diammonium salt is reported to be isomorphous with the other salts, with $c=5{\cdot}08$ A. The phosphimate formulation for these compounds has been confirmed by crystal structure determinations on two of the salts.[1349–50] Sodium trimetaphosphimate tetrahydrate,[1349], $Na_3(NHPO_2)_3,4H_2O$, is monoclinic with $a=16{\cdot}976$, $b=7{\cdot}834$, $c=8{\cdot}918$, $\beta=97°\ 08'$, $Z=4$, space group $P2_1/n$. The ring has a chair configuration with approximate skeletal symmetry $C_{3v}$. The three-dimensional difference map clearly shows the hydrogens linked to the nitrogens of the $(N–P)_3$ ring. The hydrogen locations have a lower symmetry than the skeletal, reducing the approximate molecular symmetry from $C_{3v}$ to $C_s$. Average bond lengths are P–N 1·68 A., P–O 1·495 A., with angles PNP 123°, NPN 104·5°, OPO 118°. Tetrametaphosphimic acid dihydrate,[666, 1350] $H_4(NHPO_2)_4,2H_2O$, is orthorhombic, with $a = 13{\cdot}98$, $b = 8{\cdot}32$, $c = 5{\cdot}04$ A., $Z = 2$, space group $P2_12_12_1$. The anion has a tub configuration of approximate symmetry $S_4$. The positions of the hydrogens were not determined directly but their location on the nitrogens was deduced from other structural evidence. The anions are linked by short O···H···O bonds into two-dimensional sheets perpendicular to the *c* axis. These sheets are connected into a three-dimensional net by N–H···O bonds. The PN bonds are all equal within experimental error, at 1·66 A. There are two types of PO bond: PO–H··· forming part of the network linkage (PO = 1·52 A.) and PO bonds not directly linked to hydrogen ($1{\cdot}48_5$ A.).

### Un-ionized Phosphorus–Nitrogen Compounds

The Raman and infra-red spectra of phosphoryl triamide, $OP(NH_2)_3$, and the infra-red spectrum of thiophosphoryl triamide, $SP(NH_2)_3$, have been determined.[667] The spectra were assigned on the basis of $C_{3v}$ symmetry. The symmetrical P–N stretching vibration is assigned at 832 cm.$^{-1}$ in the Raman (aqueous solution), but is apparently lowered to 725 cm.$^{-1}$ in the infra-red (KBr disc) probably as a result of hydrogen bonding. The corresponding band in $SP(NH_2)_3$ is assigned at 715 cm.$^{-1}$ in the infra-red. The PO and PS vibrations are assigned at 1174–1200 and 860 cm.$^{-1}$ respectively. The $^{31}$P NMR chemical shift of phosphoryl triamide is[1347–8] $-22{\cdot}0$ p.p.m. relative to 85% $H_3PO_4$.

The thermal dehydration of phosphoryl triamide to a compound of approximate empirical composition PNO has been followed[1352, 1390] by infra-red spectroscopy. The dehydration of deuterated products was also examined. Evidently reaction with atmospheric water leads to breaking of the PN bonds, the substitution of OH for $NH_2$, then a tautomeric rearrangement to give P–O–P bonds. Spectra were presented for different N:P ratios from 3 down to 0·81. The final product showed infra-red evidence for a structure consisting mainly of P–O–P and P–N–P linkages.[1352]

Later[1353] work on the infra-red spectrum of thiophosphoryl triamide proposes different assignments from those above; the 715 cm.$^{-1}$ band is assigned to the symmetric, rather than the asymmetric, PN stretch, and the PS stretching vibration is assigned at 615 cm.$^{-1}$ Some assignments were also proposed[1353] for the related compound $SP(NH–NH_2)_3$, including PNN stretching vibrations at 813, 865, 909 and 957 cm.$^{-1}$

The $^{31}$P NMR shift of thiophosphoryl triamide has been reported as $-61{\cdot}1$ p.p.m. in aqueous solution[1347–8] and $-59{\cdot}4$ p.p.m. in dimethylformamide solution,[1354] both relative to 85% $H_3PO_4$.

The crystal structure of triamidophosphorusborane, $(H_2N)_3PBH_3$, has been determined.[715] The unit cell is monoclinic, with $a = 9{\cdot}414$, $b = 9{\cdot}492$, $c = 6{\cdot}227$ A., $\beta = 100{\cdot}3°$, $Z = 4$. The bonding around the phosphorus atom is not quite tetrahedral, but the P–N bonds are all equal and the distortions of the angles from a tetrahedral arrangement are in the directions expected from a consideration of the intermolecular contacts. The $NH_2$ groups are therefore regarded as chemically equivalent, the distortions being due to crystal packing. Bond lengths are P–N = 1·653, P–B = 1·887 and angles N–P–N 99·6–116·8°, N–P–B 123·3–109·0°.

The infra-red spectrum of phosphorus tricyanide has been reported.[764] Only two bands were observed, at 2195 and 642 cm.$^{-1}$ in the vapour, which were assigned to C≡N and P–C stretching vibrations respectively.

### Phosphonitrilic Compounds

The bonding in phosphonitrilic compounds is considered to be analogous to that in aromatic compounds, with $\pi$-bonding between the *p*-orbitals of the nitrogen atoms and the *d*-orbitals of the phosphorus atoms.[676] Such $\pi$-bonding leads to equality and shortness of the ring bonds, and many of the other structural and spectroscopic data described below have also been related to the system of $\pi$-bonding. The nature of the $\pi$-bond system has been considered in detail.[676-8,689,923]

## PHOSPHONITRILIC CHLORIDES

The crystal structure of triphosphonitrilic chloride, $(PNCl_2)_3$, has been determined.[669,672-4,679,924-5] The structure[674] is orthorhombic, with $a = 14{\cdot}15$, $b = 12{\cdot}99$, $c = 6{\cdot}19$ A., $Z = 4$, space group *Pnma*. The $(PNCl_2)_3$ molecules lie on mirror planes which are perpendicular to the six-membered $P_3N_3$ ring. The results of References 674 and 925, although in general agreement, differ in detail. In Reference 674 slight deviations of the ring from planarity are regarded as due to crystal forces; slight differences in the ring bond lengths are regarded as insignificant. In Reference 925, on the other hand, the ring bond lengths appear to be significantly different, and all the P and N atoms appear to be equidistant from, and on opposite sides of, the mean plane, giving a chair-shaped ring. However, the treatment of the standard deviations in Reference 925 is incorrect[926] giving misleadingly low values, and the results may also be criticized[926] for the use of common isotropic temperature factors when very strong anisotropic thermal vibrations are present. For these reasons the results of Reference 674 are to be preferred, although there is an error[926] in the calculation of the mean plane. A mean structure has been calculated[926] weighted 2:1 in favour of Reference 674. This gives more regular results for the bond lengths and angles than either of the independent determinations, with a very small deviation of the ring from planarity. The bond lengths are: P–N, 1·59, 1·58, 1·58 A.; P–Cl, 1·97, 1·97, 1·98, 1·98 A. Angles are: N–P–N, 118·5, 119·5°; P–N–P, 120·7, 120·5°; Cl–P–Cl, 102·1, 101·8°, with the Cl–P–Cl planes effectively perpendicular to the plane of the ring. The triphosphonitrilic chloride molecule therefore approximates to $D_{3h}$ point symmetry; earlier electron diffraction results are in agreement with this.[670]

The structure of the metastable[675] form of tetraphosphonitrilic chloride, $(PNCl_2)_4$, has been determined[671] and recently refined.[927] The tetragonal two-molecule cell has $a = 10{\cdot}844$, $c = 5{\cdot}961$ A.,[927] space group $P4_2/n$. Molecules of $(PNCl_2)_4$ with boat-shaped rings of $P_4N_4$ lie on $\bar{4}$ axes. The point-group symmetry of the molecule is $S_4$. The bond lengths[927] are: $P–N = 1{\cdot}57_0$ and $1{\cdot}56_9$ A., $P–Cl = 1{\cdot}985$ and $1{\cdot}993$ A.; angles are: $N–P–N = 121{\cdot}2°$, $P–N–P = 131{\cdot}3°$, $Cl–P–Cl = 102{\cdot}8°$. The other form[675] is also tetragonal, with space group $P4_2/n$, and cell dimensions $a = 10{\cdot}82 \times \sqrt{2}$, $c = 5{\cdot}95$ A.; space group and packing considerations lead to the conclusion that the molecules must be on sites of $C_i$ symmetry,[680] although the results of an infra-red study are in conflict with this.[681] A preliminary note[1362] on a crystal structure determination confirms the $C_i$ site symmetry. Bond length and angle data were quoted as follows: PN 1·56, PCl 1·99 A., NPN 122°, PNP 135°, ClPCl 103°.

Pentameric phosphonitrilic chloride, $(PNCl_2)_5$, is orthorhombic, space group $P2_12_12_1$, with $a = 15{\cdot}48$, $b = 19{\cdot}44$, $c = 6{\cdot}26$ A., $Z = 4$.[682,1355] The ten atoms in the phosphonitrilic ring are surprisingly close to a planar configuration. The average PN bond length is 1·52 A., individual bonds varying between 1·49 and 1·52 A. in a non-systematic way. The average ring angles are NPN 118·4°, PNP 148°, with a range of 134°–159°. Of two or three forms of hexameric phosphonitrilic chloride, $(PNCl_2)_6$, the cell dimensions of a triclinic form are $a = 10{\cdot}6$, $b = 10{\cdot}7$, $c = 11{\cdot}4$ A., $\alpha = 93{\cdot}5°$, $\beta = 90°$, $\gamma = 117°$, $Z = 2$. Octameric phosphonitrilic chloride, $(PNCl_2)_8$, is monoclinic, with $a = 24{\cdot}7$, $b = 6{\cdot}2$, $c = 20{\cdot}4$ A., $\beta = 111°$, $Z = 4$, space group $C2/c$ or $Cc$.[913]

The *X*-ray fibre pattern of the stretched phosphonitrilic chloride high polymer has been investigated.[714] A helical chain configuration was suggested,[714,928] and the dimensions of an orthorhombic cell reported as $a = 11{\cdot}07$, $b = 4{\cdot}92$, $c = 12{\cdot}72$ A. In a more recent paper[929] it is suggested that the best agreement with the observed *X*-ray pattern is obtained from a double helical configuration with $P–N = 1{\cdot}60$ A., and angles $N–P–N = 119°$, $P–N–P = 127°$. This is quite close to a planar PN skeleton.

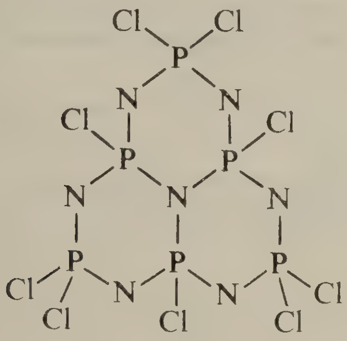
The infra-red[215, 681, 684, 686, 1356–7, 1359–60, 1363–4] and Raman[681, 683, 684, 1356–7, 1360] spectra of trimeric phosphonitrilic chloride have been extensively investigated.[681, 683–4, 1356–7, 1359–60, 1363–4] The spectra confirm that the symmetry of the molecule is $D_{3h}$ in solution[681, 684] and in the vapour.[681] The first assignments[684] of the spectra have been considerably revised,[681, 1356–7, 1359–60, 1363–4] and have been the subject of considerable controversy. Polarized infra-red measurements with oriented samples, including mixed crystals with triphosphonitrilic bromide,[1359] have been employed[1359, 1364] in attempts to sort out the assignments. The most prominent feature of the infra-red spectrum is a very strong band, arising from a degenerate member of a series[681, 687] of stretching vibrations of the phosphonitrilic ring, at 1218 cm.$^{-1}$ Some force constants calculated from the $A_1'$ frequencies,[685] were based on incorrect assignments. Later force constant work,[1365] though more complete, was based on assignments which also proved to be controversial.

In tetraphosphonitrilic chloride, $(PNCl_2)_4$, the characteristic ring absorption in the infra-red moves to 1310 cm.$^{-1}$.[681, 684] The infra-red and Raman spectra[681, 684, 1356, 1359, 1371] were first interpreted[684] as supporting $D_{4h}$ symmetry for the molecule, indicating a planar ring, although $D_{2d}$ symmetry was not excluded. Other work[681] suggested that the ring is not planar in the vapour; later work[1356] supported a planar configuration, while the latest work[1371] again supports $D_{2d}$ symmetry in solution. It is clear, however, from the difference in symmetry in the two forms that the molecule is flexible.

The ring absorption in pentaphosphonitrilic chloride, $(PNCl_2)_5$,[681, 686, 930] is split into a doublet, with components at 1285 and 1345 cm.$^{-1}$ in the vapour[681] owing to a resolution of the ring degeneracy. This indicates a low symmetry which is also indicated by the number of polarized bands in the Raman spectrum and by other data.[681]

The infra-red spectra of the higher cyclic phosphonitrilic chlorides up to the hexamer, $(PNCl_2)_6$,[686, 930] heptamer[686, 931] and octamer,[931] have been determined. The characteristic ring absorption moves to lower frequencies with increasing ring size, lying at 1325, 1310 and 1305 cm.$^{-1}$, in the hexamer, heptamer and octamer respectively. An oily mixture of cyclic phosphonitrilic chloride molecules of average composition $(PNCl_2)_{12-13}$ absorbs at 1257 cm.$^{-1}$.[931] The corresponding band in the rubbery $(PNCl_2)_n$ high polymer occurs at 1215 cm.$^{-1}$ [931]

The infra-red spectrum of the phosphonitrilic chloride, $P_6N_7Cl_9$, which is thought[682] to have the following polycyclic structure:

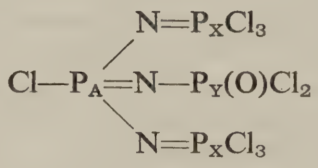


has been reported.[686] The characteristic phosphonitrilic absorption occurs at 1285 cm.$^{-1}$

The ultra-violet spectra of phosphonitrilic chloride polymers up to octamer, and the nitrilohexamer, have been reported.[675, 682, 686, 1366–7] They give no structural information. The trimer and tetramer both show peaks[1366] at 200 and 210 mμ. The spectra of $(PNCl_2)_3$–iodine–heptane solutions have been studied.[1367]

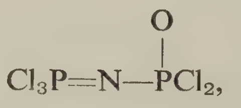
The phosphorus nuclear magnetic resonance spectra of the phosphonitrilic chloride polymers up to the octamer have been determined.[171, 675, 688, 1375] A single phosphorus peak is observed in all cases, confirming the cyclic nature of the molecules. The chemical shifts (relative to 85% orthophosphoric acid) are −19·7 p.p.m. for the trimer, +7·4 p.p.m. for the tetramer, and approximately +18 p.p.m. for the other compounds.[675, 688, 1375] It has been suggested[923] that the changes in chemical shift with increasing ring size may be due to increasing delocalization of the nitrogen lone-pair electrons.

The nuclear magnetic resonance spectra of several non-cyclic chlorine-containing phosphonitrilic compounds have been described[675, 932–6, 1368–9] and used to determine their structures.[932–6, 1368–9] The compound $P_2NOCl_5$ [932–3, 936] has been shown to have the structure $Cl_3P_A{=}N{-}P_B(O)Cl_2$. The chemical shifts of $P_A$ and $P_B$ are +0·1 p.p.m. and 14·2 p.p.m. respectively (referred to 85% orthophosphoric acid), and the coupling constant $J_{AB}$ is 15·4 c/s.[932] The infra-red spectrum of this compound is also reported[933] and shows the characteristic strong phosphonitrilic absorption at about 1340 $cm.^{-1}$. It is stated, on the basis of the infra-red and nuclear magnetic resonance spectra, that the compound described as $P_4O_4Cl_{10}$ [292, 937–40] is in fact $P_2NOCl_5$ (see page 577). The compound $P_3NCl_{12}$ [934, 936] has the structure $[Cl_3P{=}N{-}PCl_3]^+PCl_6^-$. The chemical shifts (in nitromethane solution), relative to 85% orthophosphoric acid, are about 305 p.p.m. for the $PCl_6^-$ ion and −21·4 p.p.m. for the $[P_2NCl_6]^-$ ion. The analogous compound with an extra phosphorus atom[934, 936] is $P_4N_2Cl_{14}$, with the structure $[Cl_3P_B{=}N{-}P_ACl_2{=}N{-}P_BCl_3]^+PCl_6^-$. The chemical shifts are respectively −12·5, 13·6 and approximately 305 p.p.m. for $P_B$, $P_A$ and $PCl_6^-$. The coupling constant $J_{AB}$ is 45·3 c/s. The members of the series of compounds $[Cl_3P{=}N(PNCl_2)_nPCl_3]^+PCl_6^-$ give peaks in almost identical positions.[935] The compound $P_3N_2OCl_7$ has the structure $Cl_3P_B{=}N{-}P_ACl_2{=}N{-}P_B(O)Cl_2$.[934, 936] The chemical shifts are respectively −7·1, +20 and +13·4 p.p.m. for $P_X$, $P_A$ and $P_B$. The coupling constants $J_{AX}$ and $J_{AB}$ are 29·5 and 26·7 c/s respectively; $J_{BX}$ was too small to be detected. The structure of the compound $P_4N_3OCl_9$[934] has been shown to be:

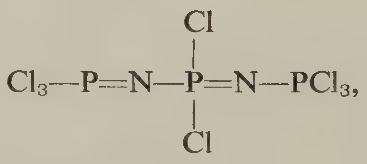


N=P<sub>X</sub>Cl<sub>3</sub>
Cl—P<sub>A</sub>=N—P<sub>Y</sub>(O)Cl<sub>2</sub>
N=P<sub>X</sub>Cl<sub>3</sub>

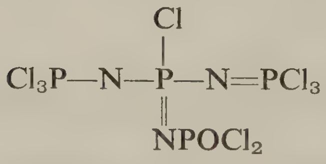
Chemical shifts are 29·6, 1·9 and 13·6 p.p.m. for $P_A$, $P_X$ and $P_Y$ respectively. The coupling constants $J_{AX}$ and $J_{AY}$ are 28·7 c/s and 31·0 c/s respectively; $J_{XY}$ was too small to be detected. The compounds $P_2NOCl_5$, $P_2NCl_2$ and $P_4N_3OCl_9$ were stated[1369] to have the following structures, determined by NMR, although no data were reported:



$$\mathrm{Cl_3P{=}N{-}\overset{\displaystyle O}{\overset{|}{P}}Cl_2},$$



$$\mathrm{Cl_3{-}P{=}N{-}\underset{\displaystyle Cl}{\underset{|}{\overset{\displaystyle Cl}{\overset{|}{P}}}}{=}N{-}PCl_3},$$



$$\mathrm{Cl_3P{-}N{-}\underset{\displaystyle NPOCl_2}{\underset{\|}{\overset{\displaystyle Cl}{\overset{|}{P}}}}{-}N{=}PCl_3}$$

The compound $NP_2Cl_7$,[1368, 1370] indicated by infra-red spectra[1368] to be $NPCl_2,PCl_5$, was found by NMR[1368] to ionize in nitrobenzene solution to $PCl_4^+NPCl_3^-$.

Chlorine nuclear quadrupole resonance spectra have been reported for several phosphonitrilic chlorides.[690–4, 1373–4] For the trimer four lines are found at about 28 Mc/s[690–4] with an overall spacing of about 0·3 Mc/s at both 15°C. and −195°C.[694, 1373] Two of the lines have twice the intensity of the other two, and this observation is in complete agreement with the crystal structure,[674] since the $(PNCl_2)_3$ molecules lie on mirror planes. For the tetramer of known crystal structure,[671] metastable form, there are only two non-equivalent chlorine atoms, and only two peaks are therefore expected in the nuclear quadrupole resonance spectrum. The observed spectrum[694, 1373-4] is in agreement, showing two peaks at about 28 Mc/s with a separation which increases with temperature. An earlier report[692] agrees with this, but other reports,[690-1, 693] describe four lines. These results may refer to the form of different crystal structure,[675] for which four lines of equal intensity are expected,[680-1] but one report[691, 695] states that the lines are of unequal and variable intensity. The latest work[1373-4] on this form of the tetrameric chloride does report four lines, in agreement with the crystal structure, although in one report[1373] the lines are stated to be of unequal intensities (2:3:2:3), which is inconsistent with four molecules per unit cell. The other report[1374] does not mention any unequal intensities but notes that the separation between the two inner frequencies appears to extrapolate to zero at the melting point, suggesting a transition to $C_{2h}$ symmetry in the melt.

Nine weak lines have been observed in the pentamer chloride at −195°C., and one of two phases of the hexamer chloride showed 12 lines at −195°C.[694]

### PHOSPHONITRILIC FLUORIDES

The crystal structure of triphosphonitrilic fluoride, $(PNF_2)_3$, has been investigated[696-8] and accurately determined.[698] The cell is orthorhombic, with $a = 6{\cdot}948$, $b = 12{\cdot}190$, $c = 8{\cdot}723$ A., $Z = 4$, with space group *Pnma.*[698] The cyclic molecules lie on a mirror plane which is perpendicular to the ring, and have point symmetry approximating to $D_{3h}$. The P–N bond lengths are 1·546, 1·563 and 1·572 A. The average P–F bond length is 1·521 A.; the ring angles are 119·6° and 121·1° at the nitrogen and 119·5° and 119·3° at the phosphorus. The space group and the type of packing are the same as in triphosphonitrilic chloride.

The crystal structure of tetraphosphonitrilic fluoride, $(PNF_2)_4$, has been investigated[696-7, 699-700] and accurately determined.[699-700] The structure is monoclinic, with $a = 7{\cdot}40$, $b = 13{\cdot}83$, $c = 5{\cdot}16$ A., $\beta = 109{\cdot}5°$, space group $P2_1/a$, $Z = 2$. The molecule is centrosymmetric and approximates closely to $D_{4h}$ point symmetry, with a planar ring. The deviations from $D_{4h}$ symmetry, the main one of which is a displacement of the fluorine atoms so that they are not mirrored by the plane of the ring, are due to crystal forces. The deviations of the nitrogen atoms from the plane of the phosphorus atoms are not significant. The non-bonded separations between atoms in adjacent molecules are very large, suggesting that the fluorine atoms may be charged. The P–N bond length, 1·51 A., is much shorter, and the P–N–P angle 147·2° much larger, than the corresponding values in $(PNCl_2)_4$. The P–F bond length is 1·51 A.; other angles are N–P–N = 122·7°, F–P–F = 99·9°, N–P–F = 108·0°. Another form of $(PNF_2)_4$, obtained at low temperatures, has the same space group, $P2_1/a$, and the same cell dimensions except that *c* is doubled. Force constants have been calculated,[1365] but some of the assignments used[681] have been questioned in later work.[1356]

The infra-red[681, 687, 701-2, 1356, 1358] and Raman[681, 687, 702, 1358] spectra of triphosphonitrilic fluoride show[681, 702, 1358] that the molecule has $D_{3h}$ symmetry with a planar six-membered ring like the corresponding chloride. The characteristic phosphonitrilic ring absorption in the infra-red occurs at 1297 $cm.^{-1}$. Another strong absorption at 973 $cm.^{-1}$ was attributed[702, 1358] to another ring vibration, but has since been shown[681] to arise from the unsymmetrical in-phase $PF_2$ stretching vibration.

In the infra-red spectrum[681, 687, 701-2] of tetraphosphonitrilic fluoride, the characteristic phosphonitrilic absorption is split, with components at 1419 and 1438 $cm.^{-1}$, indicating resolution of the degeneracy, and the infra-red and Raman[681, 687, 702] spectra have been interpreted[702] as indicating $C_{2h}$ molecular symmetry. Other work, however,[681] has shown (from the variability of the spectra between different phases, and the contrast between the high symmetry in the crystal[700] and the low symmetry in other phases) that the molecule is very flexible. It has been claimed[1356] that the spectra indicate $D_{4h}$ symmetry; the splitting of the phosphonitrilic absorption was attributed to a Fermi doublet.

The numbers of polarized Raman bands, infra-red bands and Raman/infra-red coincidences in the spectra of pentaphosphonitrilic fluoride indicate that the symmetry is low.[681] The variability of the spectra again shows that the molecule is flexible. The characteristic phosphonitrilic absorption occurs at 1439 cm.$^{-1}$

The infra-red spectra of higher polymers of phosphonitrilic fluoride up to $(PNF_2)_{17}$ and of the rubbery high polymer, have been determined.[687] Regularities in an extensive system of infra-red bands arising from symmetrical $PF_2$ stretching vibrations show that all the molecules are monocyclic.[687] As in the chlorides, the characteristic phosphonitrilic infra-red absorption decreases in frequency with increasing ring size once the pentamer is reached. The frequencies, in order of ascending ring size from the hexamer to the undecamer, are 1408, 1400, 1386, 1375, 1363 and 1357 cm.$^{-1}$.[687]

The mass spectra of trimeric and tetrameric phosphonitrilic fluoride have been reported[703] to be in agreement with the cyclic structure.

The phosphorus and fluorine nuclear magnetic resonance spectra of the phosphonitrilic fluorides up to the decamer, with the exception of the hexamer, have been determined.[688] The phosphorus chemical shifts, relative to 85% orthophosphoric acid, are respectively $-9$, $+18$, $+23$, $+23{\cdot}5$ and $+24$ p.p.m. for the trimer, tetramer, pentamer, heptamer and octamer to decamer respectively. The fluorine shifts, relative to trifluoroacetic acid, are respectively $+115{\cdot}5$, $+114$, $+109{\cdot}3$, $+108{\cdot}5$, $+108{\cdot}2$, $+108{\cdot}2$, $+108{\cdot}5$ p.p.m. in trimer, tetramer, pentamer, heptamer, octamer, nonamer and decamer respectively. Both spectra are split by spin-spin interaction between the phosphorus and fluorine nuclei, the fluorine spectrum into a doublet by the single phosphorus of the $PF_2$ group, the phosphorus spectrum into a 1–2–1 triplet by the two fluorine nuclei of the $PF_2$ group. The spin-spin coupling is about 900 c/s. Both fluorine and phosphorus spectra show further fine structure, presumably due to interaction between phosphorus and remote fluorines. This structure, which is of the order of 50 c/s wide, is most clearly defined in the spectra of the trimer, and becomes less resolvable as the ring size increases.

The infra-red[681, 704] nuclear magnetic resonance[704] and Raman[706] spectra of several trimeric phosphonitrilic fluoride-chlorides have been determined, and the infra-red and nuclear magnetic resonance spectra used[704] to show that the compounds are the triphosphonitrilic, 1,1-difluoride 3,3,5,5-tetrachloride, 1,1,3-trifluoride, 3,5,5-trichloride and 1,1,3,3-tetrafluoride 5,5-dichloride. The characteristic phosphonitrilic infra-red absorptions lie between those of triphosphonitrilic chloride and triphosphonitrilic fluoride, at 1246 and 1226, 1258 and 1237, 1277 and 1253 cm.$^{-1}$ respectively.[704] The nuclear magnetic resonance spectra of the 1,1-difluoride 3,3,5,5-tetrachloride have been analysed in detail,[705] and the spin-spin coupling constants obtained. The results are $J_{PF}$ (directly connected) $= +934$ c/s $J_{PF}$ (nonbonded) $= -14$ c/s, $J_{PP'} = -100$ c/s. The NMR spectra of triphosphonitrilic monofluoride pentachloride have also been studied.[1372] The $^{31}P$ spectrum shows an $AB_2$ system with $\delta_A = -14{\cdot}4$ p.p.m., $\delta_B = -23{\cdot}0$ p.p.m. (ref. $H_3PO_4$), $J_{AF} = +1012$ c/s, $J_{BF} = -11$ c/s, $J_{AB} = -78{\cdot}3$ c/s.

Spectroscopic data have also been reported[1376] for the complete series of tetrameric phosphonitrilic fluoride chlorides and the geminal substitution pattern confirmed by $^{31}P$ and $^{19}F$ NMR. The phosphonitrilic infra-red absorption frequencies are as follows, in order of increasing fluorine substitution: 1330 (1F), 1346 (2F), 1362 (3F), 1377 (4F), 1390 (5F), 1400 (6F), 1408 (7F). $^{19}F$ NMR data (shifts relative to $P_3N_3F_6$) were as follows: $P_4N_4FCl_7$ $\delta = -30$ p.p.m., $J_{PF} = 950$ c/s; $P_4N_4F_2Cl_6$ $\delta = 0{\cdot}9$, $J = 925$; $P_4N_4F_3Cl_5$ $\delta = 0{\cdot}3$, $J = 925$ ($PF_2$) $\delta = -32{\cdot}5$, $J = 950$ (PFCl); $P_4N_4F_4Cl_4$ $\delta = 0{\cdot}3$, $J = 900$; $P_4N_4F_5Cl_4$ $\delta = 0{\cdot}0$, $J = 900$ ($PF_2$), $\delta = -32{\cdot}5$, $J = 975$ (PFCl); $P_4N_4F_6Cl_4$ $\delta = -1{\cdot}4$, $J = 880$ (intensity 4) and $\delta = 0{\cdot}5$, $J = 900$ (intensity 2); $P_4N_4F_7Cl$ $\delta = 0{\cdot}8$, $J = 900$ ($PF_2$), $\delta = -33{\cdot}5$, $J = 925$ (PFCl); $P_4N_4F_8$ $\delta = 0{\cdot}4$ p.p.m., $J = 850$ c/s.

## PHOSPHONITRILIC BROMIDES

Triphosphonitrilic bromide[707–9,1377] is isotypic with triphosphonitrilic chloride. The orthorhombic four-molecule cell has $a = 14{\cdot}43$, $b = 13{\cdot}36$, $c = 6{\cdot}63$ A., space group *Pnma*. A two-dimensional refinement of the structure was carried out[1377] and bond length and angle data obtained as follows: PN 1·51, 1·53, 1·54 A. (av. 1·53 A.), PBr 2·08, 2·14, 2·20, 2·22 A., NPN = 116–117°, PNP = 122, 126°, BrPBr = 102–3°. Tetraphosphonitrilic bromide is tetragonal, with $a = 11{\cdot}18$, $c = 5{\cdot}95$ A., $Z = 2$, space group $P4_2/n$.[707]

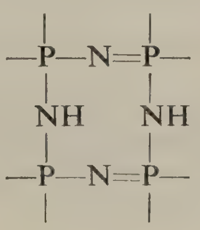
The infra-red[710,1356,1358–9,1371] and Raman[1356,1371] spectra of triphosphonitrilic bromide have been determined. They are very similar to those of triphosphonitrilic chloride. It was concluded[1356,1371] from the spectra that the molecule has $D_{3h}$ symmetry in solution, with a slight deviation to $C_{3v}$ in the crystal.[1371] Polarized infra-red measurements on oriented samples including mixed crystals with the chloride have been made.[1359] The characteristic phosphonitrilic frequency occurs[710–11] at 1178 cm.$^{-1}$ in triphosphonitrilic bromide and 1277 cm.$^{-1}$ in tetraphosphonitrilic bromide.[711] From infra-red[1356,1359,1371] and Raman[1356,1371] spectra this molecule has been described as having $D_{4h}$ symmetry by some workers[1356] and $D_{2d}$ symmetry by others.[1371]

Unit cell data have been reported[712] for three triphosphonitrilic chloride bromides, the pentachloride bromide, the tetrachloride dibromide and dichloride tetrabromide. All are orthorhombic, with four molecules per cell, and cell dimensions as follow: triphosphonitrilic pentachloride bromide, $a = 14{\cdot}24$, $b = 13{\cdot}00$, $c = 6{\cdot}28$ A.; tetrachloride dibromide, $a = 14{\cdot}27$, $b = 13{\cdot}02$, $c = 6{\cdot}34$ A.; dichloride tetrabromide, $a = 14{\cdot}29$, $b = 13{\cdot}33$, $c = 6{\cdot}48$ A. The space group of the tetrachloride dibromide is $Pn2_1a$ or *Pnma*. Recently the infra-red and Raman (solid) spectra of the complete series of triphosphonitrilic chloride-bromides have been reported,[1360] and assignments proposed[1360] on the basis of geminal substitution. For the monobromide pentachloride the Raman spectrum of the solution has also been reported[1360] and polarized infra-red measurements carried out.[1361] The phosphonitrilic absorptions occur as follows[1360]: $P_3N_3Cl_5Br$ 1209, $P_3N_3Cl_4Br_2$ 1201, $P_3N_3Cl_3Br_3$ 1195, $P_3N_3Cl_3Br_4$ 1190, $P_3N_3ClBr_5$ 1183 cm.$^{-1}$. Some infra-red data have also been reported[1358] for the complete series of triphosphonitrilic fluoride bromides. The phosphonitrilic absorptions lie between 1170 and 1400 cm.$^{-1}$ and are all doublets.

## PHOSPHONITRILIC HEXAHYDRAZIDE AND AMIDES

The phosphonitrilic absorption in the infra-red spectra of triphosphonitrilic hexahydrazide, $P_3N_3(N_2H_3)_6$, occurs[713] at 1218 cm.$^{-1}$ The infra-red spectra of tri- and tetraphosphonitrilic amides have been reported.[761] The characteristic phosphonitrilic absorptions occur at 1175 and 1240 cm.$^{-1}$ respectively, with other strong bands at 925, 1575, 3180 and 3300 cm.$^{-1}$ in the trimeric compound and 915, 1565, 3240 and 3360 cm.$^{-1}$ in the tetrameric compound. The phosphonitrilic absorption in triphosphonitrilic diamide tetrachloride, $P_3N_3Cl_4(NH_2)_2$, is broad and shows structure in the published spectrum[762]; the absorption lies between 1175 and 1220 cm.$^{-1}$. The amido-derivatives are generally regarded[1377] as having non-geminal substitution. However, a recent report[1378] claims that $^{31}$P NMR data indicate that triphosphonitrilic diamide tetrachloride and triphosphonitrilic bis(trichlorophosphazide) tetrachloride are geminally substituted.

The amorphous solid, phospham, of empirical composition, $PN_2H$, which is obtained by pyrolysis of phosphonitrilic amides, has been investigated by infra-red spectroscopy.[761,763] A polymeric structure of the type:



is proposed, and bands at 1300 and 950 cm.$^{-1}$ are assigned to vibrations of the P–N=P and P–NH–P linkages respectively.[763]

## SPECTRA–STRUCTURE CORRELATIONS IN PHOSPHORUS COMPOUNDS

### Infra-red Spectra

Most of the assignments of infra-red bands which might provide useful spectra–structure correlations for analytical purposes have been described under individual compounds or groups of compounds. However, some correlations, particularly those which have been mainly derived from the spectra of large groups of organic phosphorus compounds, may be of sufficiently wide application to justify special mention.

P=O STRETCHING VIBRATIONS

The phosphoryl group produces a strong absorption which occurs most frequently in the range 1300–1250 cm.$^{-1}$.[215, 217, 559, 661–2, 664, 765–72, 775, 782] The position of this band is strongly dependent on the electronegativity of the substituents. With strongly electronegative substituents such as fluorine the frequency is higher, as in phosphoryl fluoride,[215, 217, 275–6] which absorbs at 1395–1404 cm.$^{-1}$, while with less electronegative substituents such as carbon and hydrogen the frequency may be shifted below the range quoted above. The full range has been quoted as 1350–1160 cm.$^{-1}$ [770] or 1160–1400 cm.$^{-1}$.[1379] The dependence of frequency on electronegativity has been put on an almost quantitative basis[773, 1379–80] by relations between the frequency and the sum of the electronegativities or 'shift constants' of the substituents:

$$(\mu) = \frac{39{\cdot}96 - \sum x_i}{3{\cdot}995} \quad [773]$$

$$(\nu) = 950{\cdot}1 + 37{\cdot}5 \sum x \text{ cm.}^{-1} \quad [1379]$$
$$(\nu) = 930 + 40 \sum x \text{ cm.}^{-1} \quad [1380]$$

where the $x_i$ are the electronegativities or shift constants of the substituents. Values of these constants for some common inorganic substituents are given in Table XX. The last relationship is stated to hold within ±12 cm.$^{-1}$ for most of the 900 components considered.[1380]

*Table XX.—Phosphoryl Shift Constants*

| Substituent | Shift constant | Reference |
|---|---|---|
| –O–H | 2·3 | 773 |
| H | 2·1 | 773 |
| F | 4·0 | 773 |
| Cl | 3·0 | 773 |
| Br | 2·8 | 773 |
| $NH_2$ | 1·85 | 1380 |
| $N_3$ | 3·0 | 1380 |

The use of Taft substituent constants, instead of electronegativities, has also been suggested.[774]

These shift relations do not apply quantitatively in cases where the molecule contains OH or NH groups which may form hydrogen bonds with the phosphoryl group.[215, 768–71] In these cases the absorption frequency is lowered by 50–80 cm.$^{-1}$, and the range is quoted[770] as 1225–1140 cm.$^{-1}$.

### THE P(O)OH AND P(S)OH GROUPS

In compounds containing the P(O)OH group the absorption due to OH stretching vibrations is considerably displaced from its normal position by hydrogen bonding,[215, 656, 660, 768–9, 779–80, 782] and appears as a broad weak band in the range 2525–2725 cm.$^{-1}$.

In many compounds containing POH linkages as in some other strongly hydrogen-bonded systems, a characteristic trio of bands at around 2700, 2200 and 1600 cm.$^{-1}$ is seen. This trio and its origin have received a great deal of attention in connection with the theory of strong hydrogen-bonding. The subject has recently been reviewed.[1382]

The PO(H) stretching vibration around 1000 cm.$^{-1}$ has also been related[1381] to the electronegativity of substituent groups and a frequency–electronegativity correlation similar to those above has been proposed[1381]:

$$\nu_{\mathrm{PO(H)}} = 650 + 40 \sum x \text{ cm.}^{-1}$$

### THE P-O-P GROUP

The range (for the asymmetric POP stretching vibration) has been quoted as 901–980 cm.$^{-1}$.[1381]

### P–H STRETCHING VIBRATIONS

These vibrations lead to sharp absorptions of medium intensity[215, 525, 660, 765, 767–8, 770, 772] in the range 2440–2288 cm.$^{-1}$. The range 1150–965 cm.$^{-1}$ has been suggested[770] for P–H bending vibrations.

### P═S STRETCHING VIBRATIONS

These vibrations, although clearly assigned between 695 and 753 cm.$^{-1}$ in the thiophosphoryl halides, are much less well characterized in the infra-red spectra than the corresponding phosphoryl vibrations. The intensity of the absorption is variable and is frequently weak, but ranges of 640–680,[1383] 535–862,[1384] 750–600,[215, 660, 664, 776] 845–740[777, 782–3] and 835–713, 675–568 cm.$^{-1}$ [770] have been proposed by different authors. The frequency does not depend directly on the electronegativity of the substituents.[1384] More detailed correlations were proposed within the total range.[1384]

### P–S–(X) VIBRATIONS

Ranges have been proposed[1384] of 493–548 cm.$^{-1}$ for P–S–(H) vibrations, and 460–500 cm.$^{-1}$ for P–S–(P) vibrations.

### P═Se VIBRATIONS

A range of 473–577 cm.$^{-1}$ has been proposed.[1384]

### P–N STRETCHING VIBRATIONS

A correlation between absorption in the range 750–680 cm.$^{-1}$ and the presence of the P–N linkage has been suggested,[660–2] but molecules containing this linkage frequently show no absorption in this region[782] and the correlation should be interpreted with extreme caution. Other, tentative, assignments have been proposed in the 860–940 cm.$^{-1}$ region.[781] A number of indirect correlations have been proposed[1385] for the identification of P–N groups. A range of 1170–1438 cm.$^{-1}$ has been proposed[1385] for the characteristic absorption in phosphonitrilic and related compounds.

**Refs. p. 1230**

### P–F AND P–Cl STRETCHING VIBRATIONS

These vibrations give strong absorptions in the region 900–720 cm.$^{-1}$.[209–12, 215–8, 260–2, 276, 281, 284, 534, 656, 782] If phosphorus trifluoride and phosphoryl fluoride are excluded, the narrower range 890–805 cm.$^{-1}$ has been suggested.[770, 782] A range of 769–760 cm.$^{-1}$ has been suggested for trivalent phosphorus compounds.[770] P–Cl stretching vibrations normally give strong absorptions in the range 580–540 cm.$^{-1}$.[215, 219–20, 243, 660, 664, 777, 782] The wider range 587–435 cm.$^{-1}$ has also been proposed.[770]

## Nuclear Magnetic Resonance Spectra

Besides the inorganic phosphorus compounds of which the nuclear magnetic resonance spectra have been described individually, phosphorus chemical shifts have been measured for several hundred organophosphorus compounds.[171, 226, 612] The shifts of both trivalent and pentavalent compounds extend over a wide range (approximately 500 and 100 p.p.m. respectively), and different substituents give rise to easily measurable differences in chemical shifts. Useful empirical correlation charts may be drawn up,[171, 786] and in some cases the shift contributions of substituents are roughly additive. Empirical correlations between chemical shifts and a bond parameter related to the number of unbalanced $p$ electrons in the valence shell of the phosphorus atom have been developed.[226, 785] Recently, a LCAO-MO calculation of chemical shifts has been made[1386] and charts produced relating the theoretical shift contributions to substituent electronegativities and bond angles. The results were used to estimate $p^{\pi}$–$d^{\pi}$ bonding. In a second paper[1387] the deviation from additivity of shift contributions was calculated and related to $\pi$ bonding and angular changes in the mixed molecules.

Phosphorus–proton spin-spin coupling constants may range up to 700 c/s when the nuclei are directly bonded together,[171, 225, 612] and in compounds containing thiophosphoryl groups the coupling is about 50 c/s weaker than in the corresponding phosphoryl compound.[612] Phosphorus–proton coupling constants where two bonds separate the nuclei are 10–20 c/s, and are lower in phosphoryl than in thiophosphoryl compounds.[612] When three bonds separate the nuclei, the coupling constants are usually of the order of 10 c/s.[226] A relation has been proposed[1391] between the phosphorus–phosphorus coupling constant in unsymmetrically substituted phosphonitrilic compounds and substituent parameters of the different substituents, which are related to their electronegativities.

### *X*-RAY FLUORESCENCE LINE SHIFTS

The phosphorus $K_{\alpha}$ fluorescent line shift in a number of compounds has recently been studied.[1388] Shifts were related to a standard of disodium phosphate ($2\theta =$ 133·233) taken as zero shift. On this scale, various phosphates and tetrasodium pyrophosphate had zero shift, while other values were: phosphorous acid 0·0006 Å., phosphorus pentasulphide 0·0013 Å., phosphorus heptasulphide and sesquisulphide 0·0016 Å., calcium phosphide ($Ca_3P_2$) 0·00185 Å., and red phosphorus 0·00215 Å.

### SECTION XXXV

# THE ANALYTICAL CHEMISTRY OF PHOSPHORUS

BY S. GREENFIELD AND M. CLIFT

## QUANTITATIVE ANALYSIS

### Orthophosphates

#### GRAVIMETRIC

PRECIPITATION of ammonium molybdophosphate from nitric acid solution, by the addition of ammonium molybdate and ammonium nitrate, may be used both as a means of separation and possibly of determination of orthophosphate. The composition of the yellow precipitate varies with experimental conditions.[1] The reasons for these differences in composition may be found among the following: adsorption of other ions,[2] co-precipitation of molybdic oxide[3] or 12-molybdophosphoric acid,[4] and base exchange reactions.[2, 5] From *X*-ray studies[8] it has been assigned a theoretical formula of $(NH_4)_3[PMo_{12}O_{40}]$.[6-8] There are numerous methods of precipitation[2-5, 9,10]; some give, it is claimed, precipitates of virtually this formula, either before or after washing. In these cases the ammonium molybdophosphate may be weighed as such, usually after drying at 120°–160°C. (although higher temperatures have been used[3, 11]), or as $P_2O_5,24MoO_3$ after heating to 550°C.[2] Other procedures give different but reproducible compositions.[12-5] The precipitation is retarded by sulphuric,[2] hydrochloric[2] and hydrofluoric[16] acids and their ammonium salts, but not by moderate amounts of perchloric acid or ammonium perchlorate. Selenium, tellurium and both pentavalent and tetravalent vanadium also retard precipitation. Silicon, pentavalent arsenic, pentavalent vanadium and hexavalent tungsten react with ammonium molybdate and/or phosphate to give heteropoly complexes such as molybdosilicate, molybdoarsenate, molybdovanadophosphate and tungstophosphate. Bismuth, titanium and zirconium form insoluble phosphates and if present in appreciable amounts may cause losses[17] in the preliminary operations or lead to contamination of the final precipitate. The effect of some of these retardants and/or contaminants can be minimized by the addition of a 10–20 times greater excess of molybdate reagent than the usual amount (this has been given the minimum value of $3\frac{1}{2}$ times the theoretical quantity[5]). This applies particularly in the presence of chloride, sulphate and fluoride ions, although fluoride is best converted to the non-interfering fluoborate by the addition of boric acid.[18] Precipitation is best carried out in the temperature range 40°–60°C., since at higher temperatures some molybdic oxide may precipitate; in the presence of arsenic and tetravalent vanadium the precipitation may with advantage be made at lower temperatures. Frey,[11] however, states that if precipitation is carried out below 65°C. an ammonium 9-molybdophosphate is precipitated; at temperatures higher than 65°C. ammonium 12-molybdophosphate is formed; a recent study of precipitation conditions has also been made by Archer *et al.*[19] Pentavalent vanadium should first be reduced with ferrous sulphate[20] or hydrazine hydrochloride before precipitation of the molybdophosphate. Silicon and tungsten are best removed as insoluble oxides and filtration (it may be necessary to examine the resultant silica or tungstic oxide for occluded phosphorus). In the presence of titanium, zirconium and bismuth it is preferable to fuse any insoluble residues with sodium carbonate and extract the sodium phosphate with distilled water. Organic materials should be decomposed by wet oxidation,[21-4] Parr bomb fusion[25] and, possibly, in selected cases by dry ashing.[26-7]

In view of the uncertain composition of ammonium molybdophosphate it is preferable to dissolve the precipitate in ammonium hydroxide solution and, after acidification and the addition of magnesium and ammonium chlorides, to reprecipitate the phosphorus as magnesium ammonium phosphate hexahydrate by the slow addition of ammonium hydroxide solution.[28] Finally the precipitate is ignited at 1000°–1100°C. to magnesium pyrophosphate and weighed. It has been claimed that some molybdenum is entrained by this procedure, but is volatilized almost completely if the ignition is carried out in an electric muffle.[29] Alternatively, after dissolution of the molybdophosphate in ammonium hydroxide solution and the addition of ammonium chloride and ammonium acetate as buffers, lead molybdate[30-1] may be precipitated by the addition of lead chloride. After filtration the precipitate is ignited at a temperature not exceeding 650°C. and weighed as lead molybdate. Other suggested transformations have been to molybdyl oxinate[32] and chloropentamminechromic tetrathiomolybdate.[33]

The prior precipitation of ammonium molybdophosphate serves to separate the orthophosphate from the many elements which are precipitated from ammonium hydroxide solution. Many of these elements, including calcium, iron, aluminium, tin, vanadium and titanium, are, even when present in considerable quantities, complexed by citric acid, whereas magnesium is only slightly complexed, thus permitting the direct precipitation of magnesium ammonium phosphate.[34] Calcium, strontium, barium, lead, copper, cadmium, zinc, nickel, cobalt and manganese can be complexed with ethylenediaminetetraacetic acid (EDTA),[35-7] again enabling a direct estimation of the phosphorus to be made. Přibil[35] recommends the substitution of Tiron (pyrocatechol-3:5-disulphonic acid) for EDTA if the solution contains aluminium, chromium, bismuth, antimony, tin, ferric iron, uranium, titanium or beryllium. In the direct method any pentavalent arsenic present will be precipitated as magnesium ammonium arsenate[38] and the acid solution must be treated with ammonium bromide to volatilize the arsenic. It is preferable in most cases (almost always in those cases where citric acid is used as the complexing agent) to dissolve the first precipitate of magnesium ammonium phosphate in hydrochloric acid and reprecipitate,[39-41] since the first precipitate is seldom pure and often contains the trimagnesium phosphate. Polyphosphates have been found to give rise to more phosphorus in the magnesium ammonium phosphate than that corresponding to the monophosphate content of the original solution.[42] It has been claimed,[43-4] and to some extent disputed,[45] that the addition of ammonium acetate prior to the final precipitation helps to give a crystalline precipitate. Saint-Chamant and Vigier[46] describe a method in which magnesium ammonium phosphate is precipitated by the slow evolution of ammonia resulting from the reaction of ammonium chloride and monoethanolamine. The crystals so formed are large and easily washed and only one precipitation is necessary. All these direct methods are capable of giving good results, largely due to compensation of errors,[47] but in all cases the ignition of the final precipitate should be conducted at a low temperature until all carbon is removed, otherwise the pyrophosphate is slowly reduced and phosphorus volatilized.[48] Other metal ammonium phosphates, amongst which are uranyl,[49] manganese[45,50] and zinc[45] ammonium phosphates, have been used to determine orthophosphate gravimetrically.

Quinoline molybdophosphate has a number of advantages over ammonium molybdophosphate as a suitable precipitate for the determination of orthophosphate. It is less soluble, of constant composition and free from occluded or adsorbed impurities apart from a small quantity of neutral contaminant, probably water, which is driven off when the precipitate is heated to 200°–250°C. The method,[51] in its original form, depended upon the formation of molybdophosphoric acid in a solution free from ammonium salts, followed by its precipitation as a salt of the weak base quinoline. It was later modified[52] to overcome the interference of silica by the addition of citric acid, which forms a stable complex with molybdic acid and prevents its reaction with silicic acid. The interference of ammonium salts is overcome in a similar manner. After heating to 200°–250°C. the quinoline molybdophosphate is weighed.[53-4] Calcium, magnesium, iron, aluminium and alkali salts are without effect on the results.

A similar method to the above is the precipitation of the oxine molybdophosphate.[53-9] The thermal decomposition of this compound was investigated by Duval[60] who reported a di-hydrate stable from 176–225°C., more or less in agreement with Berg,[56] who concluded that the dried precipitate was a dihydrate:

$$3C_9H_7ON.H_7[P(Mo_2O_7)_6],2H_2O$$

Wendlandt and Brabson in a re-investigation[61] stated that the compound begins to lose water at 60°C. giving a weight plateau at 85°–285°C. which corresponds to the anhydrous compound $3C_9H_7ON.H_3(PMo_{12}O_{40})$; above 285°C. some decomposition occurs giving another plateau at 335°–375°C., which corresponds closely to the 1-oxine compound. Finally, a plateau corresponding to the oxide $24MoO_3,P_2O_5$ begins at 470°C. They conclude that washing with ammonium nitrate may account for the accelerated decomposition of the experimental material of Duval and state that phosphorus may be determined by this method if the precipitate is dried at 140°C. The precipitate is said to be free from contamination, to have a high molecular weight and low phosphorus content, thus making it suitable for gravimetric analysis.[59] Another weak base which has been used to form a salt with molybdophosphoric acid is strychnine.[62-4] The resultant strychnine molybdophosphate also has a high molecular weight and low phosphorus content. It can be dried to constant weight. The quinine molybdate complex has also been used[65] as has the 1,2-dimorpholinoethane complex.[66]

A number of metal phosphates may be used to determine orthophosphate gravimetrically. Of these, bismuth phosphate may be precipitated from nitric acid solution by the addition of bismuth nitrate.[67-71] Calcium, iron, aluminium, magnesium, manganese and cobalt do not interfere. The precipitate may be either ignited at 700°–800°C. and weighed as anhydrous bismuth phosphate or filtered on a Gooch crucible, dried in vacuum, and weighed as $BiPO_4,\frac{1}{3}H_2O$. Lead phosphate may be precipitated from acetic acid/sodium acetate solution by the addition of lead acetate. After being heated to 600°–700°C. the lead phosphate is weighed. It is claimed for this method that it is as accurate as the molybdophosphate and magnesium pyrophosphate methods.[72] Zirconium oxychloride has been used as a precipitant for the mono- and di-zirconium phosphates.[73] Both mercury[74] and silver[75-6] phosphates may be dried and weighed. In both cases iron and aluminium interfere, but nitrate, sulphate, chloride, calcium and magnesium ions are without effect on the mercury phosphate method.

Numerous gravimetric micro and semi-micro methods have been developed from the macro procedures. The high molecular weight and low phosphorus content of the ammonium,[77] strychnine,[62, 78-9] quinoline[80-2] and oxine[83] molybdophosphates make them eminently suitable for this purpose and they have been so used. The separation of phosphorus by precipitation as the molybdophosphate and subsequent conversion to magnesium ammonium phosphate has also been used on a micro scale.[84] A semi-micro method has been described in which the phosphorus is precipitated as nitratopentammine cobaltidodecamolybdophosphate by the addition of nitratopentammine cobaltinitrate and alkaline sodium molybdate.[85] Advantages claimed are speed and the use of a low conversion factor.

### VOLUMETRIC

Orthophosphoric acid is tribasic and may be titrated with many bases to the mono- and di-stages, which occur at pH 4·5 and 8·55 respectively. The third acid group cannot be titrated directly, since the ionization constant is so small ($3{\cdot}6\times10^{-13}$).[86] Conversely the salts of orthophosphoric acid may be titrated with many acids. Numerous indicators have been recommended for these titrations[87-9]; one of the best is that of Peck.[90] Sodium chloride should not be present in the titration of the monobasic acid since its presence increases the hydrogen ion concentration of primary phosphate, but its presence is advantageous in the titration of the dibasic acid to phenolphthalein, since it represses the hydrolysis which causes the colour change to occur early.[91] It should also be noted that titration with alkali between the mono- and di-stages cannot be carried out accurately in the presence of ammonium ions. Variable amounts of ammonia are evolved during such titrations and the ammonium ion should be completely eliminated by boiling with excess alkali. The solution can then be titrated with acid to the di-stage then to the monosodium phosphate end-point. The presence of various cations causes dissociation of the ordinarily weak terminal hydrogen atoms; this results in a significant shift of the pH titration curve.[92-3] Potassium ferricyanide and potassium cobalticyanide are said to complex certain cations that are likely to form insoluble phosphates and liberate hydrogen ions.[94] By titrating between and to these stages many compounds and mixtures may be analyzed, e.g. boiler compounds, cast iron and organophosphorus compounds,[95] mixtures of tri- and di-sodium phosphate,[96] phosphoric acid,[97-8] phosphoric acid and ammonium, sodium and calcium phosphates in the presence of one another and of a strong acid or base.[99] The method is also applicable to the analysis of superphosphates.[100-1]

The third acid group may be titrated indirectly by the addition of neutral calcium chloride at the di-stage. It is probable that in the cold solution there is an initial partial precipitation of calcium monohydrogen phosphate (1) $Na_2HPO_4 + CaCl_2 = CaHPO_4 + 2NaCl$ which in solution or suspension is unstable and is in equilibrium with mono- and tricalcium phosphate[102-4]:

$$(2)\quad 4CaHPO_4 \rightleftharpoons Ca(H_2PO_4)_2 + Ca_3(PO_4)_2 \downarrow$$

Since tricalcium phosphate is very insoluble above pH 7 it precipitates from the alkaline solution, and thus the solution again becomes acid. On further titration to pH 8·5 the monocalcium phosphate is completely converted to the tricalcium salt: (3) $3Ca(H_2PO_4)_2 + 8NaOH = Ca_3(PO_4)_2 + 4Na_2HPO_4 + 8H_2O$. The net effect of stages 1 to 3 is the equation $2Na_2HPO_4 + 3CaCl_2 + 2NaOH = Ca_3(PO_4)_2 + 6NaCl + 2H_2O$. By this means mixtures of phosphoric acid, mono- and di-alkyl phosphoric acids and the trialkyl phosphate may be evaluated[102]; the neutral compound is found by difference. In the titration of acid extracts of phosphates the overtitration which would result from the presence of alkaline earths may be avoided by adding an excess of calcium chloride and titrating in effect the second and third hydrogen ions.[105-6] Cerium[107-8] and silver salts[109-11] have also been used to liberate hydrogen ion from phosphoric acid. If solutions of tricalcium phosphate are boiled in the presence of hydroxyl ion, hydroxy-apatite $[3Ca_3(PO_4)_2,Ca(OH)_2]$ is formed[112] and methods based on the reaction $6H_2PO_4^- + 10Ca^{2+} + 14OH^- = 3Ca_3(PO_4)_2,Ca(OH)_2 + 12H_2O$ have been used to determine phosphate.[113-4]

If orthophosphoric acid is titrated with calcium hydroxide solution all three hydrogen ions are titrated but only two end-points are found. The first inflection corresponds to the formation of monocalcium phosphate after which, on addition of further calcium hydroxide, calcium monohydrogen phosphate begins to form, and this decomposes above pH 5·5 as already described; the second inflection corresponds to the total precipitation of tricalcium phosphate.[103-4] The decomposition of calcium monohydrogen phosphate at lower pH values is slow and the neutralization curve may show irregularities if its titration is carried out in the normal manner; the orthophosphate concentration is also said to influence the composition of the precipitate formed.[115] The titration has found practical application in the analysis of superphosphates.[116]

If orthophosphoric acid is titrated with potassium iodide/iodate solution, one molecule of acid will liberate two atoms of free iodine.[117] Bromate has replaced iodate in a variant of this method.[118]

Many, if not all, of the gravimetric methods for the determination of orthophosphates may be finished volumetrically. Ammonium molybdophosphate may be dissolved in a known excess of sodium or potassium hydroxide and the excess back-titrated[119-23]:

$$2(NH_4)_3[PMo_{12}O_{40}]+46NaOH = 23Na_2MoO_4+(NH_4)_2MoO_4+2(NH_4)_2HPO_4+22H_2O$$ [2]

The method is subject to all the disadvantages previously mentioned, and in addition (if the determination is carried out as in the original method[124-5] and the precipitate is washed with water) has the disadvantage of losses occurring through the appreciable solubility of the molybdophosphate and its tendency to pass through the filter. Some of these effects may be reduced by washing the precipitate with potassium nitrate solution (or ammonium nitrate solution in which it is less soluble) but some error may be introduced by the occurrence of cationic exchange. The precipitate is liable to decomposition by hydroxyl ions and the presence of ammonia affects the phenolphthalein used to detect the end-point.[4] Attempts have been made to overcome this by evaporating the alkaline solution, or more advantageously by the addition of formaldehyde to form hexamine from the ammonia: 26 g.-equivalents of sodium hydroxide decompose 1 g.-equivalent of the triammonium salt in these cases. If the precipitate has been washed with potassium nitrate and cationic exchange has occurred, the use of these methods can lead to error owing to the variable amount of sodium hydroxide which will be consumed.[2-3,9] In the analysis of metallurgical samples where an oxidative attack converts phosphides to phosphate suitable for precipitation as molybdophosphate followed by a titrimetric finish, the use of a comparative standard alloy is preferred to using the method in an absolute manner, in order to eliminate some of these and other errors. This use of standard steels is based upon the following assumptions: the phosphorus content of the standard steel is known; each subsequent steel test sample will behave as the standard; the same number of the same errors will occur in the same way each time; and, finally, that a relatively complicated procedure using an empirical standard is more precise and accurate than the use of a relatively simple procedure using primary or secondary chemical standards. Methods have been described in which a precipitate of ammonium molybdophosphate containing acetone is formed[9,13,126]; the amount of sodium hydroxide consumed in the titration of these precipitates appears to be variable. Metals which interfere in the gravimetric procedures will of course also interfere in the volumetric finish, although this volumetric procedure has been applied in the presence of titanium[127] and vanadium.[128-9]

Methods have been described based on the dissolution of the ammonium molybdophosphate in sodium or ammonium hydroxide solutions, followed by reduction of the molybdenum using zinc and hydrochloric acid, lead, zinc, bismuth amalgams, silver or mercury and subsequent titration of the reduced molybdenum with ammonium vanadate,[130-1] ceric sulphate,[132] potassium permanganate[133-4] or methylene blue.[135] In another method,[136] ammonium sulphomolybdophosphate is precipitated, dissolved in sodium hydroxide solution, reduced by means of zinc and titrated with permanganate in the presence of benzidine. In view of the uncertainties associated with the formation of the molybdophosphate, such as the co-precipitation of molybdic oxide, it is questionable whether these procedures offer any marked advantages.

Magnesium ammonium phosphate may be dissolved in hydrochloric acid, a known excess of EDTA or its disodium salt added, and the excess titrated with standard magnesium solution using Eriochrome Black T as indicator.[137-40] Alternatively, the phosphate may be precipitated as magnesium ammonium phosphate by the addition of a known excess of magnesium chloride with ammonium chloride and ammonium hydroxide; after filtration and washing of the precipitate, the excess of magnesium in the filtrate is then determined by titration with EDTA or its disodium salt.[141-2] Another variant is to titrate the orthophosphate directly with standard magnesium solution using Eriochrome Black T as indicator.[143-6] The solution should be at pH 10 before commencement of the titration. It has also been claimed that orthophosphate may be titrated directly with the disodium salt of EDTA in the presence of Eriochrome Black T and sulphosalicylic acetate.[147] Of a number of methods critically reviewed by Eschmann and Brochon,[148] the compleximetric titration of the magnesium in the magnesium ammonium phosphate obtained by the Saint-Chamant and Vigier method[46] was considered to be the best.

Of the other metal ammonium phosphates, the uranyl salt can be reduced to the trivalent state using zinc amalgam, or to the tetravalent state with bismuth amalgam or aluminium and titrated back to the uranyl condition with potassium permanganate or dichromate.[149-50] The manganous ammonium phosphate may also be dissolved in acid and titrated with potassium permanganate at 80°–90°C.[151] Zinc ammonium phosphate may be converted into zinc oxalate by treatment with oxalic acid and subsequently titrated with potassium permanganate.[152] Alternatively the precipitate may be dissolved in hydrochloric acid, neutralized with ammonium hydroxide and titrated with EDTA using Eriochrome Black T as indicator.[153]

Amongst the best of the volumetric methods is the quinoline molybdophosphate procedure of Wilson.[51-2] In this procedure the precipitate is dissolved in a known excess of sodium hydroxide and the excess back-titrated:

$$(C_9H_7N)_3H_3(PMo_{12}O_{40}) + 26NaOH = Na_2HPO_4 + 12Na_2MoO_4 + 3C_9H_7N + 14H_2O.$$

The advantages of this method over the analogous volumetric ammonium molybdophosphate method lie in the greater insolubility of the precipitate, its freedom from ammonia and its consistent composition. A number of applications of this method have been described[154-5] including its application to the determination of phosphate in the presence of vanadium[156] and to the combined determination of phosphorus and arsenic.[157]

Oxine molybdophosphate, after dissolution in hydrochloric acid, may be titrated with standard bromate/bromide solution, and the method has been used to determine phosphate.[158-63] In another variant[164] the excess oxine in the filtrate following the precipitation of the oxine molybdophosphate has been determined[165] and the phosphate content deduced. In another the phosphate solution is titrated with an oxine–molybdate solution. These methods, although novel, would seem to have little advantage over the quinoline procedures, apart possibly from the last which may be rapid, although not very accurate.

Procedures involving the precipitation of metal phosphates have their volumetric variants. Orthophosphate can be titrated directly with a bismuth salt using potassium iodide as indicator; excess of bismuth is indicated by the formation of the red bismuth oxy-iodide.[166] In one method[167] the maximum turbidity due to the precipitation of bismuth phosphate is used to detect its end-point when titrating orthophosphate with bismuth oxy-perchlorate; in another[168] the end-point is indicated by the formation with thiourea and excess titrant of a bright yellow complex. A known amount of a bismuth salt may be added to an orthophosphate solution and the excess determined by titration with EDTA,[169-72] using pyrocatechol violet[169-70,172] or xylenol orange[171] as indicator; organic complexing agents interfere.[173] High accuracy is claimed for the titration of orthophosphate with lead acetate in an acetic acid buffer, using dithizone to detect the end-point,[174] and with lead nitrate using Eriochrome Black T as indicator.[175] Mercuric phosphate may be dissolved in dilute nitric acid and the mercuric ion titrated with potassium thiocyanate, affording a measure of the phosphate content; this method is said to be unaffected by nitrate, sulphate, chloride, calcium or magnesium ions but gives low results in the presence of ferrous, ferric and aluminium ions.[74] Other possible methods include the precipitation of silver phosphate and subsequent determination of the silver content of the precipitate by Volhard's method,[75,176-7] or in one case[178] by titration of the precipitate in the presence of ceric ion and starch with potassium iodide. Initially silver iodide is formed; excess of potassium iodide reacts with the ceric salt, liberating free iodine which, by forming starch iodide, marks the end-point. Ceric sulphate has also been used to precipitate ceric phosphate and the excess determined in the filtrate with ferrous sulphate[179]; cerous salts have been used in a similar reaction except that excess is detected by the use of Eriochrome Black T.[180] Lanthanum ion precipitates phosphate preferentially in the presence of calcium and barium and the excess of lanthanum can be determined compleximetrically.[181]

Benzidine phosphate is sufficiently insoluble in neutral or weak acetic acid solution to enable orthophosphate to be determined. The benzidine phosphate is titrated with sodium hydroxide after its precipitation and filtration. The method has been applied to superphosphate analysis, and it is claimed that it enables a distinction to be made between phosphate and sulphate.[182]

If orthophosphate in the presence of hydrochloric acid is shaken with ethyl ether and an alkali-metal molybdate,[183] or with a mixture of butyl ether and methyl ethyl ketone and an alkali-metal molybdate,[184] a complex is formed which is insoluble in both the aqueous and organic phases. By measuring the volume of this insoluble liquid phase a measure of the phosphate content of the original solution can be obtained.

Several micro- and semi-micro procedures for the volumetric determination of orthophosphate are known. These are based on macro-procedures such as alkali titration of ammonium molybdophosphate,[185–6] with variants such as determination of the molybdenum content of the precipitate by reduction and titration of the reduced solution with an oxidizing agent,[187] or estimation of the nitrogen content by a micro-Kjeldahl procedure.[188] Strychnine molybdate has also been used to precipitate orthophosphate and the carbon content of the precipitate determined by the gas volumetric method of Van Slyke.[189] Magnesium ammonium phosphate precipitation has also been used on a micro and semi-micro scale, and the precipitate titrated compleximetrically.[190–1] Heterometric titrations have been used for the determination of phosphorus on the micro scale.[192]

### SPECTROPHOTOMETRIC

A yellow hue develops when excess of molybdate solution is added to an acidified solution containing orthophosphate ions. The colour may be attributed to the formation of the 12-molybdophosphate anion[193–4] which exists only in acid solution.[195] The yellow solution gives an absorption maximum at 332 mμ[196] and at this wave-length obeys Beer's Law up to a concentration of 1 p.p.m. of phosphorus and is thus suitable for the spectrophotometric determination of phosphorus. A large excess of molybdate over the stoicheiometric amount is necessary for maximum colour development, and since the molybdate ion (which appears to have an absorption maximum around 210 mμ) absorbs strongly in the molybdophosphate absorption region, it is necessary to read the absorption at 380–420 mμ if higher concentrations are to be determined.[197] At the higher wave-length, concentrations of up to 25 p.p.m. of phosphorus still obey Beer's Law. The pH of the solution should lie between 0·5 and 1·2 depending upon the acid used which may be sulphuric, hydrochloric or nitric.[197] The presence of other ions which form heteropoly anions such as silicon, germanium, arsenic and tungsten will cause interference and these must be removed, as must ferric ions which are yellow-coloured (this interference can be minimized by the use of a test solution without added molybdate in the reference cell) and bismuth which causes a change in hue.[197] Ammonium salts are said to reduce the intensity of the colour developed but this does not preclude the use of ammonium molybdate, as the resultant ammonium molybdophosphate is sufficiently soluble to allow its utilization to determine low concentrations of orthophosphate spectrophotometrically or colorimetrically.[198] It has been mentioned that a large excess of molybdate must be present; this has the effect of reducing the sensitivity of the method (the molar extinction coefficients in litres per mole cm. for phosphorus by this procedure are 14,000 at 332 mμ, 2540 at 380 mμ, 1330 at 400 mμ and 750 at 420 mμ). Since at the longer wave-lengths measurement is made on the slope of the absorption curve, the reproducibility must also suffer: for this reason (and because silicon and other elements form heteropoly anions) it is often preferable to use other methods.

The structure of the heteropoly acids is 'open' and can accommodate numerous water or other solvent molecules[199]; thus a molybdophosphate–acetone complex is known and methods have been developed utilizing this fact.[200-1] The absorption maximum for the complex occurs at 320 mμ and, at this wave-length, the molar extinction coefficient in litres per mole cm. for phosphorus is 19,800: the procedure is therefore rather more sensitive than methods based on molybdophosphate alone. Much that has been said before concerning the excess of molybdate which is necessary, applies with equal force to this procedure.

Molybdophosphoric acid may be extracted with many solvents and by this means can be separated from the necessary excess of molybdate ion and also, by choice of solvent and acidity conditions, from other heteropoly-acids. Esters, ketones, aldehydes and ethers are good solvents; carbon disulphide, carbon tetrachloride, chloroform, benzene and toluene are not.[202] Keggin[203] has stated that oxygen-containing liquids are good solvents. Of the esters, *n*-butyl acetate is very selective for molybdophosphoric acid[204]; *iso*-amyl acetate has also been used selectively to extract molybdophosphoric acid from molybdosilicic and molybdoarsenic acids.[196] *n*-Butanol, either alone,[205] or in chloroform,[204, 206-7] is much favoured as an extractant. The selectivity decreases and its sensitivity increases as the concentration of *n*-butanol increases. In 20% v/v butanol/chloroform the molybdophosphoric acid shows an absorption maximum at 310 mμ and the extinction coefficient in litres per mole cm. for phosphorus is 25,400. *iso*-Butanol in chloroform has also been used to extract molybdophosphoric acid from a mixture of molybdoarsenic, molybdosilicic and molybdogermanic acids in 0·14 N. nitric acid solution.[208] Other methods have been described using ethyl acetate,[209] butyl acetate[210-1] and amyl acetate[212] as extractants. In nearly all cases, however, butanol/chloroform is the preferred solvent, the method being of high sensitivity and, with suitable control of conditions, of high selectivity.

Another sensitive method is that of Denigès,[213] based upon the reduction with stannous chloride of the molybdophosphate ion to 'molybdenum blue' (first proposed by Osmond[214]). As well as the papers of general interest[215-7] there are those describing specific applications of the method to the determination of phosphorus as phosphate in blood,[218] phosphorus acids,[219] cerebrospinal fluid,[220] oil,[221] soils,[222] air,[223] soil extracts,[224-5] organophosphorus compounds,[226] sea water,[227] steel (both manually[228] and automatically[229]) and acetylene.[230] Reducing agents other than stannous chloride have been used in some of the subsequent developments of the method: 1-amino-2-naphthol-4-sulphonic acid,[231-40] hydroquinone,[241-8] ascorbic acid,[249-55] hydrazine sulphate,[256-61] *p*-methylaminophenol,[262-9] 2:4-diaminophenol hydrochloride,[270-1] thiourea,[272-4] ferrous,[275-8] sulphite ion,[279] thiosulphate ion,[280] pyrogallol,[281] potassium iodide[282] and *p*-semidine.[283] It is claimed[284] that higher values of molar extinctions are obtained with a number of reductants if *o*-dianisidine molybdate is used instead of ammonium molybdate. A very comprehensive list of reductants, acidity conditions and applications, is given by Jean[285]; there are also other reviews.[286-8] Colourless molybdenum trioxide when partially reduced in strongly acid solution yields an unstable 'blue' which disappears on dilution. A 'blue' colour is reformed and stabilized by the addition of orthophosphate. Several methods are based on this procedure[289-99] and it is claimed[300] that the absence of reducing agents in the final solution leads to a more stable 'blue'. The composition of the reduced molybdophosphate is uncertain; a formula which appears frequently in the literature is $(MoO_2.4MoO_3)_2H_3PO_4$, but it is also claimed that the complex contains two compounds: I, $H_3PO_4.10MoO_3.Mo_2O_5$ and II, $H_3PO_4.8MoO_3.2Mo_2O_5$. (A mixed reducing agent of sodium metabisulphite, sodium sulphite, 1-amino-2-naphthol-4-sulphonic acid and sodium-1-aminonaphthalene-4-sulphonate is claimed to reduce molybdophosphate to $H_3PO_4.10MoO_3.Mo_2O_5$ in 20 min.[301]) The 'blue' has an absorption maximum at 830 mμ with an inflexion at 640 mμ and at 830 mμ the molar extinction in litres per mole cm. for phosphorus is 25,700. The reaction is not specific for phosphorus since other elements which form heteropoly acids with molybdenum also give blue compounds on reduction, as does the molybdate reagent itself. At acid concentrations of the order of 0·35 N. and above, the excess molybdate reagent will not be reduced.[302-5] Where stannous chloride is used as a reductant it is claimed that the presence of potassium chlorate prevents the reduction of excess molybdate reagent.[306-7] Molybdosilicate, molybdoarsenate and molybdophosphate are formed at low acidities[308] and at such acidities all will be reduced. However, having formed the heteropoly compounds, if the acid concentration is then raised sufficiently, only molybdosilicate is reduced. On the other hand, at intermediate acidities only molybdophosphate and molybdoarsenate are formed and may be reduced.[309] Thus by controlling the acidity at the formation and reduction stages some selectivity may be achieved.[310-11] The acidities necessary to achieve this selectivity will vary with the concentration of the molybdate reagent and with the reducing agent chosen, and should be determined for each method.[216, 312-3] The interference of arsenic may be overcome by reducing it to its arsenious condition, in which state it does not form a heteropoly compound[314]; there are also differences in rates of reduction[315-6] and types of reaction with certain reducing agents.[317] Another method of overcoming the interference of other heteropoly compounds is to use complexing agents such as tartaric acid[318] which inhibit the 'moly-blue' complexes of silica and arsenic; these have been discussed in some detail by Jean.[285-6] Extraction with organic solvents followed by measurement of the phosphorus as 'moly-blue' in the aqueous phase has also been used to achieve selectivity.[319-21] The effects of a number of cations and anions on the determination of phosphorus by 'moly-blue' have been discussed[302, 322]: barium, lead, mercury, silver, strontium and zirconium are said to give precipitates; bismuth, cadmium, chromium, copper, iron and zinc are said to form complexes which bleach the colour. Ferric iron interferes by virtue of its oxidizing action and must be reduced.[304, 308, 310, 323] Fluoride inhibits the formation of molybdophosphate[324] and trichloroacetic acid enhances the colour.[325]

Mention should be made of the procedures whereby molybdophosphoric acid is extracted by various solvents and then reduced to the 'blue' which is measured in the organic phase.[326-33] These procedures combine high selectivity with high sensitivity and freedom from element interference. The molar extinction coefficient in litres per mole cm. for phosphorus at 800 mμ is 29,800.

Misson[334] proposed the use of molybdivanadophosphate for the determination of phosphate. The orange-yellow complex is formed when a soluble vanadate, followed by a soluble molybdate, is added to an orthophosphate solution. The complex (formulated $(NH_4)_3PO_4.NH_4VO_3.16MoO_3$ by Misson), is written $P_2(V_2O_5)(Mo_2O_7)_{11}$ by Maksimova and Kozlovskiĭ,[335] but it would appear that the exact nature of the compound is in doubt. The colour is stable for at least 14 days,[336-7] and the method has been used to determine phosphorus in steels,[338-43] iron ores,[336, 344] organic phosphates,[345-7] calcium compounds,[348] fertilizers,[349] vanadic acid,[350] petroleum products,[351] soils,[352] tributyl phosphate,[353] uranium ores,[354] tungsten ores,[355] basic slag[356] and plant substances.[357-8] It is similar to the molybdophosphate procedure in that the absorption maximum occurs where the reagents are absorbing strongly and for this reason measurement of the colour is often made between 400 and 450 mμ on the slope of the absorption curve with a resultant loss in sensitivity and reproducibility. The molar extinction for phosphorus in litres per mole cm. at 420 mμ is 1500. Recent work has shown that the absorption maximum lies between 315 and 340 mμ.[359, 360] The acidity of the solution should lie between 0·2 N. and 1·6 N,; colour development is slower at higher acidities.[337] Sulphuric, nitric, hydrochloric and perchloric acids behave much alike when used in adjusting the acid concentration. The stoicheiometric ratios of vanadate to phosphate and molybdenum to phosphorus are approximately 1 : 1 and 14 : 1[337, 359] respectively and a 50% excess of these reagents should suffice. The vanadate must be added before the molybdate, otherwise the yellow molybdophosphate will be formed (although mixed reagents have been used).[361] Temperature effects have been reported.[343, 362] Ferric salts interfere since in solution they absorb in the same region as the complex; silica interferes in a similar manner by the formation of molybdosilicate. Both interferences may be overcome by a preliminary fuming with perchloric acid; ferric salts are decolorized and silica is rendered insoluble.[336] Ions which complex molybdenum should be removed.[363] Arsenate gives a similar colour to phosphate. The effects of these and other diverse ions have been dealt with in a number of papers,[337, 359] which, together with papers dealing with conditions for the formation of the complex, have been reviewed by Jean.[285-6] One of the most important applications of the method is in the determination of relatively large quantities of phosphate by differential spectrophotometry.[359] In this application the comparatively low sensitivity and high stability are advantageous. The method has been used in an automated procedure.[364]

Molybdivanadophosphoric acid can be extracted into an organic solvent such as *iso*-amyl alcohol[365-7] or methyl *iso*-butyl ketone[368] and in these solvents it has a molar absorptivity similar to that of the complex in aqueous solution. It is possible that such a treatment offers a method of overcoming the interference by coloured ions.

Molybdophosphate has been reduced with benzidine in weakly acid solution to molybdenum blue[369]; in this case the colour is augmented by the formation of benzidine blue. The molar extinction coefficient for phosphorus in litres per mole cm. at 885 mμ is 11,600. In another application benzidine molybdophosphate is precipitated. After filtration, hydrazine sulphate solution is added to the precipitate and, after removal of the benzidine sulphate, molybdenum blue remains.[370]

Hydrazine hydrochloride and ammonium oxalate added to molybdophosphate in ammonium hydroxide solution give a reddish-orange colour which obeys Beer's Law. The colour is attributed to a quadrivalent molybdenum-oxalate complex.[371] $\epsilon_{425\,m\mu}$ is 984 litres mole$^{-1}$ cm.$^{-1}$ for phosphorus.

Strychnine molybdophosphate after dissolution in sodium hydroxide solution has been examined between 350 and 400 mμ.[372] Clearly, the absorption of the molybdophosphate anion is measured. In another application the strychnine molybdophosphate, dissolved in sodium carbonate solution, is reduced with phenylhydrazine and the wine-red colour of the reduced molybdenum measured.[373] $\epsilon_{497\,m\mu}$ is 105,000 litres mole$^{-1}$ cm.$^{-1}$ for phosphorus.

The decrease in intensity of a ferric salicylate complex (measured at 550 mμ) in the presence of phosphate ion is the basis of a method for the determination of phosphorus in soils and non-ferrous metals.[374] $\epsilon_{550\,m\mu}$ is 269 litres mole$^{-1}$ cm.$^{-1}$

Lueck and Boltz[375] describe a method in which molybdophosphoric acid is extracted with an ether/*iso*-butanol mixture followed by a retrograde extraction with a basic buffer solution which results in the decomposition products being transferred to the aqueous phase. The extinction of the basic molybdate solution is then measured at 230 mμ. It is claimed that a value for $\epsilon_{230\,m\mu}$ of 57,400 litres mole$^{-1}$ cm.$^{-1}$ can be achieved. A number of ions were studied for interference effects; of these, arsenate, arsenite, germanate, nitrite and silicate must be absent.

A mixed ammonium molybdate/methylene violet reagent has been used as a precipitating agent to determine phosphate in blood. The precipitate is dissolved in acetone and the deep purple colour compared with standards.[376]

Lanthanum chloranilate reacts with phosphate in a solution buffered at pH 7 to give lanthanum phosphate and release chloranilic acid, the absorption of which is measured at 530 mμ.[377] A value of 269 litres mole$^{-1}$ cm.$^{-1}$ for $\epsilon_{530\,m\mu}$ is given. Wynne, Burdick and Fine remove interfering cations and anions with strongly acidic or basic ion exchange resins before colour development.[378]

A sensitivity far higher than any method so far discussed is claimed for a procedure in which safranine molybdophosphate is extracted with acetophenone and the extinction measured at 532·5 mμ.[379] A value for $\epsilon$ for phosphorus of 190,000 litres per mole cm. at 532·5 mμ is reported. The extraction is quantitative at pH 1·5, but arsenate, arsenite and vanadate interfere. Beer's Law is not followed, hence the molar absorptivity quoted is obviously an average figure. The following values have been obtained in the authors' laboratory; $\epsilon^{-1}{}_{\text{molar}}$ (20°C., 1·24 μg P) = 140,000, $\epsilon^{-1}{}_{\text{molar}}$(25°C, 1·24 μg P) = 115,000 and $\epsilon^{-1}{}_{\text{molar}}$(25°C. 1·55 μg P) = 132,000.

### NEPHELOMETRIC AND TURBIDIMETRIC

A number of nephelometric[380-6] and turbidimetric[387-9] methods have been described. They all depend upon the formation in acid solution of molybdophosphates of alkaloids such as strychnine. A comparison of the respective merits of colorimetric and nephelometric methods of determining phosphate has been made.[390]

### ION EXCHANGE SEPARATIONS

Some phosphatic minerals can be brought into solution by agitating their aqueous suspensions with a cation exchange resin in its 'acid' form. By this treatment the cations are held on the resin and the orthophosphate anion is liberated as orthophosphoric acid. After removal of the resin by filtration the acid can be titrated with alkali.[391-3] Other materials require prior treatment with acid to effect solution, in which case the acid solution is passed down an exchange column and, after neutralization of the dissolving acid, the phosphoric acid is titrated between pH 4·6 and pH 9.[394-404] It is said that ferric ion should first be reduced to the ferrous state.[405] Vanadium should also be reduced.[406-7] It must be noted that the method is rarely as simple as this description would suggest. Many minerals require an alkali fusion to effect solution; others leave siliceous residues which after removal of the silica with hydrofluoric acid also require a fusion to dissolve the metal oxides remaining. In these cases the ion exchange column has to be increased in size to accommodate the extra sodium or potassium ion, greatly extending the time required for an analysis. Also the large quantity of acid other than phosphoric has to be neutralized, thus causing a marked salt effect on the end-point in the final titration. Other anions which would titrate have to be removed.[408] In general, if all the precautions are taken to obtain a result of reasonable accuracy, the time required is much greater than is required by other more precise methods. It must, however, be conceded that these ion-exchange methods might be useful where only moderate accuracy is required.

### RADIOMETRIC

Phosphorus in a material can be very accurately determined by irradiating a sample together with a known standard in the same flux density for the same time. The specific activities induced by the reaction $^{31}P(n, \gamma)^{32}P$ will be the same, so a comparison of activities will allow a determination of the mass of phosphorus in the sample.[409-20] After conversion of the phosphorus in the sample to orthophosphate by hydrolysis and/or oxidation, inactive phosphate is added as a carrier and the orthophosphate is isolated in a suitable form. After filtration and drying the activity is counted by means of a Geiger–Müller tube with associated apparatus, or by means of a scintillation counter. The method is sensitive, specific and independent of impurities in the reagents. In those cases where a prior separation is not necessary it can be non-destructive and is very rapid. On the other hand, there are limitations to the size of sample, since a measure of self-shielding may occur, or the sample may be larger than the region of highest flux. Heating may occur, necessitating the sealing of some samples. Side reactions may happen (e.g. $^{32}S(n,p)^{32}P$) while impurities in the reference standard may be disadvantageous to the use of the technique.

Isotope dilution analysis is a versatile method and depends on the determination of specific activity. A mass of active phosphate (or active precipitant) of known specific activity is added to an unknown mass of inactive phosphate. After equilibrating, a small portion of pure orthophosphate is isolated; the specific activity is measured and the phosphorus content of the unknown sample determined.[421-3] A variant of this method is one in which a sub-stoicheiometric amount of inactive precipitant is added to a solution containing inactive phosphorus and a known amount of active phosphorus. After removal of the precipitate the residual activity is counted.[424]

Active phosphorus ($^{32}_{15}P$) has been used to enable separated spots on chromatograms to be detected and the quantity of phosphate present to be determined by counting the activity of the spots.[425-7]

Use has been made of active phosphate as a tracer to study the efficiencies of gravimetric methods of determining and removing phosphate.[428-30]

Finally, mention should be made of radiochemical methods of tracing phosphorus in plant material.[431-4]

### ELECTROMETRIC

Many of the titrimetric methods discussed in a previous section can be performed potentiometrically, using various electrode systems in place of indicators. These methods include the titration of orthophosphoric acid and its salts with alkali or lime,[93, 435-7] precipitation of quinoline[438] or ammonium[439] molybdophosphate or magnesium ammonium phosphate,[440] followed by acid–alkali titration of the filtered precipitate. There are many other possible applications of the technique. This finish is particularly advantageous when dealing with coloured solutions, or when salt and/or solvent effects decrease the rate of change of pH (or e.m.f.) with titrant addition. In these cases it is difficult to detect end points with indicators. In general pH curves give more information than is obtainable by indicator titrations, as for instance when titrating dialkyl phosphates the presence of an inflexion on the pH curve before that due to the di-compound indicates the presence of monoalkyl phosphate.

Polarized bimetallic electrode systems and platinum indicator electrodes have been used to determine end points in the redox titration of the molybdenum content of molybdophosphate with titanous sulphate solution.[441] Platinum–calomel electrode combinations have been used in a similar procedure where stannous chloride solution has been used as the titrant.[442]

Potentiometric precipitation titrations have had their advocates; the excess of mercurous nitrate (following the precipitation of the phosphate) has been titrated potentiometrically with sodium oxalate solution.[443] Phosphate ion has also been titrated potentiometrically with mercuric nitrate solution[444] and with lead acetate solution.[445] Mention should also be made of the use of the silver electrode and silver/silver chloride reference electrode in argentometric titrations.[446-7] Lévy[448-9] used a system in which the e.m.f. of the titration cell is opposed to that of a potentiometer standardized to the e.m.f. of a reference cell containing the same ions. At the equivalence point the titration cell has the same potential as the reference cell.

A number of amperometric methods have been developed for the determination of phosphate. In these methods the decrease and/or increase of a polarographic wave, following the addition of titrant, is used to plot titration curves. In one of these methods molybdophosphate is extracted with *iso*-butanol, and after reduction with zinc amalgam, the molybdenum content is determined by titration with ferric chloride solution.[450] Direct amperometric titrations of phosphate have been made with ferrous ammonium sulphate,[451-2] uranyl acetate,[453-4] bismuth nitrate,[455] vanadyl sulphate,[456] and lead acetate solutions.[457] A method has been described in which a solution of hydroxyquinoline and ammonium molybdate is titrated amperometrically with phosphate solution.[458]

There are methods in which phosphorus is precipitated as metal phosphates or complex phosphates, and either the excess of precipitant or the metal content of the precipitate or the complex itself is determined polarographically by measurement of the wave height, thus affording an indirect measurement of phosphate content. These polarographic methods include the measurement of the wave height of the quinoline molybdophosphate complex,[459] the determination of the molybdenum content of molybdophosphate[460-1] and the determination of the excess of molybdate following the precipitation of molybdophosphate.[462-3] Finally, mention should be made of the polarographic determination of bismuth in bismuth phosphate[464] and excess of lead acetate following the precipitation of lead phosphate.[465]

Conductimetric titration techniques have also been used to determine end points as in the titration of phosphate with uranyl nitrate,[466] sodium hydroxide[467] and bismuth nitrate[468] solutions. Two interesting applications of this technique are the determination of both the 'ammonia' and 'phosphoric acid' contents of fertilizers by conductimetric titration of a single sample with sodium hydroxide solution[469] and the titration of phosphoric acid with bismuthyl perchlorate solution.[470] This last application is carried out in perchloric acid solution and it is claimed that good results are obtained in solutions containing magnesium, calcium, copper, zinc, nickel, ferrous iron, manganese, aluminium, small amounts of ferric iron, nitrate, chloride and silica.

High frequency titrations do not seem to have received much attention for phosphate titrations and one worker has reported peculiar results by this technique.[471]

Coulometric methods have been used to titrate molybdophosphate[472] and quinoline molybdophosphate[473] with electrolytically produced hydroxyl ions. The molybdenum content of molybdophosphate has also been determined coulometrically.[474]

## Condensed Phosphates

### GRAVIMETRIC

Pyrophosphate can be determined in the presence of orthophosphate by precipitation of barium phosphate, $Ba_3(PO_4)_2$, and barium pyrophosphate, $Ba_2P_2O_7$, with barium hydroxide solution.[475] The amount of precipitant consumed is determined by precipitating and weighing the excess of barium as barium sulphate. The total phosphorus is then estimated by an alternative procedure. From the two results the pyro content can be calculated. However, ortho, pyro, and triphosphate are incompletely precipitated by the barium ion; only the higher linear phosphates are precipitated quantitatively. This fact is used to determine cyclic metaphosphates in the presence of higher linear phosphates after removal of the lower linear polymers by anion-exchange chromatography.[476] Zinc pyrophosphate may be quantitatively precipitated at a pH of 3·8 from solutions containing ortho- and tri-phosphate.[477-9] The precipitation is said to be quantitative in the presence of triphosphate only if the ratio of pyrophosphate to triphosphate is $>1:9$ and the precipitate is allowed to stand for 12 hours, but accurate results are readily obtained when orthophosphate is the only other constituent.[480]

The barium and zinc precipitates are not particularly amenable to direct weighing and better precipitants for quantitative determination are the halide or nitrate salts of the hexammine cobalt complex. Pyrophosphate may be weighed as hexamminecobalt(III) monosodium pyrophosphate, $[Co(NH_3)_6]NaP_2O_7$, after precipitation from cold 5% ammoniacal solution.[481] Ortho, pyro and triphosphate may be determined as hexamminecobalt(III) phosphate tetrahydrate $[CO(NH_3)_6]PO_4,4H_2O$, precipitated at pH 12·3, hexamminecobalt(III) monohydrogen pyrophosphate $[Co(NH_3)_6]HP_2O_7$, precipitated at pH 7·9 and sodium hexamminecobalt(III) triphosphate $[Co(NH_3)_6]Na(P_3O_{10})_2$, precipitated at pH 7·9, with a claimed precision of ±2·5% for single components.[482] The formulae hexamminecobalt(III) monohydrogen phosphate $[Co(NH_3)_6]_2(HPO_4)_3$, precipitated at pH 11·8, and hexamminecobalt(III) dihydrogen triphosphate $[Co(NH_3)_6]H_2P_3O_{10}$, precipitated at pH 8·3–8·6, have also been quoted, [483] using similar precipitation and drying conditions. Tris(ethylenediamine) cobalt bromide has also been used as a precipitant for pyro- and tri-phosphate, forming tris(ethylenediamine) cobalt(III) monohydrogen pyrophosphate dihydrate $[Co(en)_3]HP_2O_7,2H_2O$ at pH 6·5–6·7 and tris(ethylenediamine) cobalt(III) dihydrogen triphosphate dihydrate $[Co(en)_3]H_2P_3O_{10},2H_2O$ at pH 3·4–3·5.[484] Tris(ethylenediamine) cobalt(III) chloride has been used as a selective precipitant for triphosphate [485] which is precipitated at pH 3·5; pyrophosphate does not interfere. At pH 6·5 pyrophosphate is precipitated with no interference from triphosphate. In neither determination is orthophosphate or trimetaphosphate precipitated. Weiser[486] maintains that the triphosphate precipitate may co-precipitate some pyrophosphate; a compensating method is suggested for overcoming this interference.

Benzidine is a non-specific reagent and will precipitate all phosphates. It has been used as a precipitant for long chain phosphates[487] after prior removal of the lower phosphates. Partial selective separations of condensed phosphates may be achieved using other amines dissolved in acetic acid solution: aniline, *p*-phenylenediamine, *m*-phenylenediamine, *m*-tolylenediamine, phenylhydrazine and piperazine precipitate only linear phosphates of fairly long chain; 2-naphthylamine will precipitate all phosphates except trimetaphosphate; and diaminobenzidine and *o*-tolidine will precipitate all phosphates except orthophosphate and trimetaphosphate.[488–9]

### VOLUMETRIC

The gravimetric methods using the zinc or barium ion as precipitants have, as in orthophosphate analysis, their counterparts in volumetry. Excess of barium hydroxide may be determined by simple acidimetric titration[475]; this rapid method is to be preferred to the gravimetric barium sulphate finish. The sulphuric acid liberated when zinc pyrophosphate is precipitated with zinc sulphate may be titrated with alkali using bromophenol blue as indicator[490] or electrometrically[478]; prior adjustment to the bromophenol blue end point with acid or alkali is necessary. Better recovery figures have been obtained for pyrophosphate by titrating to pH 3·8 both before and after adding the zinc sulphate solution[479]; sodium chloride, sodium sulphate, sodium perborate and sodium silicate, common constituents of detergents, were shown not to interfere but quinhydrone must be added when peroxy compounds are present.[491] Pyrophosphate may be determined in the absence of other phosphates by the addition of barium chloride solution at pH 4 and subsequent titration with alkali of the liberated hydrion.[480] The precipitate formed is claimed to be

$$Ba_2P_2O_7.Ba_{1.5}HP_2O_7,3H_2O.$$[492]

The precipitation of heavy metal phosphates is essential at some stage in all the titrimetric methods of determining mixtures of condensed phosphates. Dworzak and Reich-Rohrwig[493] determined pyrophosphate in the presence of orthophosphate by titration with uranyl acetate solution, a permanent precipitate due to orthophosphate being produced with excess of the reagent.

The above method is long (6 hr.) and somewhat empirical; Nielsch and Giefer[494] in much later work precipitated manganese pyrophosphate at pH 4·1, dissolved the filtered precipitate in a solution of the disodium salt of EDTA and titrated the excess of manganese chloride with zinc sulphate solution. Recent papers describe methods based on the precipitation of zinc[495–6] and calcium pyrophosphates.[495]

Whilst several methods exist for estimating mixtures of condensed phosphates[497–8] good accuracy is difficult to achieve, particularly where one or more of the constituents is obtained by difference. Chromatography (q.v.) has shown that there can be twenty or more constituents in a phosphate glass so that when using older 'wet' methods on this type of sample results should be interpreted with caution. Ortho-, pyro- and meta- phosphoric acids have been estimated by Aoyama[499] by first precipitating the silver salts in neutral solution, measuring the excess of silver nitrate solution by a Volhard titration, then removing the silver with hydrogen sulphide. The free acids left are titrated to both methyl orange and phenolphthalein, with sodium hydroxide solution. This method was criticized and a modified procedure suggested,[493] but further work by Aoyama[500] verified his own method. Another procedure[501] omits the silver sulphide precipitation stage but titrates the hydrogen ion liberated when silver phosphate is precipitated. However, the indicator colour match required by this method is tedious, requiring the construction of a nomograph curve, but an allowance can be made for the presence of any strong mineral acids. Brown[502] discusses the analysis of commercial mixtures of the three acids.

The presence of linear phosphates in mixtures adds greatly to the difficulty of making an accurate analysis. Jones[503] has developed a volumetric method, based upon the precipitation of barium and manganese salts, which gives a total linear phosphate figure but unless the linear phosphate content is small compared with the pyrophosphate content the manganese pyrophosphate precipitate may not be quantitative owing to the complexing action of the linear phosphate. An extension of this method for the analysis of Graham's salt has also been described.[504] An improved method developed by Raistrick *et al.*[487] for the analysis of commercial sodium triphosphate combines volumetric and gravimetric procedures. Zinc pyrophosphate and zinc sodium triphosphate are quantitatively precipitated and the zinc content of the precipitate determined by oxine, thus enabling the amounts of the two constituents of the precipitate to be calculated. The filtrate from the zinc pyrophosphate and zinc sodium triphosphate precipitation, which contains orthophosphate and trimetaphosphate, is boiled with sulphuric acid to ensure hydrolysis and the total orthophosphate determined. Phosphate glass is estimated using benzidine and a separate total orthophosphate determination is carried out. It is suggested that the zinc precipitate is not of theoretical composition and a standard curve using pure materials be used[505]; the determination of the zinc using an EDTA titration is also preferred. Akiyama *et al.*[506] also suggest quantitative precipitation of triphosphate and pyrophosphate with zinc ion followed by an EDTA titration of the zinc triphosphate precipitate dissolved in ammonia.

A somewhat empirical method for the determination of 'sodium hexametaphosphate' is described[507] in which a precipitate formed with calcium chloride solution redissolves on the addition of more calcium chloride solution. The end point is the point at which any cloudiness has disappeared; the reactants must be kept at pH 7.

Thermometric techniques have been applied to the volumetric analysis of mixtures of ortho-, pyro- and 'meta-' phosphoric acids.[508] One advantage claimed is that neutralization may be carried out at low temperatures, so avoiding any hydrolysis.

Sodium triphosphate hydrolyzes in 1% sodium hydroxide solution in 60 hr. to give equimolar quantities of ortho- and pyro-phosphates[509]:

$$Na_5P_3O_{10} + 2NaOH \rightarrow Na_4P_2O_7 + Na_3PO_4 + H_2O$$

This reaction has been made the basis of a method using boiling 10–20% sodium hydroxide solution to raise the temperature and hence increase the speed of the reaction. The original orthophosphate is first determined, then the total phosphate, and finally the orthophosphate after hydrolysis.[510]

Acid hydrolysis is an effective method of determining the average chain length of a condensed phosphate sample. It is claimed to compare well with ion exchange methods.[511]

### SPECTROPHOTOMETRIC

Clearly, all condensed phosphates can be determined by a prior hydrolysis to orthophosphate followed by a spectrophotometric finish. This technique is used when a particular species has been isolated, for example by paper or ion exchange chromatography. It also may be used to determine total condensed phosphates in orthophosphates by solvent extraction of the orthophosphate as the molybdophosphate complex[204] and then determining the total condensed phosphates in the aqueous layer.

The complexing effect of sodium pyrophosphate and sodium triphosphate on the ferric ion has been made the basis of a method.[512] The optical density of ferric thiocyanate solution is reduced by both the compounds, but by measuring the decrease at two pH values the proportion of each is found. No large excess of either of the components should be present. The complexing effect of pyrophosphate on the 1:10 phenanthroline ferrous complex is used[513] to determine less than 1% of pyrophosphate in the presence of orthophosphate. Kolloff *et al.*[514] have determined 0·01% of pyrophosphate in orthophosphate using the ferric thiocyanate procedure. Interference may be expected from those ions which normally interfere in the thiocyanate procedure for iron. The ability of various condensed phosphates to form complexes with ferric ion has been the subject of a spectrophotometric study.[515]

### TURBIDIMETRIC

Long chain (glassy) phosphates in detergent mixtures, it is claimed, may be determined by a turbidimetric procedure. After removal of any peroxy compounds or anionic surfactants, an acetic acid solution of the sample is caused to react with *o*-tolidine and the turbidity measured at 425 mμ.[516]

### CHROMATOGRAPHIC SEPARATIONS

Chromatographic methods (paper, ion-exchange and thin-layer chromatography) have superseded nearly all 'wet' methods of condensed phosphate analysis by virtue of speed, accuracy and, particularly by using ion-exchange techniques, the ability to resolve complex mixtures.

#### *Paper*

Following earlier qualitative work[517–9] on the separation by one-dimensional paper chromatography of some of the components of a mixture of orthophosphate, pyrophosphate, triphosphate, trimetaphosphate and tetrametaphosphate, Ebel and Volmar,[520] by using two-dimensional techniques employing both an acidic and a basic solvent, separated such a mixture with the addition of hexametaphosphate. These workers showed that the cyclic and linear phosphates occupied distinct positions and within each group the $R_f$ values are a function of the molecular weight. These separations were applied quantitatively[521]; a typical basic solvent mixture for the first development contains ammonia, *iso*-propanol, *iso*-butanol and water. After drying, further separation is obtained in the second dimension with the acidic solvent, typically *iso*-propanol, water and trichloroacetic acid. The individual species are cut from the paper after being rendered visible, are wet-oxidized and the orthophosphate determined colorimetrically. The bands (from streak application) or spots, after being hydrolyzed *in situ* with acid molybdate, followed by reduction with stannous chloride or hydrogen sulphide, may be eluted sequentially from the paper and the phosphorus determined colorimetrically.[522] A third method, applied to the determination of small amounts of orthophosphate in triphosphate mixtures[523] is to leach the spot from the paper with water prior to colorimetry.

Cellulose column chromatography has been successfully applied to the separation of linear from cyclic phosphates using either acidic or basic solvents.[524]

Orthophosphates and eight condensed phosphates have been determined[525] by techniques based on methods developed by Grunze and Thilo,[526–7] who themselves used modifications of the methods of Ebel *et al.*[520] Variables affecting the separation of condensed phosphates have been studied[528] using an ascending technique, deliberate variation of solvent serving to identify higher polymers. Small amounts of the ammonium cation are necessary in solvent systems containing water, trichloroacetic acid and *iso*-propanol. This may be replaced by other bases, and the number of components separated decreases and the extent of the separation increases with increasing amounts or strength of base.[529] Breakdown of the paper with perchloric acid prior to colorimetry has been used,[530] the suggested amount of sample per spot containing 70–100 μg. of phosphorus.

The densitometer has been applied to the quantitative evaluation of the spot after spraying: ortho- and pyro-phosphate have been determined to ±2%[531] in binary mixtures, whilst results on mixtures of condensed phosphates give good agreement with elution methods.[532] It is normally considered that only unidimensional chromatograms are suitable for quantitative evaluation with this type of machine. For these the sample is applied in the form of a uniform streak across a paper strip. The concentration of component will then vary only in the direction of development and not in the direction of the streak. With streak traces, it can be seen that providing the scanning slot is narrow enough to allow discrimination of traces, and long enough to even out irregularities in the surface or in the component concentration, then its size is not critical. On the other hand for spot form traces, the aperture must be longer than the widest trace, as the concentration of component is varying in two dimensions. It can be shown that for such spot form traces reproducible calibration curves cannot be obtained. Consider such an amount of sample that will reduce the incident light falling on it by 50%, and let it be in the form of a strip of length $b$

and width $a$. Let the scanning aperture be of the same dimensions. If now the sample is concentrated into an area of length $b/2$ and width $a$, the total transmission will be 12½% due to the sample plus the 50% transmitted where there is no sample, giving a total of 62½%. Thus the smaller is the sample area the less will be the integrated counts even though the amount of sample remains constant. The preparation of reproducible calibration curves thus appears impossible, and work in the authors' laboratory has verified this.

One way out of this difficulty of calibration is to scan the spot with an aperture several times smaller than the smallest spot (the multiple scanning technique). It can be shown that this method, theoretically, gives reproducible calibration curves.

The use of mineral acids to adjust the acidity of solvents should be avoided in order to prevent hydrolysis[521] and where the separation may take several hours, as in the analysis of phosphate glasses,[533] a reduced temperature of 4°C. is recommended.[534] If this is not practicable a correction procedure may be applied.[535] To estimate the average chain length of very long chain phosphates, up to 5000, a diluted Ebel's[521] reagent is used.[536]

Specific applications of quantitative paper chromatography include the analysis of simple and condensed phosphates in water treatment plants,[537] the analysis of commercial sodium triphosphate and detergents,[535] the analysis of phosphate glasses,[538] the determination of condensed phosphates in rat urine[539] and in sausage meat,[540, 541] and the determination of less than 0·1% of pyrophosphate in orthophosphate.[542] A general review is given by Hettler.[543] A paper impregnation method is described by Kiełczewski in which sodium pyrophosphate may be determined in the presence of sodium orthophosphate. The sample solution forms a white spot on copper ferrocyanide-treated paper, the area of which increases linearly with the amount of pyrophosphate present.[544]

### *Ion-Exchange*

Beukenkamp, Rieman and Lindenbaum[545] showed both theoretically and practically that good buffering is necessary in order to separate ortho-, pyro- and triphosphate on anion exchange resins. The buffering should be in the pH range of 5·0–7·0. The ion exchange equilibria may be represented[546]:

$$\begin{aligned}
2RCl + HPO_4^{2-} &\leftrightharpoons R_2HPO_4 + 2Cl^- \\
2RCl + H_2P_2O_7^{2-} &\leftrightharpoons R_2H_2P_2O_7 + 2Cl^- \\
2RCl + H_3P_3O_{10}^{2-} &\leftrightharpoons R_2H_3P_3O_{10} + 2Cl^-
\end{aligned}$$

So that the concentration of each species leaving the column shall be approximately constant, it was suggested that three buffer solutions be used, each increasing in potassium chloride strength.[547] Ortho-, pyro-, tri-, tetrameta- and trimeta-phosphates were separated in this order with this technique, using potassium acetate/acetic acid buffer at pH 5·0 and Dowex 1 × 10 ion exchange resin. Ammonia/ammonium chloride is also an effective buffer and again using various concentrations of potassium chloride tri-, tetra-, trimeta- and tetrameta- were separated.[548] The use of gradient elution has eliminated the need for several elutant solutions. A closed mixing bottle containing 0·1 M. potassium chloride buffered at pH 5·0 is connected to a reservoir containing 1 M. potassium chloride buffered to pH 5·0. The column is fed from the mixing bottle and the concentration of the eluate at time $t$ may be calculated from the equation:

$$\log \frac{(M_1 - M_2 - M)}{M_1} - \frac{v}{2{\cdot}303\,V}$$

where $M_1$ = molarity in reservoir, $M_2$ = molarity in mixing bottle, $M$ = molarity of eluant entering the column, $V$ = volume of solution in mixing bottle and $v$ = total volume of eluate. Mixtures containing only ortho-, pyro- and tri-phosphate are best separated with water initially in the mixing bottle.[549] By using smaller resin particles (200–400 mesh size instead of the usual 100–200 mesh size) the efficiency of separation may be increased, but this requires the use of a pressure head at the column inlet for a reasonable flow rate to be maintained.[550] Complete separation of species up to heptaphosphate is claimed[551] whilst the use of anion exchange resins to separate species up to undecaphosphate is suggested.[552]

Later workers have separated the linear polymers up to tridecaphosphate and three cyclic polymers; evidence is also given that the linear polymers are eluted in the order of their increasing degree of polymerization.[553] Commercial sodium triphosphate is analyzed for ortho-, pyro-, and tri-phosphate[546] and also for trimetaphosphate[554]; in each case the fractions are hydrolyzed with sulphuric acid and the resulting orthophosphate determined colorimetrically. Sodium triphosphate has also been analyzed by a reverse flow ion exchange method, the phosphate species being fractionated on a resin column with a pressurized, continuous gradient, and then eluted by reverse eluant flow.[555] Pyrophosphate, below 0·2% by weight in orthophosphate, may be determined by eluting the orthophosphate from the column with a 0·05 M. hydrochloric acid/0·1 M. potassium chloride solution, followed by a molar potassium chloride solution to elute the pyrophosphate.[556] Pyrophosphate may also be determined in bone tissue by a similar technique.[557]

The Technicon AutoAnalyser has been applied to the determination of total phosphate in the column eluate, each species being represented as a Gaussian peak on a recorder chart, the area of which is proportional to the concentration of the species in the sample.[558]

### RADIOMETRIC

The pyrophosphate and triphosphate content of commercial sodium triphosphate may be determined by isotope dilution, since both sodium pyrophosphate and triphosphate may be prepared from the mixture in a high state of purity. A determination requires 1–3 days to complete (using 2–4 man hours) so is unlikely to compete with chromatographic methods; however, it is a useful method.[559] The technique has also been applied to the study of the tris(ethylenediamine)cobalt(III) pyrophosphate precipitate.[486] Orthophosphate containing $^{32}P$ has been used to confirm the absence of orthophosphate contamination of the pyrophosphate eluted from an anion exchange column.[557] Migrations of several condensed phosphate species labelled with $^{32}P$ have been followed both on paper chromatograms and on electrophorograms.[560] Quantitative comparisons of the different amounts of the constituents of phosphate glass, resulting from heating $Na_2HPO_4$ and $NaH_2PO_4$, both labelled with $^{32}P$, have been made by measuring the activity of each spot on the chromatogram; a sensitivity down to $10^{-9}$ g. of phosphorus is claimed.[561]

### ELECTROMETRIC

Orthophosphate may be titrated amperometrically in perchloric acid solution with bismuthyl perchlorate solution as titrant.[562] This finish has been applied to the determination of trimetaphosphate in the presence of orthophosphate, pyrophosphate, or tripolyphosphate after prior separation of the trimetaphosphate with barium perchlorate solution.[563]

Hexamminecobalt(III) chloride may be used as an amperometric titrant for determining pyrophosphate in the presence of orthophosphate.[564] The dropping mercury electrode is used as the indicator electrode, with sodium nitrate added as the supporting electrolyte. When the pyrophosphate content is small, alcohol is added to reduce the solubility of the hexamminecobalt(III) monosodium pyrophosphate, $[Co(NH_3)_6]NaP_2O_7$, precipitate. Triphosphate and hypophosphite do not give a precipitate but hypophosphate does. 'Glassy' phosphates also interfere by preventing the precipitation of the pyrophosphate. A similar method, using hexaureachromium(III) chloride, $[Cr(CON_2H_4)_6]Cl_3$, as titrant has also been used.[565–6] Sodium dihydrogen phosphate, disodium hydrogen phosphate, sodium metaphosphate and sodium pyrophosphate have been titrated potentiometrically at 350°C. with sodium peroxide in molten potassium nitrate. An oxygen electrode is used as indicator and the Ag/Ag$^+$ electrode as reference. The average error claimed is ±2% for the mixture of the four compounds.[567]

## Reduced Phosphates

### GRAVIMETRIC

Silver hypophosphate, $Ag_4P_2O_6$, is precipitated from acid solution containing up to 0·5 M. nitric acid; to prevent any possible reduction of the silver nitrate by other reducing oxy-anions of phosphorus present, Palmer[568] has suggested the prior precipitation of zinc hypophosphate in M. sodium acetate solution. This separates hypophosphate from phosphite and hypophosphite, separation from any phosphates then being achieved by dissolution in nitric acid followed by precipitation of silver hypophosphate. The precipitate is filtered, dried and weighed.

Excess of mercuric chloride solution will quantitatively oxidize, in 3 hr., the hypophosphite ion producing a stoicheiometric amount of mercurous chloride which is filtered off, dried and weighed. This method was recommended for the assay of pharmacopœial sodium hypophosphite,[569] but Bond[570] found that the method was unsatisfactory. Hypophosphite is also claimed to precipitate silver quantitatively from silver nitrate solution containing nitric acid, and has been determined in mixtures with phosphate and glycerophosphate using this technique.[571] These indirect gravimetric methods are not, however, to be recommended, owing to the ease with which volumetric methods may be applied.

### VOLUMETRIC

Hypophosphate can be determined in mixtures of orthophosphate and phosphite by the precipitation of silver hypophosphate at pH 1–2.[572] The precipitate is filtered off and the excess of silver in the filtrate titrated with potassium thiocyanate solution by the method of Volhard. It is claimed that at pH 1–2 the reducing action of any hypophosphite is negligible.

Whilst phosphorous, hypophosphorous and hypophosphoric acids may be titrated easily with alkali – or their sodium salts titrated with acid – in mixtures, end points are difficult to distinguish, and also phosphoric acid, if present, would be titrated. Therefore redox titrations are invariably employed.

In a neutral solution of the three acids, only phosphorous acid is oxidized by an excess of iodine solution; oxidation is complete and quantitative in one hour.[573–5] Hypophosphorous acid may be determined, together with phosphorous acid, by iodine oxidation under acid conditions. Oxidation is said to be complete in 10 hours,[574] but improved methods[575–6] reduce this time to 3 hours. Excess of iodine may be determined by arsenious acid solution or sodium thiosulphate solution. A bromine/potassium bromide solution may also be used to determine phosphorous acid either by titration of the excess of the reagent[577–8] or titration of the orthophosphoric acid formed during the oxidation.[579] A combination of these two methods has been used to determine mixtures of phosphorous and hypophosphorous acids.[577] Hypophosphites used in pharmaceutical preparations have been determined using bromine oxidation methods, excess of bromine being determined by the addition of potassium iodide and titration of the liberated iodine with sodium thiosulphate solution using starch as indicator.[580–2] Whereas bromine will oxidize hypophosphite and phosphite in strongly acid solution (the kinetics of which have been discussed by Griffith and McKeown[583]), hypophosphate is quantitatively oxidized only within the range pH 6–9, the maximum oxidation rate occurring at pH 7·7.[568]

Hypophosphorous, phosphorous and hypophosphoric acids are quantitatively oxidized at the boiling point in acidified potassium permanganate solution. Hypophosphorous and phosphorous acids have been determined in this way, the excess of potassium permanganate remaining after 25 minutes oxidation being titrated with oxalic acid solution.[584] Using ammonium molybdate as catalyst Schwicker[585] found that the oxidation of hypophosphite may be accomplished at 50°C. in 30 min. In boiling neutral solution hypophosphite, whilst still oxidized quantitatively to phosphate, only reduces the permanganate to manganese dioxide, which can be filtered off prior to the determination of the excess of permanganate.[586] This method has been criticized[587] owing to the probable reduction of some of the permanganate on boiling. The reduced acids in red phosphorus have been determined by extracting the phosphorous acids with boiling hydrochloric acid, neutralizing to methyl orange and boiling this solution with potassium permanganate. Excess of potassium permanganate is determined by the addition of potassium iodide and hydrochloric acid and titration of the iodine liberated with sodium thiosulphate solution.[588] Permanganate is reduced by hypophosphites or phosphites in alkaline solution first to manganate, then to manganese dioxide. The first stage is complete after one minute at room temperature when complete conversion to phosphate occurs. The second stage is slow and it is necessary to boil the solution. Normally the excess of permanganate cannot be titrated after the first stage; otherwise the manganate would also be titrated, but if a barium salt is added then insoluble barium manganate is precipitated and the excess of permanganate may be titrated (using a formate titration) without interference.[589] Heredia[590] has confirmed this method but he prefers to back-titrate the excess permanganate using sodium oxalate solution.

Other oxidants may be used to convert the reduced phosphate to orthophosphate. Both phosphorous and hypophosphorous acids are oxidized by iodic acid in sulphuric acid solution; the iodine liberated is distilled off and absorbed in potassium iodide solution[591] or the excess potassium iodate determined.[591–2] Phosphorous and hypophosphorous acids are also oxidized in acidified, boiling (under reflux), potassium dichromate solution. Oxidation is complete in 1 hr. and the excess of potassium dichromate is determined by the addition of potassium iodide and titration of the liberated iodine.[593]

Cerium$^{IV}$ will oxidize hypophosphite to phosphite in sulphuric acid solution in 1·5 hr. at 20°C. or in 0·5 hr. at 60°C. In excess of boiling cerium(IV) both phosphite and hypophosphite are oxidized to phosphate. Bernhart[594] estimated both hypophosphite and phosphite in mixtures of the two by applying both these reactions. The addition of silver sulphate as catalyst is said to make the oxidation of both hypophosphite[595] and phosphite[596] take place more smoothly, and at steam bath temperatures.

Hypophosphite is quantitatively oxidized to phosphite by titration with ferric ammonium sulphate, the excess of which is estimated by titration with standard ceric sulphate solution [597] or sodium vanadate.[598] This reaction has been applied to the determination of hypophosphite in nickel plating electrolytes.[599] Palladium chloride is claimed to catalyze the further oxidation with ferric ion of phosphorous to phosphoric acid; the reaction is complete in ten minutes on the steam bath using 100% excess of ferric ammonium sulphate solution.[600] Both silver and manganous ions have also been used as catalysts, hypophosphite requiring 7 min., and phosphite 10 min. at 100°C. for complete oxidation.[601]

The hypophosphite content of electroless plating solutions has been determined by catalytic oxidation to phosphorous acid and hydrogen, using a catalyst prepared by successively plating silver and palladium on to a copper gauze. In the plating solution the palladium black becomes coated with nickel, so that the activity of the catalyst is then constant, and hydrogen is produced in an amount proportional to the concentration of hypophosphite. The hydrogen is burnt at a jet and the flame temperature measured using a thermocouple and recorder.[602]

### SPECTROPHOTOMETRIC

Ammonium molybdate in sulphurous acid solution forms a blue colour with hypophosphites but not phosphites.[603] The intensity of this colour is read at 470 mμ against a blank, and the percentage of hypophosphite read from a calibration curve; 470 mμ is an absorption minimum, chosen deliberately to reduce the sensitivity; measuring at 680 mμ gives much greater sensitivity. Phosphate interferes in the method but may be determined separately by the molybdovanadophosphoric acid method. Boiling ammonium molybdate solution is also reduced by the hypophosphite ion to give a blue colour; phosphate interferes but is removed by precipitation as magnesium ammonium phosphate.[598]

The reagent of Lucena-Conde and Pratt[297] contains molybdenum(VI) and molybdenum(V) in molar ratio 3 : 2, in 10 N. sulphuric acid together with 3 N. hydrochloric acid. At room temperature this reagent forms a blue colour with hypophosphoric acid with absorption maxima at 590 mμ and 670 mμ.[604] Hypophosphorous and phosphorous acids do not form a coloured complex, whilst moderate amounts of orthophosphate can be tolerated.

Sodium hypophosphite has been determined in electroless plating solutions by the decolorizing effect of the hypophosphite ion on methyl orange, the decolorization time being in inverse proportion to the amount of hypophosphite in the solution. Ferric iron and aluminium cause serious interference.[618]

## CHROMATOGRAPHIC SEPARATIONS

### *Paper*

Whilst several workers have separated mixtures of reduced phosphates by paper chromatography,[605–10] little attempt has been made to adapt the methods quantitatively; presumably once a reduced phosphate has been identified, a volumetric method applied to the original mixture is quicker and gives greater accuracy. Chromatographic separations are necessary where other oxidizable compounds are present which would interfere in the oxidimetric methods. Any of the quantitative finishes described for the paper chromatography of the condensed phosphates (*q.v.*) may be applied, provided that the reduced phosphate is first oxidized with nitric acid and bromine to convert it to phosphate.

A typical mobile phase separating phosphite, hypophosphite, hypophosphate and phosphate, on Whatman No. 4 paper, is a mixture of *iso*-propanol, *iso*-butanol, water and 20% *d* 0·880 ammonia solution in the ratio by volume 30 : 15 : 47·5 : 7·5.[606] Separation is very slow (20 hr.) and a faster separation (2–4 hr.) is achieved for the same mixture using methanol, dioxan, and N. ammonia solution in equal volumes. Using this mobile phase, and a quantitative finish based on the Lucena-Conde and Pratt reagent,[297] recoveries within 2–3% of the content of each spot are claimed.[611]

### *Ion Exchange*

Hypophosphite, phosphite and phosphate in admixture have been separated by ion exchange chromatography[612] by a gradient elution technique similar to that applied to condensed phosphates (*q.v.*) by Grande and Beukenkamp.[549] Two schemes of separation were developed. The one using potassium chloride solution buffered to a pH of 6·8 eluted the components in the order: hypophosphite, phosphate, phosphite. The other, using potassium chloride solution adjusted to a pH of 11·4 by the addition of ammonia solution, eluted the components in the order: hypophosphite, phosphate, phosphite. The effect of temperature on the separation was also studied, the retention volumes being lowered with decrease in temperature and the effect being greatest for phosphite. The scheme used at pH 6·8 has been extended to cover the separation of hypophosphite, phosphate, phosphite, hypophosphate, diphosphite (added as the sodium salt $Na_3HP_2O_5.12H_2O$), pyrophosphite ($Na_2H_2P_2O_5$), isohypophosphate ($Na_3NP_2O_6.4H_2O$), pyrophosphate,[613] and the sodium salt of the acid, designated $Na_5P_3O_8,14H_2O$. The anions were eluted in the order given, maximum separations being achieved when the amount of phosphorus per species was less than 2 mg.

A general scheme for the adaptation to the AutoAnalyser of ion exchange separations of phosphorus anions including reduced phosphates has been developed.[614]

**Refs. p. 1287**

ELECTROMETRIC

A mixture containing hypophosphorous acid, phosphorous acid and phosphoric acid can be resolved by a pH titration.[615] The quoted pK values are $H_3PO_2$, $pK = 1{\cdot}0$; $H_3PO_3$, $pK_1 = 1{\cdot}4$, $pK_2 = 6{\cdot}7$; $H_3PO_4$, $pK_1 = 2{\cdot}16$, $pK_2 = 7{\cdot}16$, $pK_3 = 12{\cdot}4$. If the amount of standard sodium hydroxide solution used to the first end point is *a* ml., to the second is *b* ml. and to the third *c* ml., then the amount of hypophosphorous acid is equivalent to $(a-b)$ ml., phosphorous acid to $(b-c)$ ml., and phosphoric acid to *c* ml. The third end point (see 'Orthophosphates: volumetric', p. 1257) can be obtained only after the addition of barium chloride solution. These authors have also used thermometric and conductimetric titrations for the analysis of the same three acids but report less accurate results.

Hypophosphorous acid has been determined by a potentiometric titration with silver nitrate solution using a silver foil indicator electrode with a saturated potassium nitrate/calomel reference electrode. The test solution was neutralized to phenolphthalein and then buffered with disodium hydrogen phosphate solution near to the end point of the titration. Orthophosphate did not interfere in the determination.[616] Grundmann and Hellmich[617] carried out a similar titration in a buffered acetate solution using a silver iodide electrode against a normalized silver electrode. Neither phosphoric nor phosphorous acid interfered in this titration.

## Elemental Phosphorus, its Compounds other than Oxyanions

### Miscellaneous

GRAVIMETRIC

Crude phosphorus is condensed from the gas leaving the electric furnace by a water spray. A sludge is the main impurity produced; this contains some yellow phosphorus, small amounts of red phosphorus, and lower oxidation products of the element. The total yellow phosphorus content of this sludge may be determined by distillation in an inert atmosphere (nitrogen or coal gas) the phosphorus being condensed in a suitable receiver.[619] Warm water is then added to the receiver and the phosphorus is collected into a bead, which, after cooling, is rapidly dried on a filter paper, transferred to a tared beaker of water, and weighed. Volatile tarry matter, soluble in phosphorus, will also be determined as phosphorus. A less hazardous method involves the conversion of the distilled phosphorus to copper phosphide.[620] After distillation, again in an inert gas, the phosphorus is passed through a glass tube containing a tight spiral of copper gauze, 10 cm. long by 1·5 cm. diameter. Over this tube is fitted an iron gauze cylinder which is heated to dull red heat. The tube is finally cooled and weighed. The water content of the sample may be determined by fitting a tared calcium chloride U-tube after the copper gauze tube; prior drying of the inert gas is then necessary.

Crude white phosphorus,[621] or white phosphorus present in a mixture with phosphoryl chloride and phosphorus trichloride,[622] may be extracted with benzene, then precipitated as cupric phosphide by shaking this solution with cupric nitrate solution. The precipitate is not weighed directly, since elemental copper may also be precipitated, but the phosphide is oxidized to orthophosphate before determination.

Tetraphenylarsonium chloride, when added to an ammoniacal solution of potassium hexafluorophosphate at 60°C., precipitates tetraphenylarsonium hexafluorophosphate. The precipitate is filtered, washed with dilute ammonia solution, dried to constant weight at 105°–115°C. and weighed as $(C_6H_5)_4AsPF_6$.[623] The results agreed with those obtained using the reagent nitron (4:5-dihydro-1:4-diphenyl-3:5-phenylimino-1:2:4-triazole), which was first proposed as a precipitant for hexafluorophosphate by Lange and Müller.[624]

VOLUMETRIC

The total phosphorus content of red or yellow phosphorus may be determined by oxidation with 1:2 nitric acid under reflux and the resulting orthophosphate (*q.v.*) determined. This reducing action of elemental phosphorus may be utilized for its determination. The ceric ion is quantitatively reduced to cerous by refluxing an excess of ceric sulphate solution in 4 N. sulphuric acid with red phosphorus. When the red phosphorus has fully dissolved the solution is cooled and the excess of oxidant back-titrated with standard ferrous ammonium sulphate solution.[625] Iodine in buffered potassium iodide solution will also react quantitatively with red phosphorus, excess of iodine being titrated with sodium thiosulphate solution. At room temperature with a phosphorus to iodine mole ratio of 1 : 4, the reaction time is 24 hr. but this reduces to 10 hr. on heating to 60°–65°C.; a phosphorus to iodine mole ratio of 1 : 3 is necessary at the higher temperature.[626] Potassium iodate,[627] potassium periodate[628] and potassium bromate[629] in sulphuric acid solution have been used as oxidants for red phosphorus. Bromine, prepared *in situ* by acidifying a bromide/bromate mixture, will quantitatively oxidize red phosphorus at 20°C. in 3–4 hr. Excess of bromine is determined by the addition of potassium iodide and titration of the iodine produced with sodium thiosulphate solution.[630] Both bromine[631] and iodine[632-3] have been used to determine phosphorus in pharmaceutical preparations. Potassium permanganate, in acid solution, oxidizes red phosphorus to orthophosphate and this reaction has been suggested[634] as a means of determining red phosphorus; the optimum phosphorus to potassium permanganate mole ratio is 1 : 1 in a solution of N. sulphuric acid. Any temperature up to 40°C. may be used.

Yellow phosphorus is extracted from a mixture of yellow and red phosphorus with benzene, carbon disulphide, or a mixture of equal volumes of carbon disulphide and carbon tetrachloride. This last solvent, though less effective, is non-inflammable and is to be preferred for routine work, After extraction with benzene, and the addition of 3 times the quantity of ethanol, the yellow phosphorus has been rapidly determined by adding an excess of iodine/potassium iodide solution, allowing to stand for 15 min., and titrating the excess of iodine with sodium thiosulphate solution.[635]

Direct titration of phosphide phosphorus is not satisfactory and phosphides are generally determined by liberating phosphine with acid. Hydrochloric acid (1 : 3) has been used for liberating phosphine from zinc phosphide rodenticide, the phosphine being absorbed in potassium permanganate solution and the orthophosphate formed being estimated volumetrically.[636] Phosphine has also been liberated by heating the phosphide in 30% sulphuric acid, and absorbing the gas in mercuric chloride solution. After filtering, the hydrochloric acid formed was titrated with sodium hydroxide solution.[637] Phosphine has been determined in air by drawing the air through a solution of mercuric chloride, forming the complex $P(HgCl)_3$. After the addition of iodine solution, which destroys the complex, excess of iodine is titrated with sodium thiosulphate solution, the amount of iodine consumed affording a measure of the phosphine content of the air.[638] The limit of this method is 1 p.p.m. of phosphine. The contaminated air has also been passed through silver nitrate solution, which precipitates silver *via* the yellow intermediate $Ag_3P,3AgNO_3$. The excess silver nitrate is titrated with potassium thiocyanate solution.[639]

### CHROMATOGRAPHIC

The katharometer has been used as a detector for phosphine. It is claimed that 0·5 p.p.m. in air may be determined on a column, 13′ by 0·25″, of 30% Apiezon *L* on 40–60 mesh firebrick. A temperature of 35°C. was used with a helium flow rate of 25 ml./min.[640] Increased sensitivity to phosphine (and to phosphorus compounds in general) is shown by the sodium detector.[651]

Phosphorus oxychloride and phosphorus trichloride have been separated and determined using a 6′ × 0·25″ column at 63°C. of 20% silicone E301 on 80–120 mesh celite.[641] A katharometer detector was used with nitrogen as carrier gas at a flow rate of 30 ml./min.

### MISCELLANEOUS METHODS

Small amounts of yellow phosphorus in red phosphorus have been estimated by placing a drop of the carbon disulphide extract on copper sulphate impregnated filter paper. The intensity of the spot obtained is compared with standards.[642] A similar method uses filter paper impregnated with silver nitrate.[643] A review including various methods of determining red and yellow phosphorus has been published.[644]

Phosphine in acetylene has been estimated by using a fixed amount of mercuric sulphate solution of known strength and passing the gas through it until the solution is exhausted, as indicated by silver nitrate paper across the exit. The time for exhaustion is proportional to the phosphine content of the acetylene.[645] An estimate of the phosphine content of air by methods suitable for routine use may be made by drawing a known volume of air through an absorption tube containing silica impregnated with a suitable reagent. Impregnants used have been silver nitrate,[646] a copper salt together with a mercury complex,[647] and a mercury salt together with auric chloride.[648] The length of stain is compared with standard stains obtained for known amounts of phosphine in air. A strip of filter paper impregnated with silver nitrate, through which a known volume of air is passed, is also a suitable and sensitive detector.[649] In the reaction of phosphine with mercuric chloride solution, $PH_3 + 3HgCl_2 \rightarrow P(HgCl)_3 + 3HCl$, the hydrochloric acid is produced quantitatively and has been used to measure the phosphine content of air.[650] A known volume of air is drawn through the solution inside a conductance cell and the change in conductivity measured; a calibration curve is prepared by adding to the cell known amounts of hydrochloric acid. Impurities in the air other than phosphine are removed by tubes of granular calcium chloride and potassium carbonate pellets.

## Organophosphorus Compounds

### VOLUMETRIC

Mixtures of dialkyl and trialkyl phosphites may be determined by the method of Bernhart and Rattenbury.[652] In an excess of alcoholic alkali solution dialkyl phosphites react with one equivalent of alkali whereas trialkyl phosphites do not react. In alcoholic acid solution trialkyl phosphites are converted to dialkyl phosphites which may then be caused to react with a known excess of alkali. The difference in the amount of alkali consumed is a measure of the trialkyl phosphite content. The reaction of dialkyl phosphites with alcoholic alkali is also an excellent method of assay; the monoalkyl phosphite content should however be estimated by a preliminary titration to pH 6·5 with alcoholic alkali and an allowance made for the alkali consumed. Reproducible, but not stoicheiometric, results have been obtained by reaction of dialkyl phosphites with iodine dissolved in pyridine. After 30 min. in the dark the excess of iodine can be titrated with sodium thiosulphate solution. It is claimed that by this method, using a calibration curve, dialkyl phosphites may be determined in the presence of other phosphorus compounds.[653]

Assay of trialkyl phosphites may be carried out by rapid titration with iodine in methanol; reaction with any dialkyl phosphites present is slow.[654] Better oxidizing agents for trialkyl phosphite determination are perbenzoic or *m*-chloroperbenzoic acid; the latter is to be preferred as it may be obtained commercially. The trialkyl phosphite is treated with a solution of *m*-chloroperbenzoic acid dissolved in benzene. Potassium iodide is then added and the iodine, released by the excess of reagent, is titrated with sodium thiosulphate solution using starch as an indicator. This reaction is also applicable to triphenyl phosphite.

Some organophosphorus halidates and pyroesters react quantitatively with peroxide, added as sodium pyrophosphate peroxide ($Na_4P_2O_7,2H_2O_2$). The reaction is carried out in an alkaline borate buffer, the excess of peroxide being titrated iodimetrically. The following compounds were determined: *iso*-propyl ethylphosphonofluoridate, di-*iso*-propyl phosphorofluoridate, tetraethyl pyrophosphate, tetra-*iso*-propyl pyrophosphate, tetra-*n*-butyl pyrophosphate, bis(ethyl methylphosphonic) anhydride, bis(*iso*-propyl methylphosphonic) anhydride, di-*iso*-propyl phosphorochloridate and *iso*-propyl methylphosphonochloridate.[655]

Organic phosphonium salts and phosphoranes may be titrated, in acetic acid solution, with perchloric acid using crystal violet as indicator. An excess of mercuric acetate should be added before titrating the phosphonium salts.[656]

Dialkyl dithiophosphates and diaryl dithiophosphates have been determined by oxidation with iodine, which reacts forming dialkyl and diaryl phosphates. The excess of iodine was determined by titration with sodium thiosulphate solution.[657] Various thiophosphoric acid ester preparations have been determined, after initial saponification, by oxidation with bromine, followed by an iodimetric finish.[658] Dialkyl hydrogen phosphorodithioates have also been determined iodimetrically after prior conversion to their nickel salts. This is claimed to overcome interference by hydrogen sulphide and thiols by precipitation of nickel sulphide and nickel mercaptide respectively.[659]

A method is described in which zirconium is extracted from a standard solution in perchloric acid by tributyl phosphate, but only in the presence of mono-or dibutyl phosphate. The zirconium remaining in the aqueous layer is determined by an EDTA titration. By reference to calibration curves the mono- or di-butyl phosphate content of the sample may be determined.[660] Shilin *et al.*[661] have determined tributyl phosphite in kerosene solution by shaking the sample with 9 N. perchloric acid and allowing the three layers to separate. Kerosene forms the top layer, tributyl phosphate acid complex the middle layer, with perchloric acid at the bottom. By reference to a calibration curve the volume of the centre layer may be related to the amount of tributyl phosphate in the sample. A mixture of phosphoric acid, mono-, di- and tributyl phosphate can be titrated directly with alkali, and the amount of each constituent determined.[90] At pH 4·5, phosphoric acid, monobutyl phosphate and dibutyl phosphate are titrated; at pH 8·5 in the presence of sodium chloride to repress hydrolysis, monobutyl phosphate and dibutyl phosphate are titrated; and finally, after the addition of calcium chloride, the third end point of phosphoric acid is effectively reached by again titrating to pH 8·5. A mixed indicator solution is used for detecting the end points. From the volumes of sodium hydroxide solution used at the various end points the amount of each constituent may be calculated, the tributyl phosphate being obtained by difference.

### SPECTROPHOTOMETRIC

1,3,5-Trinitrobenzene in alcoholic solution reacts with dialkyl phosphites forming a wine-red colour with an absorption maximum at 465 mμ.[662] This colour obeys Beer's law and, except for di-*iso*-propyl phosphite the reaction is rapid. Whilst the method is suitable for estimating the dialkyl phosphite content of trialkyl phosphites the use of purified ethanol is necessary in order to avoid high blanks and the volumetric method of Bernhart and Rattenbury is to be preferred. Similar reactions for the determination of dialkyl phosphites have been described using cacotheline[663] and 3:5-dinitrobenzoic acid.[664]

A sensitive method for the determination of tributyl phosphate is based on the extraction of 3 ml. of uranyl nitrate solution plus ammonium nitrate solution into 25 ml. of tributyl phosphate.[665] The uranium (VI) extracted was measured at 415 mμ or 280 mμ, the latter wave-length giving increased sensitivity though less reliability than the former.

Parathion (*O,O*-diethyl *O-p*-nitrophenyl phosphorothioate) and dimethyl parathion have been estimated in technical samples and formulations by hydrolysing the ester, and measuring the ultra-violet absorption of the *p*-nitrophenol formed.[666] Measurement is made in a 50% ethanolic solution of 0·1 N. sodium hydroxide. An allowance can be made for any free *p*-nitrophenol present in the sample. At a pH of 8·5 di-*iso*-nitroso acetone forms coloured complexes with certain phosphorus-containing insecticides and chemical warfare agents.[667–8] The following compounds were determined by measuring the absorption due to this complex at 486 mμ or 580 mμ: Tabun (ethyl phosphorodimethylamidocyanidate), Sarin (*iso*-propyl methylphosphonofluoridate), DFP (di-*iso*-propyl phosphorofluoridate), TEPP (tetraethyl pyrophosphate), methyl phosphonochloridate, paraoxon (diethyl paranitrophenyl phosphate) and parathion. Acid chlorides also reacted positively to the reaction. The above compounds also catalyse the oxidation of benzidine, forming a colour the intensity of which serves as a measure of the phosphorus compound present.[669] This reaction was first proposed by Schönemann.[670] Parathion has been estimated in the infra-red by Yu-Shih Chen[671]; absorption peaks were obtained at 7·37 μ, 9·75 μ and 10·9 μ.

A sensitive method proposed for detecting and estimating nerve gases is based on their reaction with indole and sodium perborate in which the highly fluorescent indoxyl is formed.[672]

The dimethyl, diethyl, di-*iso*-propyl and diphenyl esters of dithiophosphoric acid have been determined by the direct measurement of the colour produced by their nickel salts which were prepared by shaking a benzene solution of the sample with nickel carbonate.[673]

A non-specific method for the determination of organophosphorus compounds has been developed in which the sample, dissolved in dibutyl phthalate, reacts with an ether solution of lithium aluminium hydride forming phosphine. Air is drawn through the solution and passed through silver nitrate treated paper; the colour on the paper, due to the phosphine, is measured photometrically.[674]

## CHROMATOGRAPHIC SEPARATIONS

### *Paper*

Where separation is achieved on paper chromatograms of mixtures of organophosphorus compounds, any constituent, after being rendered visible, may be determined by wet-ashing the spot, and determining the phosphorus, as suggested by Hanes and Isherwood.[675]. To obtain enough phosphorus for reasonable accuracy it may be necessary to apply the sample in the form of a streak, or to apply several spots close together.

Several workers have separated phosphoric acid, monobutyl phosphate and dibutyl phosphate. Cerrai *et al.*[676] used downward elution of a butanol–formic acid solvent, followed by a Hanes–Isherwood[675] spray reagent or bromophenol blue solution. A quicker separation (30 min.) was achieved using upward elution of *n*-butanol-acetone-water-ammonia mixture[677]; the spray used was ferric iron solution followed by sulphosalicylic acid solution as used by Wade and Morgan.[678] Alcohol–water–ammonia mixtures were used by Shvedov and Rosyanov,[679] who revealed the spots by the Hanes–Isherwood[675] reagent. Many esters of phosphorous and phosphoric acids have been separated using various mobile phases, and using where necessary stationary phases on the paper.[680] Octyl and phenyl phosphites were separated with a liquid paraffin stationary phase and methanol, nitromethane or 2-methoxyethanol nitromethane or 2-methoxyethanol as mobile phases; allyl phosphites and phosphates with polyethylene glycol 400 stationary phase and petrol/chloroform as mobile phase, and esters of phosphoric acid with *n*-propanol/2 N. ammonia as mobile phase. Alkaline potassium permanganate solution, alkaline Universal Indicator solution, and ferric thiocyanate solution were used as spray reagents. Methylphosphonic acid, methylphosphinic acid, dimethylphosphinic acid and trimethylphosphine oxide have been separated on paper, and $R_f$ values compared with a separation using paper electrophoresis.[681]

Various phosphoric esters have been identified in muscle tissue and leaf extract using the solvent system methanol/ammonia/water.[682] Acid-soluble phosphorus compounds from plant tissues have also been separated and identified.[683-4] Sugar phosphates have been separated and identified by paper chromatography[685] and electrophoresis[686]; Agarwal *et al.*[687] claim an improved separation when borate impregnated papers are used. Good separations on circular chromatograms have been obtained of phospholipids extracted from rat tissue.[688] A sensitive spray reagent for biological phosphate esters has been developed by Rorem[689]; after development the chromatogram was immersed in 0·51% alcoholic quinine sulphate solution, dried, and examined under the ultra-violet lamp; spots containing 0·007 μ-moles of phosphorus were detected. Methods of determining the phosphorus in the spots obtained from biological material have been reviewed by Delsal and Manhouri.[287] In a later paper Usher[690] wet-ashed the spots with perchloric acid, and determined the orthophosphate formed by a molybdenum-blue method due to Bartlett.[691]

Parathion and related compounds (paraoxon, methylparathion, ethyl *iso*-chlorothion, methyl *iso*-chlorothion, *O*-ethyl-*O*-*p*-nitrophenylbenzene thiophosphate, *p*-nitrophenylacetate and *p*-nitrophenol), have been separated on a silicone impregnated paper with a 1: 1: 1 chloroform/ethanol/water mixture as mobile phase.[692] Malathion and its related compounds have been analyzed by various methods, including paper chromatography, by Yu-Shih Chen.[671] Thiophosphoric insecticides have been identified, and hydrolysis products shown by simple test-tube chromatography.[693] Malathion, Parathion, Diazinon, Guthion, Systox and Trithion have been identified in kale, after an extraction procedure. A two-dimensional procedure is recommended for the best resolution.[694] Techniques for separation of 11 insecticides have been described by Mitchell.[695] Phosphoric, phosphonic and phosphinic acid esters have been converted to acetylcholinesterase inhibitors by exposure to ketene vapour. By spraying with the enzyme (in horse serum), followed by acetylcholine chloride and bromothymol blue indicator solution, blue spots are obtained on a yellow background.[696] Acetylcholinesterase inhibition has also been applied to the detection of pesticide residues in plant tissue.[697] The method of spot detection by radioactive labelling has been applied to the detection of phosphate esters by Boursnell[698] and Winteringham.[699]

### *Thin Layer*

Esters of phosphoric acid have been separated on silica gel coated plates, and rendered visible by spraying with acid ammonium molybdate, followed by drying and exposure to ultra-violet light. Twenty-six esters were separated (using eight different mobile phases); these included trialkyl phosphates, trialkyl phosphites, amidophosphoric esters and thionophosphoric esters.[700] Alumina and silica gel have been used to separate esters and amides of various thiophosphoric acids; hexane/acetone mixtures were used as the mobile phase with potassium permanganate solution as the spray reagent.[701]

Bäumler and Rippstein[702] have separated thiophosphate pesticides on silica gel plates with hexane/acetone (4 : 1) as the mobile phase. The spots were detected using palladium chloride in hydrochloric acid. Conditions for the separation of 27 phosphorus-containing pesticides have been defined by Walker and Beroza[703]; three reagents were used for revealing the spots: iodine vapour, bromine vapour/fluorescein, and silver nitrate solution. Braithwaite[704] has shown that 0·1 μg. of certain thiophosphate pesticides may be detected on silica gel layers with 2 : 6-dichloro-*p*-benzoquinone-4-chloroimine. Good sensitivity (0·1 μg.) has been achieved using a cholinesterase inhibition technique for spot detection; 17 pesticides were detected on both silica gel and alumina.[705]

### *Vapour Phase*

The butyl esters of phosphoric acid can be converted to the volatile methyl esters by reaction with diazomethane in ether. Separation is then achieved on a 3-foot column of silicone DC 200 on firebrick at 188°C., or silicone E301 on a celite support at 197°C. This method was applied to samples of tributyl phosphate.[706] Dimethyl phosphite and diethyl phosphite have been separated using dibutyl phthalate or Apiezon K on Fluopack 80. Helium was used as a carrier gas at a temperature of 107°C.[707]

A general method has been proposed for the extraction and subsequent separation of organophosphorus pesticides in sub-microgram amounts in plant tissue, using an electron-capture ionization detector.[708] The highest sensitivity was obtained using a detector designed by de Faubert Maunder *et al.*[709] The sodium wire detector in comparison with the flame ionization detector will also give an increased response to organophosphorus compounds.[651]

The organic radical in certain organic phosphates was identified by pyrolyzing the sample and identifying the pyrolysis products by infra-red spectrophotometry or mass spectrometry after separation on the chromatograph.[710]

### ELECTROMETRIC

Trimethylphosphine oxide, tetra-*n*-octylphosphine oxide and triphenylphosphine oxide have been titrated in acetic anhydride with perchloric acid dissolved in dioxan.[771] Sharp inflexion points were obtained using a modified[712] calomel and a glass electrode.

An oscillometric method has been used to determine tributyl phosphate in kerosene solution. Oscillometric readings, which measure the change in the dielectric constant, were taken of the filtered tributyl phosphate solution after extraction of the uranyl nitrate residues with sodium carbonate solution. A calibration curve was prepared in a similar manner.[713]

Dialkyl and diaryl phosphites, either alone or in mixtures with the corresponding trialkyl or triaryl phosphite, react with carbon tetrachloride and diethylamine forming the amine hydrochloride. This reaction has been applied quantitatively,[714] the hydrochloride being titrated with sodium methoxide in methanol/benzene/pyridine solution, the end point being detected with a high frequency titrimeter.

Cathode-ray polarography has been applied to the determination of pesticide residues after separation into individual components by paper chromatography.[715-6] This technique also offers some specificity.

## Direct (Instrumental) Methods of Determining Phosphorus

Since the general application to phosphorus chemistry of spectroscopy in its many forms, has been dealt with in some detail in Section XXXIV (page 1129), it is proposed to high-light only a few specific quantitative applications here.

Of these applications mention should be made of the use of arc and spark source photographic and direct reading spectrographs in the determination of phosphorus in ferrous[717-42] and non-ferrous[743-46] metals, titanium dioxide,[747] plants,[748-9] soils[750] and phosphating baths.[751] Some work has been done on the development of nebutizers for solution analysis[752] and on sources.[753-54] Detection limits for phosphorus around 20–30 p.p.m. have been claimed.[752-4] Work in the authors' laboratory using an H.F. plasma torch as a source in solution analysis has pushed the detection limit down to 4 p.p.m. The atomic line 2535 A. was used in this work with a power of 4·9 kw. in the plasma.[755] It may be of interest to mention a solution technique based on the extraction, with butyl alcohol, of phosphorus as molybdophosphate. The extract is absorbed on powdered graphite and examined spectrographically.[756]

Flame photometric methods for determining phosphorus have been described; these employ direct emission from inorganic and organic phosphorus compounds in various solvents[757-8] or the depressive effect of phosphorus upon the emission of strontium.[759]

The *X*-ray fluorescence spectrometer has been used for the determination of phosphorus in minerals[760-2]; *X*-ray absorption methods have also been used.[763]

Radioactive phosphorus has been used to monitor the phosphorus content of molten steel in steel-making processes; the final measurement is carried out with Geiger-Müller tubes and associated equipment.[764-5]

An interesting application of nuclear magnetic resonance is that of Guffy and Miller,[766] who applied the method to the analysis of polyphosphoric acids. Finally, mention might be made of the infra-red analysis of tripolyphosphate by Suzuki *et al.*[767]

## BREAKDOWN PROCEDURES

### Inorganic

In general phosphate rocks are not completely soluble in acid although with some rocks the degree of breakdown is sufficient for many purposes; in nearly all cases an insoluble residue is left which may contain phosphorus. Rocks from the Moroccan and Florida deposits may be effectively decomposed by fusion with sodium carbonate. However, others such as those from the Senegal deposits will require fusion with sodium peroxide which in the authors' opinion is the most generally acceptable method of decomposition for phosphate rocks. Alkali hydroxide fusions may also be used but losses of phosphorus will occur if pyrosulphate fusions are attempted.[768] Acid breakdown by nitric and hydrofluoric, or nitric, hydrofluoric and perchloric acids, is also used but the presence of fluorine in the resulting solution may lead to complications in later stages of the analysis. Care should be taken both in fusions and digestions that any residue remaining is not discarded, otherwise losses of phosphorus may occur.

Alkali and alkaline-earth phosphides should be decomposed with extreme caution; violent reaction may occur with certain oxidizing agents, but cold concentrated sulphuric acid has been used to decompose sodium phosphide.[769] The authors of this Section have also decomposed calcium and magnesium aluminium phosphides with cold concentrated sulphuric acid. Metallurgical samples, where the phosphorus is present as phosphide, must be decomposed under strongly oxidizing conditions, in order to prevent loss of phosphorus as phosphine. Acid breakdown with various combinations of nitric acid, hydrofluoric acid and perchloric acid, or fusion with sodium peroxide, is generally employed.

Where the total phosphorus content of condensed phosphates, or of the individual species after, for example, ion exchange separation, is required, conversion to orthophosphate is easily effected by hydrolysis in hot strong acids.[770] Reduced phosphates may be oxidized by nitric acid and bromine water.

Inorganic phosphorus compounds that are difficult to hydrolyze, for example the phosphonitrilic chlorides, may be treated in the same manner as organophosphorus compounds and decomposed in the sodium peroxide bomb. The halides and oxyhalides of phosphorus are simply carefully hydrolyzed; where phosphorous acid results this should then be oxidized to orthophosphate.[771]

### Organic

Wet digestion procedures are greatly favoured for the breakdown of organophosphorus compounds. A variety of acid mixtures has been tried. Sulphuric acid and nitric acid mixtures have been used for microchemical breakdowns both with[85, 772–3] and without[346, 774] the final addition of hydrogen peroxide to clear the solution. Sulphuric acid and hydrogen peroxide have been used[775, 244] and this combination was found to be particularly effective for decomposing organophosphine compounds,[244] considered difficult to decompose. A mixture of sulphuric acid and potassium persulphate also effectively decomposed triphenyl phosphine.[776]

Two acid breakdown procedures have been suggested by Simmons and Robertson[777]: alkyl phosphates were completely decomposed by refluxing with hydriodic acid, and both alkyl and aryl phosphates decomposed in a mixture of nitric, sulphuric and perchloric acids with sodium molybdate added as catalyst. Selenium has also been used as an effective catalyst.[778] Alkyl and aryl phosphates also decomposed with nitric acid and, when partial breakdown had occurred, with perchloric acid.[779] The so-called liquid-fire reaction of Smith[780–1] using perchloric acid/nitric acid mixtures has been used to decompose high-explosive compounds containing phosphorus.[782] A semi-micro procedure using a mixed sulphuric perchloric acid reagent has been described by Saliman.[261] This author also used, for micro amounts of phosphorus, a digestion mixture consisting of hydriodic acid, calcium iodide, water, phenol and acetic acid; it was found particularly effective for phosphate insecticides. Kirsten and Carlsson[212] found wet oxidation methods both fast and simple.

Decomposition of biological material may be accomplished with sulphuric acid heated in a sealed tube; the method developed for nitrogen[783] was applied to phosphorus determination.[784] The Carius method of breakdown, using nitric acid in a sealed tube, can yield low results with phosphate compounds owing to attack on the glass tube; the addition of potassium chloride prevents this and good recoveries are obtained.[785] The wet oxidation and ignition of soil have been studied in order to prevent losses of phosphorus; 500°C. is suggested as an optimum temperature.[786]

Fusion methods are favoured by many workers. For microchemical determinations sodium carbonate and sodium nitrate mixture in a platinum boat has been used,[772] as has sodium hydroxide and potassium nitrate,[787] potassium hydroxide and potassium nitrate,[788] and sodium carbonate.[453] Fusions with potassium manganite[789] and sodium[790] have also been suggested.

Sodium peroxide fusion in a nickel bomb is a generally applicable method of breakdown, giving good results for triphenylphosphine.[267] The usual fusion mixture for the semi-micro bomb consists of sodium peroxide, potassium nitrate and sucrose,[267, 791–3] but a mixture of sodium peroxide and ethylene glycol has been used.[794–5] The macro bomb, using sodium peroxide and sucrose for the fusion, is also an efficient method of breakdown.[796–7] Fluorinated organic materials containing phosphorus have been decomposed in the micro bomb using semi-micro amounts of sample.[80]

Rapid micro and semi-micro determinations have been accomplished[191] by applying the Schöniger flask technique[798–9] to organophosphorus compounds, but Kirsten and Carlsson[212] found a tendency towards low results as have the authors of this Section.

## QUALITATIVE

### *Orthophosphate*

Many of the quantitative procedures which have been described are equally applicable to the qualitative detection of orthophosphate. Thus ammonium molybdate is one of the most commonly used reagents for the detection of orthophosphates.[800–3] The bright yellow precipitate of ammonium molybdophosphate can be characterized under the microscope.[804–5] Due regard must of course be taken of the previously mentioned elements that also give a precipitate with ammonium molybdate.

Magnesia mixture will give a white precipitate of magnesium ammonium phosphate with orthophosphate solutions; this again can be identified under the microscope.[804, 806]

As little as 1 microgram of pentavalent phosphorus is said to be detected in a solution containing 1 part in 50,000 as a result of the formation of quinoline molybdophosphate on a circular paper impregnated with a solution of quinoline molybdate.[807–9] *o*-Dianisidine molybdate has also been used for the detection of phosphate.[810, 811]

The various colorimetric systems for the quantitative estimation of orthophosphate are eminently suitable for its detection. Amongst these may be mentioned the various 'moly-blue' methods, both with and without extraction, the molybdovanadophosphate method and the benzidine blue methods.[800, 812–7] It may also be noted that a mixture of acid sodium molybdate solution and ferrous sulphate solution, which is colourless, becomes coloured blue upon the addition of orthophosphate solution followed by alkaline fluoride solution.[818]

### Condensed Phosphates

Whilst the most important procedures for the identification of condensed phosphates are undoubtedly those involving chromatography, some of the older methods may be of interest and these will be mentioned.

Pyrophosphoric acid may be detected in the presence of orthophosphoric acid by the characteristic appearance of copper pyrophosphate crystals when copper sulphate solution is added to the mixture.[819-21] Silver pyrophosphate, white, is less soluble than silver phosphate, yellow, in acetic acid solution; this property combined with the colour difference, has been used as a test for pyrophosphate.[819,822] The insolubility of barium pyrophosphate precipitate in acetic acid has also been used to distinguish orthophosphate from pyrophosphate.[823] Zinc pyrophosphate crystals have been examined microscopically by Heinerth.[824] The qualitative behaviour of sodium triphosphate, sodium trimetaphosphate and sodium hexametaphosphate towards sixteen metal ions has been examined.[825]

Hexamminocobalt(III) chloride gives characteristic crystals with pyrophosphate,[826] which have been examined microscopically.[821,827] This reagent has also been used for the identification of unknown condensed phosphates by examination of the crystals obtained.[828]

Highly condensed phosphates, in the presence of orthophosphate, pyrophosphate and triphosphate may be detected down to a limit of 1 part in 20,000 with cinchonine.[829] Various basic organic compounds have been used[488,830] to characterize both poly- and meta-phosphates.

Clearly, the quantitative paper chromatographic methods may also be used qualitatively, either by reference to known $R_f$ values or simple comparison with standards treated under the same conditions as those of the test. Most of the qualitative separations were described before quantitative paper chromatography became established: the separation of phosphate from arsenate, hypophosphite and pyrophosphate,[605] and the separation and identification of various condensed phosphates in synthetic mixtures[831-3] and in mayonnaise and vegetable thickening agents[834] have been described. Paper electrophoresis has been applied to the separation of condensed phosphates[835] and a general review of electrochromatographic methods has been given by Sato.[836] Singh[837] found that, of fifty-eight organic dyes tested for the detection of condensed phosphates on paper, *o*-toluidine blue was to be preferred.

Thin-layer chromatography in general gives a much faster separation than paper chromatography but does not lend itself so easily to quantitative applications. The technique has been applied qualitatively to the separation of orthophosphate and pyrophosphate[838] and, following on his earlier work on paper chromatography,[839] Roessel[840] has separated both linear (up to $n=8$) and cyclic phosphates using cellulose powder with added corn starch as binder.

## Reduced Phosphates

Hypophosphite may be distinguished from phosphite by its reaction with copper sulphate solution with which it gives, on warming, a red precipitate of cuprous hydride,[841-2] phosphite giving a light blue precipitate of cupric phosphite. Hypophosphates do not reduce copper sulphate.

Under strongly acid conditions phosphites and hypophosphites react very slowly with sodium selenite, whereas hypophosphates precipitate red elementary selenium.[843]

Whereas both phosphites and hypophosphites reduce silver nitrate solution to metallic silver,[844] hypophosphates precipitate silver hypophosphate which is not reduced even on heating.

Barium chloride solution with phosphites and hypophosphates gives white barium salts; the barium phosphite precipitate is soluble in dilute acids whereas the barium hypophosphate precipitate is difficultly soluble. Hypophosphites do not give a precipitate with barium chloride solution.[823,845]

Lead phosphite is insoluble in neutral solution and is precipitated when lead acetate solution is added to a mixture of phosphite and hypophosphite. This has been used as a method of separating hypophosphite from phosphite and phosphate.[846]

Two further methods have been mentioned by Gutbier[847] to distinguish hypophosphite from phosphite: on reaction with concentrated alkali hydrogen is released from hypophosphites, not from phosphites, and on warming with concentrated sulphuric acid only hypophosphite will liberate free sulphur.

Microscopic examination of various metal precipitates has been used for qualitative recognition of hypophosphites, *viz.* with mercurous nitrate,[848] thallous acetate,[804] lead acetate,[804] silver nitrate.[804] Phosphite precipitates have also been examined microscopically; suitable precipitants are calcium acetate and barium acetate.[805]

The reaction with iodine solution may also be used to distinguish phosphites from hypophosphites, phosphites being oxidized in neutral solution whilst hypophosphites require strongly acidic conditions.[844, 849] Acidified potassium permanganate solution has no action in the cold on phosphites, but is decolorized on warming; hypophosphites reduce it in the cold.[845] Potassium permanganate solution has also been used to detect the presence of lower oxides in phosphorus pentoxide.[850]

## Elemental Phosphorus, Its Compounds Other than Oxyanions

### Miscellaneous

The early Dusart–Blondlot method for detecting phosphorus in biological materials involves its reduction to phosphine with zinc and sulphuric acid. The phosphine, in a stream of hydrogen, is burnt at a jet, where it imparts a green coloration to the flame. It can be caused to react with silver nitrate solution and the phosphine in the precipitate regenerated with more zinc and sulphuric acid. The latter variant overcomes interference from the organic material. Modifications of the method have been proposed by Křepelka and Chmelař,[851] and Lieb and Soltys.[852] Yellow phosphorus and phosphides may be detected by passing air through the specimen contained in a sulphuric acid solution at 100°C. and passing the vapour through silver nitrate impregnated paper, when a brownish-black spot is formed. The result is confirmed by testing for phosphate after oxidation of the silver phosphide to phosphate.[853–5] A microchemical procedure for yellow phosphorus estimation based on steam distillation has been described: less than 10 $\mu$g of phosphorus is claimed to be detected.[856] Both phosphorus and phosphine have been semiquantitatively determined by measuring the amount of precipitate formed in a capillary tube immersed in ammoniacal silver nitrate solution.[857]

Following the work of Schenk and Scharff on the detection of phosphorus using the gold-leaf electroscope, Treadwell and Beeli[858] have determined phosphorus in ethylene dibromide solution and in mixtures with tetraphosphorus trisulphide.

The luminescence of yellow phosphorus, detectable in the dark, has fallen into disuse as a qualitative method, but may be used to estimate the element in the presence of phosphorus–sulphur compounds. The sample is mixed with zinc oxide and an inert solvent, then heated in the dark, the temperature at which luminescent vapours are observed being recorded. Concentrations of 0·02–0·03% of yellow phosphorus may be detected.[859]

Phosphorus in organic compounds may be detected by fusing the sample with magnesium powder, and hydrolyzing the magnesium phosphide formed. The green flame of the phosphine is characteristic.[860]

The phosphine resulting from heating pharmaceutical preparations containing calcium hypophosphite has been detected by reaction with sodium aurichloride on filter paper; a violet coloration is obtained.[861] Silver diethyldithiocarbamate gives a colour reaction with phosphine, the absorption maximum differing from that of arsine and stibine, and has been used by Vašák[862] for its detection. This author also proposed the silver salt of 2-mercaptobenzimidazole for the detection of phosphine, white phosphorus and lower oxidation products of phosphorus.

Chemical microscopy has been applied to the identification of the phosphoramidic, phosphorodiamidic, triphosphenimidic and tetraphosphenimidic acids by examination of their *o*-tolidine, ammonium and silver salts.[863]

2-Chloro-1 : 3 : 5-trinitrobenzene (picryl chloride) in acetone reacts with filter paper impregnated with alkaline hydrazine sulphate solution, forming a pink colour. This reaction has been used to detect phosphorus pentachloride in the presence of phosphorus trichloride; the sample is heated with picric acid forming, in the case of phosphorus pentachloride, picryl chloride, which is then used in the test. Phosphorus trichloride does not form picryl chloride.[864]

The ions phosphate, difluophosphate and monofluophosphate may be detected in mixtures by paper electrophoresis at pH 7, which gives a spot for phosphate and one for mono and difluophosphate.[865]

Using a solvent containing *iso*-propanol, water, trichloroacetic acid and ammonia, Steger and Seener[866] have separated the phosphate, monothiophosphate, dithiophosphate, monothiophosphite, monothiohypophosphite and dithiohypophosphite ions by paper chromatography; dithiophosphate which hydrolyzes at ordinary temperatures was found to give an $R_f$ value at 4°C.

## Organophosphorus Compounds

Some colour reactions of organophosphorus compounds have been studied by Hecker and Hein.[867] Phosphine oxides and dialkylphosphinic acids give a deep blue colour when heated with anhydrous nickel bromide in toluene. Alkyl phosphine oxides and tetra-alkylphosphonium salts form a deep violet colour with *m*-dinitrobenzene in sodium hydroxide solution. Tertiary phosphines react with 3 : 5-dinitrobenzoic acid to give a red-violet colour, alkylphosphine sulphides give a blue colour when heated with vanillin and hydrochloric acid, and alkylphosphine oxides give a brown or green colour when heated with carbon disulphide, sodium hydroxide and a molybdate.

## SECTION XXXVI

# THE RADIOCHEMISTRY OF PHOSPHORUS AND ITS COMPOUNDS

### BY N. R. LARGE

## TABLE OF PHOSPHORUS ISOTOPES

THE following Table presents a complete list of all the radioactive and stable isotopes of phosphorus, together with a number of their salient features, as recorded in the literature or by private communication by approximately February, 1958. It has been prepared directly from the *Table of Isotopes*, by Strominger, Hollander, and Seaborg[1] with the kind permission of the authors. This introduction is based on that to the original Table.

A description of the entries in the various columns is given below.

### ISOTOPE

The first column contains the atomic numbers, chemical symbols, and mass numbers of the nuclear species. The stable isotope is underlined.

### HALF-LIFE

All half-life values have been determined by direct measurement of decay rate. An attempt has been made to list the most precise value or values first.

### TYPE OF DECAY

Since many classes of data are included in the third column, the entry denoting mode of decay is preceded by the special symbol for radiation, ⊙. Symbols used are

| | |
|---|---|
| $\beta^-$ | Negative beta-particle (negatron) emission. |
| $\beta^+$ | Positive beta-particle (positron) emission. |
| $\alpha$ | Alpha-particle emission. |

When experimenters have searched for and failed to find a particular mode of decay, this is indicated, for example, as 'no $\beta^+$'. Experimental upper limits are given, and are indicated by 'lim', but no theoretically predicted limits have been quoted.

### CLASS AND IDENTIFICATION

The degree of certainty of each isotopic assignment is indicated by a letter in the third column according to the following code:

| | |
|---|---|
| A | Element and mass number certain. |
| B | Element certain and mass number probable. |

Data which have been shown to be in error have not, in general, been included in the Table.

The means by which the mass assignments were made are next tabulated. In general, several references are given here, the first of which denotes the probable discoverer of the isotope. Following this, references are given to the papers which contributed most significantly toward giving the isotope its best or present rating. Some indication of the experimental methods used in making the various assignments may be had from the following symbolism:

| | |
|---|---|
| chem | Chemical separations, establishing uniquely the chemical identity (atomic number) of the isotope. |
| genet energy levels | Proof of isobaric relationship with an identified nuclide by observation of identical energy levels following decay of both, implying decay to the same product. |
| excit | Loosely refers to energetic considerations which have aided in making the mass assignment. Some of these might be<br>(1) excitation or yield experiments to establish the nuclear reaction which produces the isotope,<br>(2) bombardments with low energy particles, in which possible products are few,<br>(3) mass calculations, or other estimates or measurements of $Q$ values. |
| cross bomb | Studies of yields of the isotope in several different types of bombardments, in which the target elements as well as the projectiles have been varied. |
| *n*-capt | Cases where bombardments with slow neutrons ($n-\gamma$ reactions) have provided key evidence in the mass assignments. |
| decay charac | Identification of expected or predicted decay characteristics. |

Data on genetic relationships which have been demonstrated experimentally are located in column three underneath the class-assignment information.

### NUCLEAR MOMENTS

Measured values of the nuclear moments are also given in the third column. Unless otherwise stated, the measured value is that of the ground state. The mechanical or spin moment, I, is given in units of ħ. The magnetic dipole moment, $\mu$, is given in units of nuclear magnetons. The value is given without the diamagnetic correction.[2] In selecting these data much use was made of the compilations of Mack,[3] Walchi,[2] and Kopfermann.[4]

Experimental methods are described as follows:

| | |
|---|---|
| atomic spect | Hyperfine structure from optical spectroscopy (includes both line and band spectra). |
| nucl induct | Nuclear resonance absorption or induction. |

### ENERGY OF RADIATION

The energies of particles and photons are included together in column four. The symbol '⊙' always denotes absolute percentages of total decay. The particle energies are followed by other relevant information pertaining to the decay scheme and by a description of the experimental methods used in obtaining the data. Beta-particle energies correspond to the upper limits of the spectra, except where indicated as E (average).

Experimental methods for the measurement of the properties of particles and gamma rays are described as follows:

| | |
|---|---|
| abs | The upper limit of the $\beta$-ray spectrum is estimated from the range of the most energetic $\beta$-particles in an absorber. |
| spect | The $\beta$-particle energies are determined by magnetic deflection (magnetic spectrograph or spectrometer or counter with magnetic field). |
| scint spect | The $\beta$-particle or $\gamma$-ray energies are determined by measurement of pulses produced by a scintillating crystal or solution. |
| ion ch | The average $\beta$ energy is determined by measurement of the ionization produced in an ionization chamber by a sample whose absolute disintegration rate is known. |

**Refs. p. 1305**

| | |
|---|---|
| calorimeter | The average $\beta$ energy is determined by measurement of the heat produced in a calorimeter by a sample whose absolute disintegration rate is known. |
| cl ch | The $\beta$-particle energies are determined by the use of a cloud chamber with a magnetic field. |

Gamma transitions are described by the following information:

### ENERGY OF THE NUCLEAR TRANSITION

This corresponds to the difference between the energy contents of the initial and final nuclear states and is equal to the photon or gamma-ray energy (if a photon is emitted in the transition).

### ABUNDANCE OF GAMMA RAYS

Intensities given with the percent sign refer to the number of unconverted photons emitted per 100 disintegrations. When attempts to find gamma radiation have failed, this is indicated by 'no $\gamma$'. Experimental upper limits are indicated by 'lim'. *X*-Rays are not mentioned.

### DISINTEGRATION ENERGY AND SCHEME

The disintegration energy, or $Q$ value, of a nuclear transformation is defined as the mass difference (expressed in Mev.) between the initial and final systems under consideration. For radioactive decay processes, $Q$ is equal to the sum of the particle kinetic energy, nuclear recoil energy, and the energies of any gamma transitions necessary to de-excite the final nucleus to its ground state. In $\beta^+$ decay the $Q$ value is given as $Q_{\mathrm{EC}}$, to avoid ambiguity associated with the addition of $2m_0c^2$ to the positron energy. Where $Q$ values have been estimated or calculated by the authors of the compilation[1] from which this Table is adapted, the special reference 'SHS' is used; otherwise, reference is made to the paper from which the quoted value is taken. In all instances $Q$ values have been obtained from decay data.

Energy-level diagrams have been drawn for all radioactive iostopes; these are not necessarily complete representations of the data, but include only those features which seem to be reasonably well established and unambiguous. Heights of the various energy levels above the ground state are indicated at the side of the drawing. Occasionally the energy value of a level is inferred from nuclear reaction data not given in the table. When the authors have altered a decay scheme in any significant way from that given in the original paper or papers, they include their own code reference (SHS).

In many cases, the total angular momentum (spin) and parity of the states are given in the level schemes. When the spin of a state has been measured directly, it is denoted by underlining that quantum number in the decay scheme, i.e. $\underline{\tfrac{1}{2}}+$. If the spin is determined uniquely by other methods, it is designated by the quantum number without any other modification, i.e. $3-$. The $0+$ character of the ground states of even-even nuclei is in this latter category except in a few cases where direct measurements of the spin have been made. Probable spin values are indicated with parentheses around the quantum number, i.e. $(2+)$. Since parity assignments depend heavily upon theory, the foregoing nomenclature does not apply to them.

The percentage figures given in the decay drawings total 100% for the total decay. In some cases the symbol † is used to designate the relative branching of one mode of decay.

## PRODUCTION AND PREPARATION OF PHOSPHORUS ISOTOPES

## METHODS OF PRODUCTION

Radioactive isotopes of phosphorus may be produced in a large variety of ways by subjecting suitable targets to bombardment by nuclear particles or $\gamma$-rays. The amount of energy liberated in any particular reaction is dependent on the difference in mass between the reactants and the products, and is known as the $Q$-value of the reaction. The main nuclear reactions in which phosphorus isotopes have been observed as products are given in Table I; the $Q$-values in this Table are taken from 1960 Nuclear Data Tables.[81] The feasibility of any nuclear reaction is to a large extent dependent on its $Q$-value, a high negative value indicating that only particles of very high energy could be effective. In general, the bombarding particle or photon will need more energy than is apparent from the $Q$-value, since there will be some

*Table I.—Nuclear Reactions for Production of Phosphorus Isotopes*

transfer of momentum to the products, and since charged particles entering or leaving the nucleus have to surmount a Coulomb barrier. This minimum effective energy is the 'threshold' energy, and some experimentally determined values are given in the Table.

In addition to the reactions listed in Table I there are certain other nuclear processes which give rise to isotopes of phosphorus, usually together with a wide variety of other products. $^{32}P$ has been observed amongst the products of spallation of copper,[82-4] iron,[85] and other elements,[86-7] and $^{33}P$ has also been observed under these conditions.[86, 88] (Spallation is a nuclear process, resulting from bombardment with high energy particles, in which a number of fragments are produced.) $^{30}P$ and $^{32}P$ are formed during the bombardment of aluminium with $^{16}O$ and $^{14}N$ ions,[89-90] and $^{32}P$ has been detected in the proton-induced fission of lanthanum and gold.[84] The formation of $^{34}P$ by the reaction $^{79}Br(p, 2n)^{34}P^{44}Sc$ has been deduced from the observed threshold for the formation of $^{44}Sc$.[91] $^{32}P$ and $^{33}P$ have been found in rain water, and are believed to arise from the spallation of atmospheric argon by cosmic rays.[92-4]

The number of atoms of a product formed in a nuclear reaction is given approximately by:

$$N = I(1-e^{-n\sigma x})$$

where $N$ is the number of product atoms formed,
$I$ is the number of incident particles or photons,
$n$ is the number of target atoms per c.c.,
$\sigma$ is the cross section for the particular nuclear process in cm$^2$,
$x$ is the target thickness in cm.

For most reactions the cross-section is a complicated function of the energy of the bombarding particle, and its values under various conditions may be found in the references to Table I. However, the cross-section for irradiation by thermal neutrons usually varies inversely as the neutron velocity, and since the thermal neutron flux of a reactor is always quoted for an arbitrary velocity of 2200 m./sec. the use of the cross-section for neutrons of this velocity will give the thermal neutron contribution to the rate of formation of the product irrespective of the actual thermal neutron energies. Where reactions having positive $Q$-values are induced by neutron bombardment the absence of any barrier to neutrons enables thermal neutrons to take part in the reaction, and it can be seen from the data of Table I that only three of the nuclear reactions for the production of phosphorus isotopes are in this category: their thermal neutron cross-sections are[95]: $^{31}P(n, \gamma)^{32}P$, $190 \pm 10$ mb.; $^{35}Cl(n, \alpha)^{32}P$, $< 0{\cdot}05$ mb.; $^{33}S(n, p)^{33}P$, $15 \pm 10$ mb. (1 mb. = $10^{-27}$ cm.$^2$). For reactions induced by neutrons of higher energy, graphs showing the variation of cross-section with neutron energy are given by Hughes and Schwartz.[95]

With the exception of $^{32}P$ and $^{33}P$ the radioactive isotopes of phosphorus have very short half-lives, and are therefore of little practical use. From the point of view of nuclear properties one might expect $^{32}P$ and $^{33}P$ to be of about equal importance, but the difficulties inherent in $^{33}P$ production have resulted in $^{32}P$ being the only isotope of importance.

## PREPARATION OF $^{32}$P

Of the nuclear reactions given in Table I there are three that are induced by neutrons, and since nuclear reactors provide an abundant and relatively cheap supply of neutrons these are the reactions used for the production of $^{32}P$. The $^{31}P(n, \gamma)^{32}P$ reaction yields radiophosphorus in the presence of a large amount of inactive phosphorus, from which it can be separated to a considerable extent in suitable cases; on the other hand the $^{32}S(n, p)^{32}P$ and $^{35}Cl(n, \alpha)^{32}P$ reactions produce $^{32}P$ in a carrier-free condition, that is with no inactive phosphorus present except for the small amount which may have been present as an impurity in the target material. A number of other nuclear reactions will take place giving rise to other radioactive species, but by chemical separation all impurities other than phosphorus isotopes can be removed. (Thus Fermi[49] separated radiophosphorus by chemical processes from the products of all three neutron-induced reactions. For the separation of radiophosphorus from irradiated sulphuric acid or from a solution of irradiated ammonium chloride in dilute nitric acid, sodium phosphate was added as a carrier and the phosphorus was precipitated as a phosphomolybdate. Irradiated phosphoric acid was diluted and treated with sulphuric acid and sodium silicate; the silicate was then converted to an insoluble form which carried the radiophosphorus.) Other phosphorus isotopes will very rapidly decay to insignificant levels with the exception of $^{33}$P which is present to the extent of about 1% or less in the radiophosphorus produced from sulphur as a result of the $^{33}S(n, p)^{33}P$ reaction.

### The $^{32}S(n, p)^{32}P$ Reaction

This is the most important reaction for the production of $^{32}$P. Early attempts to obtain radiophosphorus by this process involved the use of neutrons emitted by radium–beryllium sources, and in view of the very small flux available the amounts produced were very small. The target material in these early experiments was usually carbon disulphide, which was used by Alikhanov[96] at about the same time as Fermi carried out the separations from sulphuric and phosphoric acids and from ammonium chloride. Govaerts showed that by simultaneous irradiation and electrolysis of carbon disulphide between copper electrodes radiophosphorus was deposited on the electrodes, and could be recovered by treatment with nitric acid[97–8]; an increase in weight of the anode was observed[97] which could not be due to the minute amounts of radiophosphorus formed, and appears to have arisen from the deposition of decomposition products of carbon disulphide.[98] Oxidation of the radiophosphorus to phosphoric acid by means of bromine, and extraction from the organic phase with water after the addition of inactive phosphoric acid as carrier, enabled sources of any desired activity and weight to be produced.[99] Carrier-free $^{32}$P was obtained by the irradiation of a solution of white phosphorus in carbon disulphide; the white phosphorus was converted to insoluble red phosphorus during the irradiation, and radiophosphorus produced was absorbed by the precipitate and could be separated from it by extraction with water.[100] The $^{32}$P in this case could be formed by both the $^{32}S(n, p)^{32}P$ and the $^{31}P(n, \gamma)^{32}P$ reactions. In an extensive review[101] Govaerts has described a great deal of the early work on radiophosphorus preparation, and has discussed those properties of phosphorus-32 which were known at that time. A later review by Dzantiev and Neĭman[101a] includes an extensive bibliography.

### Methods of Separation

Other methods used for the separation of radiophosphorus from irradiated carbon disulphide include precipitation as ferric phosphate,[102] removal of the carbon disulphide by distillation,[102] and extraction of the phosphorus by nitric acid in the presence of air and a small amount of iodine.[103] The radiophosphorus can be recovered from the aqueous medium by precipitation as a phosphomolybdate or as magnesium ammonium phosphate in the presence of a phosphate carrier. In more recent work a combination of these techniques has been employed[104]: extraction with nitric acid, hydrogen peroxide, water, or 10% sodium hydroxide solution gave yields of 70 to 80%, and these are increased by distillation of the carbon disulphide during the last stages of the extraction process. The electrolytic method of separation has been applied more recently to carbon disulphide irradiated by neutrons from a Cockcroft–Walton machine.[105]

A few investigations have been carried out on the separation of radiophosphorus from other sulphur compounds. McIsaac and Voigt[106] developed a method of separation from irradiated sodium sulphate by adsorption on a cation exchange resin which has been saturated with iron and subsequently treated with ammonium hydroxide. The phosphorus was removed from the column by elution with sodium hydroxide solution and the solution was then passed through a second ion exchange column, this time in acid form, in order to remove the sodium ions.

Radiophosphorus is adsorbed when a solution of an irradiated salt such as a sulphate or sulphite is passed through an alumina column.[107-8] The target salt can be removed from the column by treatment with ammonium hydroxide and hydrogen peroxide. This does not appreciably affect the adsorbed phosphorus which can then be desorbed by sodium hydroxide. Another possible adsorbent is magnesium oxide,[107] which can subsequently be dissolved in acid; magnesium ions can then be removed by ion exchange. If magnesium sulphate is used as the target material and a solution of the target is then treated with ammonium hydroxide, the suspension of magnesium hydroxide formed acts as an adsorbent and the adsorbed phosphate can subsequently be recovered in the same way as from magnesium oxide.[108]

Korshunov and Shafiev[109] found that radiophosphorus can be extracted from irradiated sulphur monochloride by adsorption on an air-dried silica-gel column. The target material is eluted with carbon tetrachloride and the phosphorus obtained in 95% yield by elution with acidified water.

Although some of these methods are convenient for the preparation of small quantities of radiophosphorus in the laboratory, they are not readily adapted for large scale production. The most suitable target material for bulk irradiation in a reactor is elemental sulphur, and a number of processes have therefore been devised for the extraction of radiophosphorus from irradiated sulphur.

### EXTRACTION FROM A MELT

The first method of producing large amounts of radiophosphorus by this process involves pouring molten sulphur into boiling concentrated nitric acid.[110] The aqueous phase, which contains nearly all the phosphorus together with a little sulphuric acid and other impurities, is evaporated to dryness and taken up in water to which a little hydrochloric acid is added. The phosphorus is then removed from the solution by co-precipitation with ferric hydroxide, and finally freed from the iron by means of a cation exchanger, or by extraction of the iron into *iso*propyl ether from a solution in 9 N. hydrochloric acid.

This method did not prove to be very satisfactory in practice and was difficult to adapt to remote operation, and it therefore underwent a series of modifications. Instead of the sulphur being melted and then poured into boiling acid it was melted and mixed with 16 N. nitric acid in an autoclave, and for the subsequent separation of phosphorus by co-precipitation lanthanum hydroxide was used instead of ferric hydroxide. (The small amount of iron present as an impurity in the nitric acid phase was removed as the hydroxide before the lanthanum was added, the precipitation being carried out at a pH of over 11 so that phosphorus would not be co-precipitated.) An ion exchanger was used to separate the lanthanum from the radiophosphorus, which was obtained in a carrier-free solution as phosphoric acid.[111] Kenny and Spragg[112] suggested that adsorption of the phosphorus on dialyzed iron in the presence of a suitable amount of sulphate, instead of co-precipitation with a trivalent metal hydroxide, would lead to separation of the phosphorus from chromium and aluminium, which are present as impurities if stainless steel equipment is used, and which interfere in the final purification step by retaining some of the phosphorus on the ion-exchange column.

Meanwhile it was found by Butler[113] that the use of dilute nitric acid, under sufficient pressure to raise its boiling point to the melting point of sulphur, gives yields comparable with those obtained by the use of concentrated acid but gives rise to far less corrosion products from the autoclave. The purification process follows the same lines as in the Cohn method, and it is found that better yields can be obtained with lanthanum hydroxide as a carrier than with ferric hydroxide. This method, with slight modifications, has been extensively used for the large scale production of radiophosphorus at Oak Ridge in the U.S.A.[114] and at Harwell in Great Britain.[115-7] A rocking autoclave, described by Arrol,[116] was brought into use at Harwell; this was used for mixing the two phases during the extraction process, and was provided with a ridge dividing the base into two compartments so that the sulphur could be allowed to solidify in one of them and the aqueous layer then decanted into the other. The use of a container of borosilicate glass inside the pressure vessel and the elimination of metal parts of the apparatus wherever possible greatly reduce the difficulties of purification of the product.

Another reagent which has been used for the extraction stage is acetic acid to which sufficient acetic anhydride has been added to bring its boiling point to the melting point of sulphur.[118] The mixture is refluxed and mixed by a current of air, and the aqueous layer is then separated and distilled. The subsequent purification steps are similar to those already described, but the overall yield is only about 80% and the technique imposes some limitations on the amount of sulphur which can be handled. However, by an alternative purification procedure, involving evaporation to dryness of the extract solution followed by leaching of the radiophosphorus with dilute mineral acid, yields of over 90% can be attained.[119]

### EXTRACTION FROM A SOLUTION

In this method the mass of irradiated sulphur is dissolved in a suitable organic solvent and the phosphorus can then be extracted by an aqueous reagent. A wide variety of organic solvents can be used: these include tetrachlorethane, tetrabromoethane, dichloroethylene,[120] trichloroethylene,[120-1] chloroform,[109] carbon disulphide,[120,122] and toluene.[123,109] In one process[120] the radiophosphorus is extracted by a halogen acid, the yield at this stage being 60–89%. About 25% of this material is lost during the purification procedure, in which metallic impurities are removed on an ion-exchange column and the product is treated with hydrogen peroxide. Yields of about 90% can be obtained by using double-distilled water as the extracting agent.[123] The aqueous solution is then evaporated to dryness and treated with hydrogen peroxide, and the phosphorus which has been adsorbed on the walls of the evaporator is desorbed by dilute hydrochloric acid. The resulting product contains less than 1% of impurities.

A process which has been proposed for use in Japan[122] involves extraction of the radiophosphorus from a solution of irradiated sulphur in carbon disulphide; for this purpose dilute ammonium hydroxide solution was found to be the best reagent. The aqueous solution is evaporated to dryness and the product taken up in fairly concentrated nitric acid. After being evaporated again and taken up in dilute hydrochloric acid it is purified by means of ion exchange columns. An alternative method of purification involves extraction of the radiophosphorus with butyl acetate in the presence of ammonium molybdate followed by back extraction with water. The phosphomolybdate is then removed by extraction with tributyl phosphate. Yields of over 90% can be obtained by either procedure.

Poczynajło and Campbell[121] have suggested a procedure by which the irradiated mass of sulphur (carefully purified before irradiation) is digested with very dilute hydrochloric acid under reflux for an hour before the solvent is added. The mixture is then refluxed for a further half hour after which the organic solvent is distilled off and the product filtered and purified. The best solvent for this process was found to be trichloroethylene with which yields of $\sim 90\%$ can be obtained.

It is possible to extract radiophosphorus by adsorption from a solution of irradiated sulphur in carbon disulphide. Possible adsorbents include alumina[124] and silica gel.[125] A production process based on adsorption has been suggested[125]; the sulphur is converted into the $\alpha$ form before irradiation so that the irradiated mass is completely soluble in carbon disulphide. The solution in carbon disulphide is passed through a column of adsorbent and the small amount of sulphur adsorbed is eluted with pure carbon disulphide; the radiophosphorus is then removed by a suitable reagent. The best eluant was found to be 5 N. nitric acid and the best adsorbent silica gel, treated with ammonium hydroxide, hydrochloric acid, and water, and then dried by a current of air. With these reagents a yield of 80% can be obtained.

### EXTRACTION BY DIFFUSION

During the transformation of sulphur from the rhombic to the monoclinic form radiophosphorus diffuses rapidly from the sulphur grains and can be extracted with boiling water. Powdered sulphur, of grain size less than 5μ, is purified by treatment with hydrochloric acid, irradiated, and then washed with hot water containing *sec.*-octyl alcohol as a wetting agent. This washing process removes radioactive impurities from the surface of the sulphur grains, but does not extract the radiophosphorus to any appreciable extent. (The chief impurities concerned are $^{35}$S in water-soluble forms such as sulphuric acid, and active material which has recoiled from the irradiation cans.) The sulphur is then mixed with water and a small amount of *sec.*-octyl alcohol and the mixture is boiled for an hour or more, after which the alcohol is distilled off. The resulting aqueous solution is separated from the sulphur by filtration and evaporated to a suitable volume.[126-8] In an earlier purification procedure, designed for use with other wetting agents, the mixture was evaporated to dryness and organic matter was destroyed with nitric acid, after which the phosphorus was taken up in water.[129] The yield of radiophosphorus obtained by this process is only about 76% if sublimed sulphur is used, but can be increased to 93% if 5μ-micronized sulphur is used.

### EXTRACTION BY DISTILLATION

When an irradiated mass of sulphur is distilled in a nitrogen atmosphere the residue contains all the radiophosphorus. This is refluxed for an hour with very dilute hydrochloric acid and a little hydrogen peroxide to remove traces of organic matter, and a very high yield of radiophosphorus is obtained as a solution of phosphoric acid. This process, which is ideally suited to remote control, has the advantage of producing no radioactive waste, and the distilled sulphur, being in a very high state of purity, can be re-irradiated without further treatment.[130-1]

### EXTRACTION BY RECOIL

In the course of a nuclear reaction in which a particle or photon is emitted the product nucleus recoils some distance from its original position. In the case of the $^{32}S(n, p)^{32}P$ reaction the recoil distance may be up to 0·65 μ,[132] and therefore if very small particles are irradiated an appreciable proportion of the product atoms escape and can be stopped in an inert receiver in which the particles are suspended. The $^{35}$S produced as a by-product by the $^{34}S(n, \gamma)^{35}S$ reaction has a very much smaller recoil range and therefore very little of it can leave the sulphur particles. As a result the radiophosphorus is obtained more or less free from radiosulphur. $^{32}$P has been obtained carrier-free in this way with water as the receiver,[131-2] but the yield is small and the method does not form a satisfactory basis for a production process.

## Other Methods of Purification and Concentration of $^{32}$P

In addition to the purification methods already mentioned a few processes have been described which could be used in the production of radiophosphorus. The separation of phosphate ions from iron ions can be achieved by the precipitation of iron as the hydroxide followed by precipitation of bismuth phosphate.[143-4] The bismuth phosphate precipitate is then dissolved in a halogen acid and the bismuth removed by the precipitation of bismuth sulphide with hydrogen sulphide or by the hydrolysis of bismuth salt.

Carrier-free radiophosphorus can be concentrated from a solution of orthophosphate by adsorption on ignited barium sulphate.[145] Other cations are retained in solution during the adsorption stage by the addition of a calculated amount of ammonium hydroxide, and the radiophosphorus is subsequently desorbed by a small amount of very dilute hydrochloric acid and purified by treatment with an ion-exchange resin. The yield from this process is about 95%.

### The $^{31}P(n, \gamma)^{32}P$ Reaction

Since this reaction produces $^{32}P$ in the presence of a large amount of inactive phosphorus it is not generally used for the preparation of carrier-free $^{32}P$, but it is a convenient process to use when there is no objection to the presence of carrier. One important advantage is that the product does not contain $^{33}P$, which is formed when sulphur is irradiated. The target is usually red phosphorus, and as there are no significant radioactive by-products no elaborate chemical processing is required.

Although the irradiation of phosphorus compounds is not a satisfactory method for the production of carrier-free radiophosphorus, the active product can be separated from the target material in certain cases, since the recoil of the product nucleus often results in the breaking of chemical bonds and the formation of different compounds. Thus neutron irradiation of triphenyl phosphate in benzene solution yields $^{32}P$ partly in ionic form, which can be extracted by water,[134] and $^{32}P$ may also be extracted by water from a solution of irradiated triphenylphosphine in benzene.[135] The best reagent for the extraction of radiophosphorus from irradiated tributyl phosphate has been found to be potassium hydroxide of pH 12·5, which gives a yield of over 50%.[136] Another compound which may be used for the preparation of carrier-free $^{32}P$ is triphenylphosphine oxide. The radiophosphorus can be extracted by water from a solution of this target in chloroform, or can be co-precipitated with ferric hydroxide by means of ammonium hydroxide from an alcoholic solution, the phosphorus then being separated from the iron on an ion-exchange column.[137]. The difficulty with all these processes is that the organic compounds are likely to undergo extensive decomposition under reactor irradiation, and the method is therefore unsuitable for large scale production.

### The $^{35}Cl(n, \alpha)^{32}P$ Reaction

Although carrier-free $^{32}P$ can be produced by this reaction the yields are very small and the radiophosphorus must be separated from large amounts of other radioactive species. The reaction has therefore not been used in any production process, but radiophosphorus can be extracted from irradiated chlorine compounds in a number of ways. Simultaneous irradiation and electrolysis of carbon tetrachloride results in partial deposition of radiophosphorus on the electrodes,[98] and adsorption of the $^{32}P$ on silica gel or on the walls of the irradiation vessel is an alternative separation procedure.[109] Adsorption on the vessel walls may be as high as 80–90% if the carbon tetrachloride contains a trace of water. Separation of the $^{32}P$ from irradiated ammonium chloride can be achieved by co-precipitation with aluminium or ferric hydroxides or with barium sulphate. Other carriers can be used but do not give such good yields.[109] The recoil range of $^{32}P$ atoms in sodium chloride is about 0·5 $\mu$,[138] and therefore separation by recoil may be achieved from a finely powdered target material. Silica and naphthalene have been used as receivers,[133, 138] but only about 1% of the radiophosphorus is recovered.

## PREPARATION OF $^{33}P$

Although $^{33}P$ could have many applications in science and medicine, it has not so far been produced commercially. In principle any of the reactions given in Table I could be used for its production, but the only reaction by which it could be produced in a nuclear reactor is $^{33}S(n, p)^{33}P$. As production by means of an accelerator is very costly, the $^{33}S(n, p)^{33}P$ reaction would seem to be the most promising method; the difficulty is that $^{33}$S is present in natural sulphur only to the extent of 0·75%, so that under pile irradiation a very small amount of $^{33}$P is obtained together with a very large amount of $^{32}$P. Because of the positive $Q$-value for the reaction it is possible to produce $^{33}$P by means of thermal neutrons,[74] which should not give rise to the $^{32}S(n, p)^{32}P$ reaction, but it is difficult in practice to eliminate the higher energy neutrons completely without sacrificing most of the available thermal flux. The problem is therefore one of choosing the best of a number of difficult methods, which may be summarized as:

(1) Production by means of an accelerator. This would be very expensive and simultaneous production of $^{32}$P is very probable.
(2) Irradiation in a pure thermal flux. The difficulty here is one of obtaining a high enough flux with complete elimination of higher energy neutrons. It might be possible to produce small quantities of pure $^{33}$P in this way.[139]
(3) Extraction of $^{33}$P from the mixture produced by pile neutrons by some form of isotope separation technique.
(4) Elimination of most of the $^{32}$P from the mixture produced by pile neutrons by radioactive decay. The snag is that the half-lives are similar, so that there would be very little $^{33}$P left after this process unless the starting material were fairly rich in $^{33}$P.
(5) Preliminary enrichment of $^{33}$S in the sulphur target followed by reactor irradiation.

The advantages and disadvantages of each of these methods have been considered by Westermark,[140] who concluded that the last of these methods was the most promising, in that an enriched sulphur target could be used repeatedly, so that the cost of enrichment would be distributed over many batches of $^{33}$P. By elution of bisulphite ions with hydrochloric acid from an anion exchange resin an appreciable enrichment of $^{33}$S can be achieved,[141-2] and repetition of this process should yield a target material of satisfactory purity. Recovery of $^{33}$P from the sulphur target after irradiation could be carried out in the same way as in the preparation of $^{32}$P.

## PREPARATION OF $^{30}$P

Although it has a half-life of only 2·5 min., $^{30}$P has been obtained in a carrier-free condition by means of the $^{31}P(\gamma, n)^{30}P$ process, the target material being finely powdered red phosphorus mixed with tetralin. After irradiation the inactive phosphorus is filtered off, leaving the $^{30}$P in the tetralin into which it has recoiled during the irradiation.[133,143] The recoil distance, which does not exceed 0·25 $\mu$, has been calculated from the yield and the particle size of the target material for various photon energies.

## PREPARATION OF COMPOUNDS CONTAINING $^{32}$P

Because the formation of radiophosphorus is often accompanied by the rupture of chemical bonds, labelled compounds cannot usually be prepared directly by the irradiation of the corresponding inactive compounds. In some cases part of the radiophosphorus is found in the same chemical form as the target material, and the labelled compound may then be obtained by a careful purification process, but it is usually more convenient to synthesize the required compound from radiophosphorus in the form of the element or of one of its simplest compounds. A number of these syntheses have been described and brief outlines of some of them will be given here as examples of the techniques used. Many labelled compounds are commercially available, and a comprehensive list is given in Radioisotopes, Vol. II.[146] A useful compilation of inorganic syntheses has recently been published.[146a]

Refs. p. 1319

## Preparation of Phosphates

The radiophosphorus obtained from irradiated sulphur is usually found to be mainly in the form of orthophosphate, but various methods have been adopted for the preparation of pure labelled phosphates. Pure disodium orthophosphate has been prepared by warming irradiated red phosphorus with hydrogen peroxide and neutralizing with sodium hydroxide.[147] The red phosphorus used in this work was contaminated with copper during the irradiation, and this was removed by electrolysis before neutralization. Other methods of preparation were not found to give such a high degree of purity. Pure labelled magnesium ammonium phosphate was prepared by Fiskell[148] from irradiated calcium phosphate. The target material was treated with a mixture of ammonium persulphate and perchloric acid, the product diluted and neutralized, and radiophosphorus precipitated as phosphomolybdate. After purification by re-precipitation the molybdate was dissolved in hydrochloric acid and magnesium ammonium phosphate precipitated. This was redissolved and the precipitation step repeated, and the final product was washed with alcohol and ether.

Colloidal suspensions of chromic phosphate have been prepared by boiling a mixture of phosphoric acid, chromic acid, and sodium sulphite solution in the presence of gelatin.[149] Methods of preparation of ortho-, meta-, and pyro-phosphoric acids have been described by Hull,[150] and the preparation of labelled fertilizers (such as superphosphate) has been described by Hill, Fox, and Mullins.[151]

### PREPARATION OF BARIUM DIHYDROGEN HYPOPHOSPHATE

Small portions of irradiated red phosphorus were added to an alkaline solution of potassium permanganate, the mixture was heated for an hour and the manganese dioxide was then filtered off and washed. Glacial acetic acid was added to the filtrate, the mixture was heated to boiling, and barium dihydrogen hypophosphate was precipitated by the gradual addition of barium chloride.[152]

## Preparation of Phosphorous Acid

Labelled phosphorus trichloride was prepared by refluxing irradiated red phosphorus with inactive phosphorus trichloride and pentachloride. The labelled phosphorus trichloride was separated by fractional distillation, added to carbon tetrachloride, and treated with water at $-5°$C. The hydrogen chloride formed was removed by warming to room temperature and washing with carbon tetrachloride, and after filtration the product was warmed to 60°C. under vacuum to extract the last traces of hydrogen chloride.[152]

## Preparation of Phosphorus Chlorides and Oxychloride

A mixture of radioactive phosphorus pentachloride and oxychloride has been produced by passing a stream of chlorine over a heated mixture of charcoal and labelled calcium phosphate and pyrophosphate.[153] From the product phosphorus trichloride was prepared by reduction of the pentachloride with powdered antimony followed by distillation of the trichloride-oxychloride mixture, the vapour being passed over heated charcoal which reduced the oxychloride to trichloride.[153] Another method of preparation of the trichloride[152] has already been mentioned, and phosphorus oxychloride has also been produced by the reaction of labelled orthophosphoric acid with inactive phosphorus pentachloride at a low temperature[154-5] and by the reaction of labelled ferric phosphate with carbonyl chloride.[156]

## Preparation of Organic Compounds Labelled with Phosphorus-32

Full details of the syntheses which had been reported by 1955 have been given in Volume II of *Organic Syntheses with Isotopes*,[157] and a useful bibliography is given by Charlton.[158] Compounds for which syntheses have recently been reported include glycerophosphates,[159-60] glucose-1-phosphate,[159] uridine 5′-phosphate,[161] disodium $\alpha$-naphthylphosphate,[154] adenosine triphosphate,[162-4] *iso*propyl methylphosphonofluoridate,[165] and some thiophosphate derivatives.[166-7] For some of these syntheses biological processes have been used.

## THE EXCITED-ATOM CHEMISTRY OF PHOSPHORUS

In most nuclear reactions a considerable amount of energy is released, and this is in general far in excess of chemical bond energies. In bombardment by charged particles or fast neutrons kinetic energy is imparted to the target nucleus, and if particles are emitted in the reaction the resulting nucleus will recoil from its original site. In either case the nucleus is likely to have sufficient energy for any chemical bonds to be ruptured. In $n, \gamma$ reactions brought about by thermal neutrons the energy imparted by the incident neutron is not sufficient to cause bond rupture, but the $\gamma$-rays emitted have momentum $E_\gamma/c$, where $E_\gamma$ is the $\gamma$-ray energy and $c$ the velocity of light. The conservation of momentum results in the product atom recoiling with an energy of $E_\gamma^2/2Mc^2$, where $M$ is the mass of the atom in atomic mass units. For a phosphorus atom this means that the recoil energy for a 1 Mev. $\gamma$-ray will be about 17 ev., and as most chemical bond energies are between 1 and 5 ev. emission of a $\gamma$-ray of this energy would be expected to lead to bond rupture. It may happen, however, that two or more $\gamma$-rays are emitted in different directions, and in this case bond rupture may not follow.

The first chemical reaction observed to arise from a recoil process was the breakdown of ethyl iodide on neutron irradiation, the radioactive $^{128}$I appearing mainly in a form which could be extracted with water.[1] Reactions of this type, in which the target and product are isotopes of the same element, are referred to as Szilard-Chalmers reactions, and have frequently been used for the preparation of carrier-free radioisotopes. In many cases, although the radioactive product is initially formed in a form which differs chemically from the target material, only a very small fraction of it can be separated radiochemically because recombination occurs under the conditions of the irradiation.[2] Reaction of the radioactive atoms with the target material may also lead to the formation of new compounds,[3] so that in a given reaction a variety of new products may be found, together with a certain amount of apparently unchanged target material incorporating the radioactive isotope. 'Excited-atom' or 'hot-atom' chemistry is concerned with the study of the chemical changes which occur as a result of these nuclear processes.

We may also consider under this heading the chemical effects resulting from those nuclear reactions in which there is a change of atomic number. There must be a chemical change here since the target and product atoms are not of the same element. In addition recoil effects are much greater than they are for $n, \gamma$ reactions and can result in some of the product atoms leaving a powdered target,[4] and the excited state of the product atom can lead to its appearance in unexpected chemical forms.[5]

As only a very small proportion of the atoms of the target element are transformed in these reactions (except in the case of extended irradiations by neutrons in nuclear reactors), the chemical products are present only in trace amounts, and must usually be detected by means of their radioactivity. The usual method of isolation of the products involves the addition of carriers followed by chemical separation[6]; the various fractions are then examined for their radioactivity. This method has two disadvantages: firstly that the addition of carriers and the subsequent chemical operations may lead to further chemical changes in the products of the nuclear reaction, and secondly that unexpected or unknown products will be overlooked since they will usually follow one or other of the carriers added, and will be mistakenly assigned to that chemical form. Of the alternative methods available for the separation of the products, the method of paper electrophoresis or paper electrochromatography has proved of particular value in the study of the excited-atom chemistry of phosphorus,[7-9] and has revealed the presence of some products which have not yet been identified.[9]

For general discussions of the theoretical basis and methods of excited-atom chemistry reference should be made to standard works on radiochemistry[6,10] and to a review of the subject.[11]

The isotopes $^{28}$P, $^{29}$P, and $^{34}$P have very short half-lives, and their chemical forms have therefore not been investigated.

## EXCITED-ATOM CHEMISTRY OF $^{30}$P

Very little is known about the chemical forms in which $^{30}$P is produced. However, when red phosphorus is finely powdered and mixed with tetralin, and then subjected to $\gamma$ irradiation, some of the radioactive phosphorus formed by the $^{31}P(\gamma, n)^{30}P$ reaction is found in a carrier-free condition in the tetralin.[4,12] From the particle size of the target material and the fraction recovered from the tetralin the recoil distance has been calculated for the $\gamma$-energies used.

*Table II.—Recoil Range of* $^{30}$P *Produced by the* $^{31}P(\gamma, n)^{30}P$ *Reaction*[4]

| Max. $\gamma$ energy (Mev.) | 18 | 20 | 22 | 23 |
|---|---|---|---|---|
| Calculated mean recoil energy (Mev.) | 0·16 | 0·27 | 0·36 | 0·40 |
| Range ($\mu$) | 0·08 | 0·10 | 0·18 | 0·23 |
| Range ($\mu$g/cm.$^2$) | 19 | 23 | 42 | 54 |

The experimental results show a wide scatter, and therefore the values of the recoil range are subject to considerable error.

The first row of Table II gives the maximum $\gamma$-energy for each irradiation, the second row gives very approximate computed values for the mean recoil energies, and the last two rows give the observed recoil ranges in microns (for red phosphorus) and in micrograms per square centimetre. The second way of expressing the range is particularly useful, since the range of any particle in terms of the mass per unit area of the stopping medium is independent of the density of that medium.

## EXCITED-ATOM CHEMISTRY OF $^{32}$P

This aspect of the radiochemistry of phosphorus has been extensively studied, and has proved to be of considerable complexity. We shall deal first with the estimates which have been made of the recoil range, and then with the chemistry of the reactions $^{31}P(n, \gamma)^{32}P$, $^{32}S(n, p)^{32}P$, and $^{35}Cl(n, \alpha)^{32}P$ in turn. For the $^{31}P(n, \gamma)^{32}P$ reaction the irradiation of inorganic and of organic compounds will be treated separately.

## THE RECOIL RANGE OF $^{32}$P

On neutron irradiation of finely powdered sulphur suspended in water a considerable fraction of the radiophosphorus produced appears in the liquid phase from which it can be recovered.[4, 13] Similar separations can be achieved by the irradiation of sulphur or potassium sulphate intimately mixed with solid receivers, and by the irradiation of ammonium chloride mixed with silica.[4] In these experiments either the target or the receiver is soluble in dilute acid, so that the fraction of the radiophosphorus appearing in the receiver can be readily determined. With sodium chloride as target and naphthalene as receiver it was found necessary to arrange them in alternate layers for irradiation. The yield of $^{32}$P in the receiver is then only about 1%, but nevertheless the recoil range can be calculated.[14] In Table III are given details of the neutron energies used, the mean phosphorus recoil energies, and the observed recoil ranges for a number of experiments.

Subsidiary experiments showed that during the irradiation of sulphur suspended in water no appreciable diffusion of phosphorus from the sulphur grains occurred and very little sulphur entered the aqueous phase.

## CHEMICAL STATE OF $^{32}$P PRODUCED BY THE $^{31}P(n, \gamma)^{32}P$ REACTION

### IRRADIATION OF INORGANIC COMPOUNDS

The early work on the chemical state of the radiophosphorus produced by neutron bombardment of inorganic phosphorus compounds was mainly confined to the determination of the fractions of the radioactive phosphorus atoms which were 'retained' in the original chemical form on irradiation of phosphorous and phosphoric acids and their salts. The fractions 'retained' included all active phosphorus found in the original form, and much of this could well have arisen by recombination of fragments or by exchange of the active atoms with the inactive atoms of the unchanged target material. Moreover, these reactions could have been brought about either thermally or as a result of the excited state of the active atoms. However, it has been shown by Wilson[15] that thermal exchange between phosphate and phosphite is very small under a wide variety of conditions, and Hull[16] showed that exchange between ortho-, pyro-, and meta-phosphates does not occur. The results of Libby's experiments on phosphorus retention are given in Table IV.[17] From the constancy of the retention shown by phosphates under various conditions it is concluded that the retention is determined by the initial recoil process and not by any of the subsequent processes outlined above. As the radiophosphorus was separated into only two fractions (carried by phosphite and phosphate) no other species could be observed, but Libby considered that any phosphorus formed in the +4 state would be oxidized to the +5 state in aqueous solution.

*Table III.—Recoil Ranges of* $^{32}$P *Produced by the* $^{32}$S($n$, $p$)$^{32}$P *and* $^{35}$Cl($n$, $\alpha$)$^{32}$P *Reactions*[4, 13–4]

| Reaction | Target | Receiver | Neutron energy | Recoil energy (Mev.) | Percentage of $^{32}$P in receiver | Recoil range | | Remarks |
|---|---|---|---|---|---|---|---|---|
| | | | | | | (μ) | (μg/cm$^2$) | |
| $^{32}$S($n$, $p$)$^{32}$P | S | Water | Pile neutrons | | 35 | 0·37 | 77 | Dilute suspension. |
| | S | Water | Pile neutrons | | 25 | | | 0·1 g. S/cc. |
| | S | Water | 11 Mev. (max) | 0·6 | 75 | 0·65 | 135 | |
| | S | $MgCO_3$ | | | | | | Receiver soluble in acid. |
| | S | $(NH_4)_2CO_3$ | | | | | | Receiver soluble in water. |
| | $K_2SO_4$ | MgO | | | | | | Target soluble in water. |
| $^{35}$Cl($n$, $\alpha$)$^{32}$P | NaCl | Naphthalene | Pile neutrons | 0·59 | 1 | 0·5 | 105 | Receiver soluble in benzene. |
| | $NH_4Cl$ | $SiO_2$ | Pile neutrons | 0·59 | 50 | 0·7 | 107 | Target soluble in water. |

*Table IV.—Amounts of Radiophosphorus retained in the Original Chemical form*[17]

| Target | Post-irradiation treatment | Retention (%) |
|---|---|---|

| Tricalcium phosphate | 38 | | 36 | | 32 | 23 |
| Tricalcium phosphate | 48–57 | | | | | 22 |

[a] On hydrolysis 7% appeared in phosphite fraction.
[b] 4–21% found as dehydrated forms of phosphate.

*Table VI.—Chemical Forms of* $^{32}P$ *in Irradiated Phosphorus Compounds*

| Target | Percentage of $^{32}P$ found as | | | | | Reference |
|---|---|---|---|---|---|---|
| | Orthophosphate | Phosphite and hypophosphite | Hypophosphate | Pyrophosphate | Metaphosphate | |
| $Na_2HPO_3,5H_2O$ | 12 | 74 | | 15[a] | | 19 |
| $Na_4P_2O_7$ | 11 | 30 | | 59[a] | | 19 |
| $Na_4P_2O_7,10H_2O$ | 36 | 20 | | 45[a] | | 19 |
| Calcium pyrophosphate | 0·7–14 | | 20–30 | 50–59 | 15 | 23 |
| Calcium hypophosphite | | | present | | | 24 |
| Superphosphate | | | present | | | 24 |

[a] On hydrolysis 2–12% appeared in phosphite fraction.

Other workers confirmed that part of the radiophosphorus from neutron-irradiated orthophosphate was not in the original form, although the amount of non-orthophosphate phosphorus varied from case to case. Attempts were made to elucidate the composition of the non-orthophosphate fraction by the addition of a number of anions of phosphorus oxy-acids followed by careful chemical separations. The various forms of phosphorus observed are shown in Table V.
The chemical forms in which the radiophosphorus was found when other phosphorus compounds were irradiated are given in Table VI.

### CAUSES OF DISCREPANCIES

The very large discrepancies among the results obtained by different workers and the wide variation from sample to sample can be attributed to a number of factors. Fiskell[24] showed that phosphates and phosphites interact under certain conditions to give hypophosphates, and other pitfalls in the accepted analytical procedures have been pointed out.[21] Moreover, the target materials have not always been pure,[23] carriers were added for only a few of the possible products, and variations in the irradiation conditions (which were not clearly stated in most cases) could have a profound influence on the results obtained. Table VII shows the effect of temperature and neutron flux on the form of radiophosphorus produced by the irradiation of a variety of substances.[22]

*Table VII.—Percentage of Activity as Non-orthophosphate* $^{32}P$ *for Various Irradiation Conditions*

| Irradiation conditions | *A* | *B* | *C* |
|---|---|---|---|
| Target material | | | |
| $KH_2PO_4$ | 26·69 | 18·31 | 0·57 |
| Florida land pebble | 48·86 | 48·28 | 31·01 |

| Phosphate glass | 33·49 | 37·97 | 31·33 |

*A* Low neutron flux, low temperature, irradiation period 4 weeks.
*B* High neutron flux, intermediate temperature, irradiation period 11 days.
*C* High neutron flux, high temperature, irradiation period 4 weeks.

The use of paper electrochromatography for the separation of the various species present in the irradiated compounds led to the production of much more reliable data on the composition of the irradiated material, although the interpretation of these data is still a matter on which there is a wide diversity of opinion. Sato, Strain and their co-workers carried out an extensive investigation using this technique. In earlier work they detected the presence of phosphites in a number of irradiated phosphates,[25] and also observed that condensed phosphates, such as trimetaphosphate and tripolyphosphate, could be formed either by neutron or gamma irradiation or by heating of phosphates.[26] However, in all cases they found the major constituent to be the unchanged phosphate. Sellers, Sato, and Strain showed by chemical analysis that the products of neutron-plus-gamma irradiation are essentially the same as those arising from gamma irradiation alone when the irradiations are carried out in a vacuum (Table VIII).[27]

Electrochromatographic analysis showed that for the neutron-plus-gamma irradiation of $Na_2HPO_4$ the distribution of $^{32}P$ is similar to that of the inactive isotope, a

Table VIII.—*Irradiation Products of Phosphorus Compounds*

| Compound | Irradiation | Products found by direct chemical determination (mole per cent) | | | | | |

* A small amount of red radiactive solid was also formed.

very small amount appearing in non-orthophosphate forms, but this was not so for the irradiation of $Na_2HPO_3$ and $NaH_2PO_2$. Moreover, for these two compounds the electrochromatograms formed from neutron-irradiated targets differed considerably from those formed from γ-irradiated targets and subsequently neutron activated. Pairs of electrochromatograms for $Na_2HPO_3$ and $NaH_2PO_2$ are shown superimposed in Figs. 1 and 2. From these results it is clear that while the observed distri-

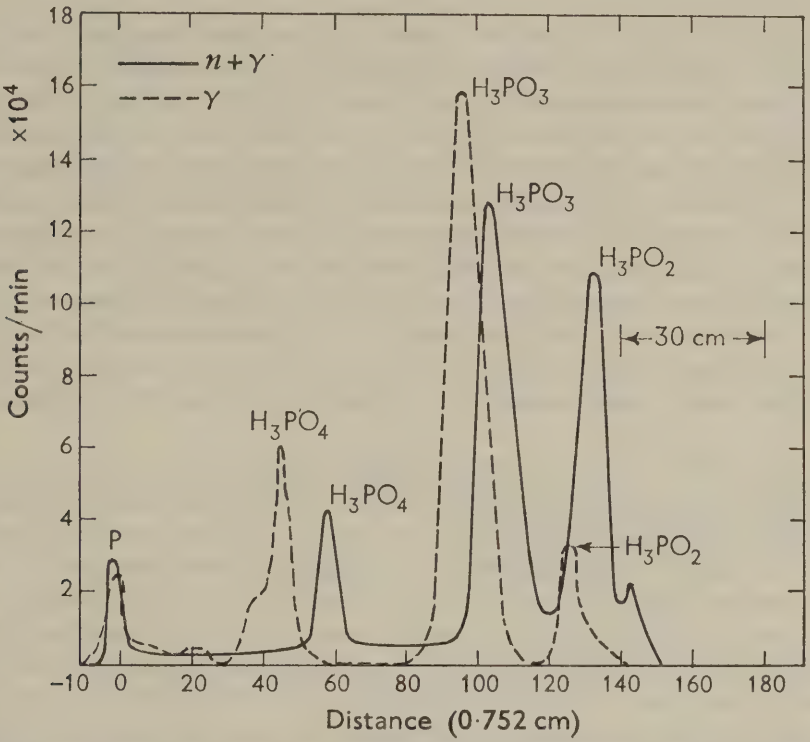

FIG. 1.—Comparison of radioactive products formed by gamma and by neutron-plus-gamma irradiation of $Na_2HPO_3$

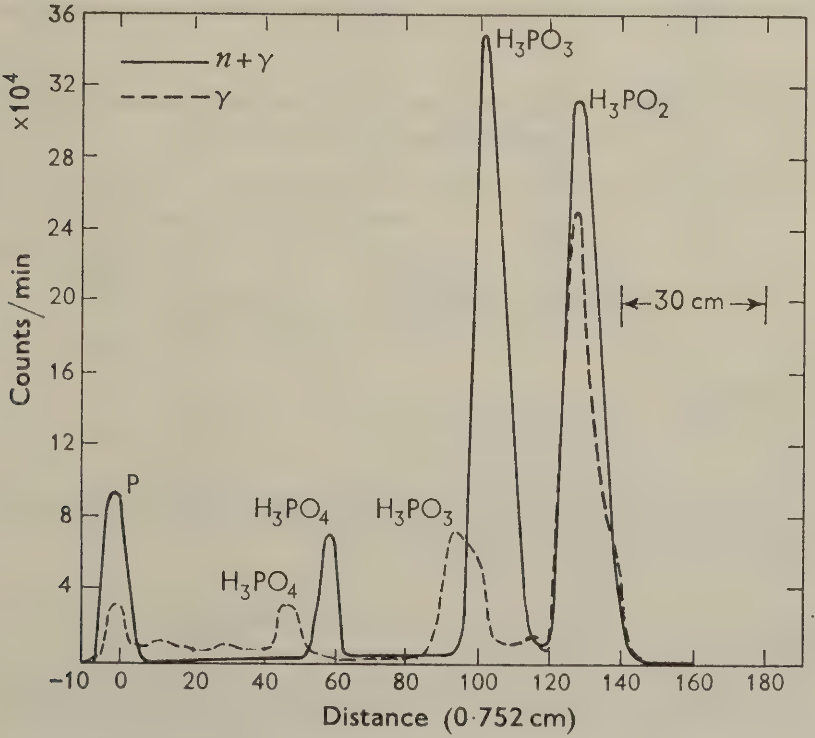

FIG. 2.—Comparison of radioactive products formed by gamma and by neutron-plus-gamma irradiation of $NaH_2PO_2$

bution of $^{32}P$ in irradiated orthophosphate could have arisen solely as a result of the effect of the high $\gamma$-ray flux, the active isotope being formed by neutron capture unaccompanied by chemical change, there must have been a large chemical effect brought about by neutrons in irradiated phosphite and hypophosphite.

### EFFECT OF TEMPERATURE

The fact that very little of the $^{32}P$ formed on neutron irradiation of disodium hydrogen phosphate appeared in non-orthophosphate form led these authors to suggest that the disruption of chemical bonds takes place to a much smaller extent than had been suggested by earlier workers, and to attribute the much lower retention previously observed to the combined effects of neutrons, gamma rays and air. Later, however, they discovered that the temperature of the specimens during irradiation had been 155°C. instead of 40°–50°C. as a result of the action of pile radiation on the quartz containers used, which contained boron as an impurity.[28-9] It had already been shown that thermal annealing can reduce the amounts of non-orthophosphate $^{32}P$ present,[21] and Table IX gives the results of an investigation[30] in which elution from an anion exchange column was used to separate the constituents of irradiated $KH_2PO_4$.[31] The Table shows clearly the change in composition brought about by annealing.

In view of the possible effects of thermal annealing in their previous work, Sato, Sellers and Strain carried out further experiments in which the temperature of the irradiated specimen was kept below 30°C. by the use of pure quartz containers and a lower neutron flux.[29] They irradiated in a vacuum a large number of orthophosphates and condensed phosphates, and in all cases found that the major part of the $^{32}P$ produced was in the form of the starting material. In the irradiated orthophosphates small amounts of other forms of phosphorus were found. These included a trace of material, probably elemental phosphorus, which did not migrate under the conditions of electrochromatography employed, and a small amount of unidentified material which did not correspond with any of the well-known phosphorus compounds; this form of phosphorus was most noticeable in the irradiated monobasic and dibasic sodium, potassium, and ammonium salts. Irradiation of pyrophosphate and trimetaphosphate produced traces of phosphate and of an unidentified product.

*Table IX.—Effect of Thermal Annealing on the Chemical Form of $^{32}P$ in Neutron-irradiated* $KH_2PO_4$ [30]

| | Percentage of $^{32}P$ found as | | | | |
|---|---|---|---|---|---|
| | Ortho-phosphate | Pyro-phosphate | Tri-phosphate | Fraction *A* | Fraction *B* |
| After irradiation | 69 | 3·4 | 14·9 | 8·0 | 4·6 |
| After irradiation and annealing at 175°C. for 24 hr. | 96·3 | 0·2 | 1·1 | 1·2 | 0·4 |

Fractions *A* and *B* were identified, but did not include phosphite, hypophosphite, tetraphosphate, trimetaphosphate and tetrametaphosphate.

In other experiments[28, 32] the effect of a high irradiation temperature on $Na_2HPO_4$ was studied. The temperatures attained by neutron irradiation of the containers were 155°C. for quartz, 368°C. for 'boron-free' glass, and 537°C. for lime glass; slightly lower temperatures were reached with samples in the containers. Samples of $Na_2HPO_4$ irradiated in 'boron-free' or lime glass were almost completely converted to pyrophosphate.

In a discussion of these results, the view is expressed that the $^{32}P$ atoms formed in irradiated phosphates are in general unable to escape from the cages of oxygen atoms which form their immediate environment. This view is based on the electronic bond structure of the phosphate group, and the chemical changes accompanying the irradiation of phosphites and hypophosphites are attributed to their having a less compact cage structure. Recent work by Yoshihara and Yokoshima,[34] in which samples were irradiated in air at temperatures below 50°C. and then subjected to paper chromatography, gave results strikingly different from those obtained by Sato. In Table X are given the chemical forms of $^{32}P$ observed in these experiments. The values quoted are those first obtained after the irradiation; in some cases the values showed a gradual change with time while in others the values fluctuated by a few per cent. With the hydrated salts there seemed to be a slow conversion of phosphite or hypophosphite to phosphate on standing for a few days, attributed to an oxidation process. In irradiated $Na_2HPO_4,12H_2O$ and $Na_4P_2O_7,10H_2O$ no phosphite could be detected, but some of the pyrophosphate present was gradually converted to phosphate. The absence of phosphite in these two cases is rather surprising in view of the large amount found in irradiated $Na_3PO_4,12H_2O$.

* Pyrophosphate and higher polyphosphates.

The results of an investigation by Lindner and Harbottle[35, 9] present an even more striking contrast to those of Sato. Essentially the same technique of paper electrochromatography was used, but the samples were usually irradiated at dry ice temperature for only half an hour and stored in dry ice before analysis. Under these conditions the retention of $^{32}P$ as orthophosphate was often as low as 10%, as shown in Table XI. Preliminary experiments showed that at dry-ice temperature it made very little difference whether the irradiation was carried out in air or in a vacuum, and the results given in Table XI show that the products from anhydrous compounds are not significantly affected by preliminary drying of the samples. It was also shown that the amount of radioactive orthophosphate formed in the irradiation of $Na_2HPO_4,2H_2O$, which was about 16% at this temperature, is increased to 37% when the irradiation is carried out with no cooling in the same position in the reactor. The effect of thermal annealing is shown in Table XII, from which it can be seen that there is a general increase in the yield of orthophosphate on annealing at 30°C. for about 4 days.

From these results it is concluded that bond rupture occurs in a very large proportion of the activated phosphate groups, giving rise to a considerable range of products, and that thermal annealing, which is a fairly rapid process at higher temperatures, occurs at an appreciable rate at room temperature. This picture fits reasonably well with the results obtained by earlier workers and by Yoshihara,[34] but does not seem to account for the very high retention of orthophosphate observed by Sato[29] at 30°C. However, in Sato's experiments the irradiation period was five days, and it is shown by Lindner that extensive annealing can occur during such an irradiation, even with a moderate neutron and gamma flux.

### EFFECT OF HYDRATION

The effect of 'dilution' of the phosphate groups by crystal water can be clearly seen from Table XI. Condensed compounds containing more than two phosphorus atoms per molecule are not readily formed when the phosphate groups in the target are separated by water molecules, so that in the hydrated target materials the yields of tripolyphosphate are lower and the yields of orthophosphate higher than in the anhydrous compounds, whilst the yields of pyrophosphate are more or less constant. The yields of the unknown species C change in much the same way as those of tripolyphosphate, and it therefore seems likely that C has two or more phosphorus atoms per molecule. The *iso*hypophosphate formed in these irradiations was found

to be specifically labelled in the trivalent part of the molecule; this implies that whilst the activated phosphorus atom may appear in a reduced state there is no appreciable effect of the phosphorus recoil on the oxidation state of the phosphate group to which it becomes attached. This is also borne out by the absence of pyrophosphate from the observed products. It is concluded that at the sites in the lattice where the recoiling $^{32}$P atoms are trapped little disorder is produced and there is little fragmentation.

A number of other phosphorus compounds were studied briefly in the course of this investigation, and gave a range of recoil products different from that observed for orthophosphates. The results are summarized in Table XIII, in which all unidentified products are combined although a number of separate peaks were observed.

EFFECT OF ANNEALING

The effects of annealing irradiated ammonium and potassium dihydrogen phosphates under a variety of conditions have been studied by Claridge and Maddock.[36–7] In contrast to Lindner's results[35] they found a threshold for thermal annealing at 40 to 50°C., but as their irradiations were carried out at reactor temperature some annealing must have occurred at this stage, resulting in the removal of all fragments capable of undergoing recombination at this temperature. They observed two parameters of the phosphates before and after annealing; these were 'orthophosphate retention' and 'total phosphate retention', the difference between them being attributable to fragments which yield, for example, hypophosphate or pyrophosphate on solution. On thermal annealing at temperatures below 100°C. the orthophosphate retention was found to increase rapidly at first, but at a later stage the rate of increase fell to a fairly constant value of about $\frac{1}{2}$% per hour. The total phosphate retention showed little change until the whole of the phosphate had been converted to orthophosphate, the effect of annealing being the formation of fragments which give rise to orthophosphate on solution, from fragments which give rise to other anions containing pentavalent phosphorus atoms. There is little contribution to orthophosphate formation from reduced phosphorus species at these temperatures, but at temperatures above 100°C. the orthophosphate and 'total phosphate' retention rise together, and the process must be either

reduced phosphorus fragments → orthophosphate fragments

or

reduced phosphorus fragments → 'polyphosphate'
→ orthophosphate fragments

Annealing with ultra-violet light or with 1·8 Mev. electrons brought about some change in the orthophosphate retention, but the effect on the total phosphate retention was much more pronounced, and the kinetic curves obtained indicate a first-order recombination process in the early stages, followed by a slower process of uncertain kinetics. Although the orthophosphate retention is only slightly increased by photon annealing, both the rate and extent of the increase on subsequent thermal annealing are found to have been enhanced, the degree of enhancement being related to the increase in total phosphate retention which had occurred during the photon annealing process. The effect of annealing by electrons is similar, but in this case there is a significant change of orthophosphate retention during the radiation annealing process as well as during the subsequent thermal annealing. Radiation annealing therefore seems to operate mainly by converting reduced phosphorus fragments to potential 'polyphosphate' fragments, the increase in orthophosphate retention on electron annealing being possibly attributable to local thermal effects of the radiation.

Some further experiments on the thermal annealing of irradiated phosphates have been briefly described.[38] On annealing of irradiated $Na_3PO_4$ at 167°C. a rapid increase in the amount of orthophosphate occurs, the proportion of $^{32}P$ found in this form changing from 30% to 70% in about an hour; in the subsequent slow stage the proportion of orthophosphate reaches about 85% in the course of 24 hr. The initial stage of the annealing of irradiated $Na_2HPO_4$ resembles that for $Na_3PO_4$, but is followed by a fairly rapid conversion of orthophosphate to pyrophosphate and other polyphosphates. In both cases the increase of orthophosphate content in the early part of the anneal is presumably due to the conversion of polyphosphate fragments to fragments which form orthophosphate in solution, as there is very little decrease in the amounts of reduced phosphorus species formed, but the behaviour of $Na_2HPO_4$ during the later stages is surprising. Annealing of irradiated sodium pyrophosphate was found to result in an increase in the pyrophosphate content at the expense of other polyphosphates.

### IRRADIATION OF PHOSPHORUS TRICHLORIDE

Apart from the studies of salts of phosphorus oxy-acids there has been little work on the effects of neutron irradiation on inorganic phosphorus compounds. Some work on phosphine[27] has already been mentioned, and the effect of irradiation of phosphorus trichloride has been studied by Hein and his co-workers.[39-40] In the course of their earlier work[39] they found that for irradiation periods of 19 hr. to 3 weeks and for temperatures of 30°–140°C. the amount of $^{32}P$ retained as $PCl_3$ is more or less constant, the mean value being 88%. The chemical state of the remaining 12% of the radiophosphorus is not very clear: 1–2% was found on distillation in the same fraction as $PSCl_3$, but it was thought unlikely that it could be in this form, a further 5% was sometimes found as $POCl_3$, and there was always a little $^{32}P$ left in the residue of high boiling-point components at the end of a distillation. Although in this irradiation $^{32}P$ can be produced by the $^{35}Cl(n, \alpha)^{32}P$ reaction, this process would contribute only about 1% of the total $^{32}P$, so that it cannot account for that part of the radiophosphorus not in the form of $PCl_3$.

In later work[40] shorter irradiation times were used, and lower values for the retention were observed, the lowest being 62%; extrapolation to zero irradiation period indicated that 50 to 60% of the radiophosphorus would remain as $PCl_3$ under these conditions. The composition of the remainder of the active material was very uncertain; a very small amount was found to distil with $PSCl_3$, and when lightly irradiated samples were distilled at atmospheric pressure a fraction of high specific activity distilled at the end of the $PCl_3$ fraction, but the rest of the activity remained in the distillation flask. The possibility of the presence of $P_2Cl_4$ was considered, as this might decompose to $PCl_3$ and give rise to the high specific activity fraction, but no firm conclusion could be reached. Irradiation by $\gamma$-rays produced a marked increase in the yield of $^{32}P$ as $PCl_3$, and it was thought that this accounted for the results

**Refs. p. 1360**

obtained in the longer neutron irradiations where up to 95% retention was observed. Some of the results of this work are given in Tables XIV and XV.

In an investigation by Henglein[40a] a value of about 65% was obtained for the retention in irradiated solutions of $PCl_3$ in carbon tetrachloride, but a marked fall of the retention was found when hydrogen-containing solvents were used (Fig. 3).

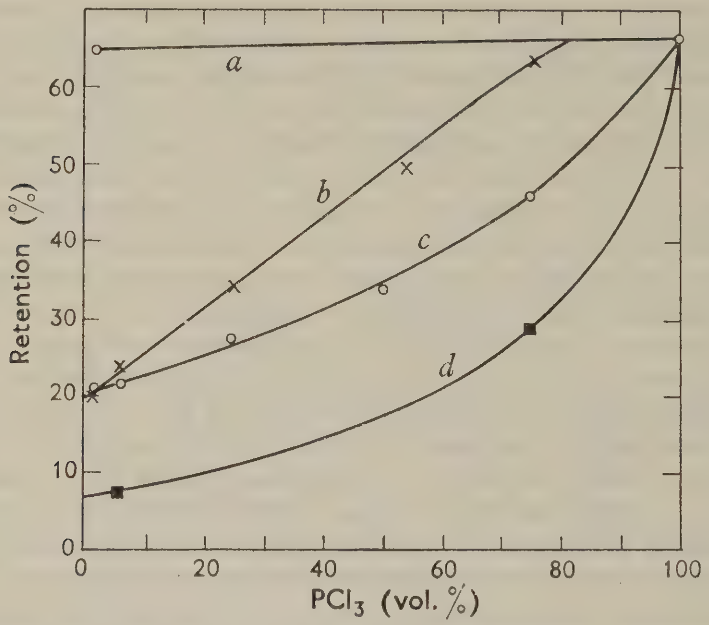

FIG. 3.—Retention of $^{32}PCl_3$ in organic solutions solvent: *a* carbon tetrachloride
*b* benzene
*c* *cyclo*hexane
*d* *cyclo*hexene

This effect was attributed to the removal of chlorine atoms formed by the disruption of the $PCl_3$ molecule, and from the fact that the change in retention with increase in solvent concentration was gradual it was concluded that the reactions leading to

retention must occur in the neighbourhood of the track of the recoiling phosphorus atom.

Preliminary work on the irradiation of $POCl_3$ indicated that a variety of products was formed.[40] These were mainly $^{32}PCl_3$ and $^{32}POCl_3$, but there appeared to be a trace of $^{32}PSCl_3$ and there was a considerable unidentified residue. A more detailed study[40b] revealed that the proportions of the various products formed were markedly dependent on the time of irradiation and on the conditions of irradiation and dissolution, as shown in Table XV. The fraction identified as 'high-boiling component' was thought to be $^{32}PCl_5$, but this could not be proved and the evidence was conflicting.

It was concluded that the chief primary product was $^{32}PCl_3$, and that conversion to other species during the irradiation resulted from radiation-induced exchange reactions. This view is supported by the effect of subsequent $\gamma$-irradiation, and by the effect of small amounts of carrier $PCl_3$ in maintaining a high yield of $^{32}PCl_3$. (The amounts of carrier used were such that there was only a small contribution to the $^{32}P$ activity from activation of the carrier.) No significant exchange between $PCl_3$ and $POCl_3$ could be detected in experiments conducted in the absence of radiation. The high-boiling component, which appears to be produced from $^{32}PCl_3$ under the influence of radiation, is itself converted to $^{32}POCl_3$ as irradiation proceeds, so that the final product is almost entirely $^{32}POCl_3$.

## Irradiation of Organic Phosphorus Compounds

Although the chemical state of radiophosphorus has not been studied as extensively in neutron-irradiated organophosphorus compounds as in inorganic compounds of phosphorus, the first investigation was carried out as long ago as 1937 when it was found that 40% of the activity produced by the irradiation of triphenyl phosphate in benzene could be extracted by water, presumably in ionic form.[41] It was also observed that the active material could be adsorbed by carbon, and carrier-free material could be produced by either method. Very little attention was given to this subject, however, until 20 years later, although in the search for methods of production of carrier-free $^{32}P$ it was observed that extraction of radiophosphorus with water from solutions of irradiated triphenylphosphine gave yields of about 50% with benzene as the solvent[42] but of only 3% with xylene as the solvent.[43] In the latter case it was suggested that the reason for the very low yield might be exchange between the radioactive phosphorus atoms and the inactive phosphorus atoms of the triphenylphosphine, but the discrepancy between the behaviour in the two different solvents has not been satisfactorily explained. More recent work[44] has shown that only 2–3% of the total activity remains as triphenylphosphine when the irradiation is carried out in vacuum, and that about half of the activity is found as triphenylphosphine oxide, diphenylphosphinic acid, benzenephosphonic acid, benzenephosphinic acid, phosphorous acid, and phosphoric acid. As in the early experiments on inorganic phosphorus compounds the identification of the products in this case was unsatisfactory as carriers were added only for species thought to be possible, and in fact about half of the total activity remained unidentified.

About 85% of the radioactive phosphorus in irradiated triphenylphosphine oxide can be extracted with water from a solution in chloroform, and about 70% can be co-precipitated with ferric hydroxide from alcoholic solution. Under these conditions all the triphenylphosphine oxide remains in the organic solvent.[45]

### IRRADIATION OF TRIMETHYLPHOSPHINE

The active volatile products of the irradiation of trimethylphosphine have been separated by gas chromatography,[44, 46] and their yields are given in Table XVI. In each experiment the remainder of the activity was found on the walls of the irradiation ampoule. It can be seen that the fraction of the radiophosphorus retained as trimethylphosphine is very small and decreases as the pressure of the target compound is reduced. Dilution of the target material with argon resulted in a reduction of the yields of all volatile products, and it was therefore concluded that bond rupture occurred in most if not all recoils, the residual $(CH_3)_3{}^{32}P$ being formed by recombination. On the other hand dilution with krypton gave rise to an increase in the yields of di- and tri-methylphosphines so that the results are not fully consistent with this explanation. In some cases the active deposit on the ampoule walls (amounting in some cases to over 99% of the total activity) was examined by electrochromatography, and it was established that the activity was not due to orthophosphate or phosphite.[44a]

### IRRADIATION OF BUTYL PHOSPHATES

A number of investigations have been carried out into the chemical state of radiophosphorus in neutron-irradiated tributyl phosphate (TBP). The amount of carrier-free $^{32}P$ which can be extracted into an aqueous phase varies with the pH,[47] reaching a maximum of 54·3% for potassium hydroxide solution of pH 12·5. Campbell, Poczynajlo, and Siuda[48] examined the active irradiation products by the addition of carriers followed by solvent extraction and conventional chemical separations. As in other studies where this technique is used there is the possibility of unknown or unidentified products appearing in some of the fractions obtained, and this has been indicated in Table XVI. It can be seen that the amounts of radiophosphorus retained as TBP increase with the severity of the irradiation conditions, and must therefore be mostly attributed to recombination of fragments produced during the recoil process, the primary retention being not greater than 5 or 6%. It is suggested that the recombination process involves organic radicals formed by the irradiation. The dibutyl phosphate (DBP) fraction is little affected by a change of irradiation conditions, most of the recombination taking place at the expense of monobutyl phosphate (MBP) and inorganic phosphorus compounds, but it must be borne in mind that the DBP and MBP fractions probably contain other unknown products. Most of the inorganic phosphorus is found in the form of orthophosphate and orthophosphite, the contribution from other oxyacids and phosphine being very small.

The effect of the conditions of the irradiation has been more fully studied.[49] A thermal neutron flux of $2{\cdot}6 \times 10^{11}$ neutrons cm.$^{-2}$ sec.$^{-1}$, and gamma and fast neutron doses of about $10^4$ to $10^5$ rads were used, so that considerable recombination

would be expected from the results given in Table XVII. The results of these experiments, presented in Table XVIII, show this to be the case, but the introduction of scavengers leads to a distribution of products similar to that previously obtained at a low neutron flux; dilution of the target TBP does not further reduce the yield of active TBP. From the effects of scavengers and of dilution, and from the distribution of irradiation products of mono- and di-butyl phosphates in the presence of air as a scavenger (Table XIX), responsibility for the yields of the various organic products can be apportioned to various types of process as shown in Table XX. The basis for this apportionment is that thermal reactions are eliminated by scavengers, which

remove any radicals formed before they can be reached by a diffusing phosphorus atom, and that dilution of the target material in the presence of scavengers leads to a reduction in the amount of recombination by either thermal or 'hot' reactions; on the other hand only 'hot' reactions can account for the active TBP formed on irradiation of DBP or MBP in the presence of a scavenger. The effect of a change of temperature on the distribution of products is attributed to an increase of the 'hot' reactions at the lower temperature as a result of the lowering of the diffusion coefficients; the excited phosphorus atom is then less likely to escape from its immediate environment of organic radicals. It can be seen that primary retention (one or more P-organic bonds remaining intact) and 'hot' reactions contribute very little to TBP formation but are entirely responsible for MBP formation. Most of the active TBP is produced after the primary event by reactions occurring outside the nest of radicals formed in the neighbourhood of the recoiling atom.

## THE CHEMICAL STATE OF $^{32}$P PRODUCED BY THE $^{32}$S($n, p$)$^{32}$P REACTION

The atoms of $^{32}$P produced by irradiation of sulphur are subject not only to 'hot' atom reactions, but also to the chemical effects resulting from their presence in trace quantities in solution or in a foreign crystal lattice. Moreover, the recoil energies of the $^{32}$P atoms are very much higher in these circumstances than they are for the $n, \gamma$ reaction. The earliest observations on the chemical state of the radiophosphorus produced from sulphur were made during investigations of possible processes for its production in a carrier-free condition. It was noticed that all the radiophosphorus formed by the irradiation of carbon disulphide could be removed from the solution by simultaneous electrolysis with copper electrodes, and was deposited in a form soluble in nitric or hydrochloric acid, but that deposition was incomplete when aluminium electrodes were used and did not occur at all on platinum electrodes.[50-1] The radiophosphorus produced by the irradiation of carbon disulphide could be adsorbed in a water soluble form on red phosphorus, formed during the irradiation from a small amount of white phosphorus dissolved in the carbon disulphide.[52] Aten[53-4] determined the distribution of radiophosphorus between phosphate and phosphite (or hypophosphite) for a number of target materials, but the use of very few carriers severely restricted the number of products which could be observed; the results obtained are given in Table XXI. Whitmore[55] observed that most of the radiophosphorus formed in sodium sulphide and thiourea gave rise to oxyanions on solution, but that a considerable part of that formed in sulphur or carbon disulphide was in the form of elemental phosphorus. No attempt was made, however, to study the products in further detail.

*Table XXI.—Chemical Form of Radiophosphorus in Neutron-irradiated Sulphur Compounds*[54]

| Target | Percentage of radiophosphorus found as | |
|---|---|---|
| | Phosphate | Phosphite and hypophosphite |
| $K_2SO_4$ | 90 | 10 |
| $Na_2SO_4,10H_2O$ | 98 | 2 |
| $Na_2SO_3,7H_2O$ | 50; 44 | 50; 56 |
| $Na_2S$ hydrate* | | 64 to 93 |

* This result indicates that there is much more of the reduced forms of phosphorus than of phosphate, but does not take into account other possible forms.

Nilsson[56] found that in irradiated sulphur containing a small proportion of amorphous sulphur (S$\mu$), insoluble in carbon disulphide, a considerable part of the radiophosphorus is associated with the amorphous sulphur, although only a small

proportion of the $^{35}S$ produced is found in the insoluble material (Table XXII). The addition of various phosphorus compounds or of more S$\mu$ to the carbon disulphide solution had in most cases very little effect on the distribution of radiophosphorus, although the amount of radiophosphorus in the S$\mu$ phase varied with the amount of S$\mu$ present at the end of the irradiation. It was therefore concluded that adsorption on the S$\mu$ did not afford a complete explanation of the phenomenon, and at least part of the effect was attributed to the formation of S$\mu$ in the 'displacement spikes' produced by the recoiling phosphorus atoms; the recoiling $^{35}S$ atoms have much lower energy and it was assumed that they would be unable to cause the formation of stable aggregates of S$\mu$. It was also shown that annealing of S$\mu$ to S$\alpha$ could occur during irradiation (Table XXIII) and it was calculated that this would account for that part of the radiophosphorus not associated with S$\mu$. An attempt was made to study the chemical state of the radiophosphorus in the soluble part of the sulphur target, but very few carriers were used and only pentavalent phosphorus was identified. In Table XXII are shown the amounts of radiophosphorus which could be extracted from the carbon disulphide solutions by water containing small amounts of phosphoric, phosphorous, and sulphuric acids as carriers, and the amounts of pentavalent phosphorus in these extracts.

A method has been developed for the separation of radiophosphorus from neutron-irradiated sulphur by extraction with water at the transition point from the rhombic to the monoclinic form.[57] It was found that the yields increased markedly with increasing porosity and decreasing particle size; the diffusion of phosphorus out of the sulphur particles must therefore be slow. The small amount of phosphorus not extracted by water could be extracted by benzene, and was thought to be probably in elemental form. The chemical form of the radiophosphorus extracted by water has been examined by Dahl and Birkelund.[58-9] Solutions were examined for a wide range of phosphorus compounds, but most of the phosphorus was found to be present as orthophosphate (Table XXIV). A more detailed examination of the radiophosphorus present at various stages of the process was carried out by means of two-directional paper chromatography. A preliminary washing of the irradiated sulphur

yielded a mixture of small quantities of ortho-, pyro-, tri-, tetra-, and tetrametaphosphates, together with other long-chain polyphosphates. At the beginning of the extraction process about 70% of the radiophosphorus was in the form of orthophosphate, the remainder being present as polyphosphates which were hydrolyzed to orthophosphate during the extraction, so that at the end of the extraction process about 98% of the phosphorus-32 was in the form of orthophosphate; the residual amounts of pyrophosphate and other polyphosphates were attributed to the interaction of processes of adsorption and desorption with formation at hot spots on the glassware and hydrolysis in the solution.

The chemical state of radiophosphorus in irradiated sulphates has been studied by Fomin and Maslova,[60] who examined the distribution among phosphate, phosphite, and hypophosphite. The results obtained are given in Table XXV. The three forms of phosphorus investigated appear to have been formed in roughly equal amounts in solutions containing carriers, but most of the radiophosphorus appeared as phosphate in the absence of carriers. The difference in behaviour was attributed to oxidation of tracer amounts of the lower valency forms, probably by dissolved oxygen, or by the products of radiolysis of water, but this oxidation process does not appear to be very important in irradiated sulphuric acid. In irradiated crystalline sulphates there was

little difference between the distributions with and without carriers, and the predominant formation of phosphate in these cases was attributed to interaction between the 'hot' phosphorus atoms and the oxygen of disrupted sulphate ions. The amounts of phosphorus used as carriers in the irradiations were not large enough for an appreciable contribution to the yield of $^{32}P$ from the $^{31}P(n, \gamma)^{32}P$ reaction.

In another series of investigations[61] it was found that the radiophosphorus formed by the irradiation of sulphur monochloride was in the form of $^{32}PSCl_3$. The amounts of $^{32}P$ in the lower valency states of phosphorus were measured for a number of targets under a variety of conditions (Table XXVI). It can be seen that for sodium sulphate, particularly in the hydrated form, a large proportion of the radiophosphorus was in pentavalent form, but that lower valency states were prevalent for sulphuric acid and for targets containing sulphur in less highly oxidized forms. The results show broad agreement with those obtained by Fomin and Maslova[60] (Table XXV), and Aten[54] (Table XXI).

An extensive investigation of the chemical forms of radiophosphorus in irradiated sulphates, sulphites, and sulphides has been carried out by Lindner.[62] Some of the results of this investigation are summarized in Tables XXVII, XXVIII, and XXIX. The values given in these Tables are generally the extreme values obtained in a series of experiments; most of the irradiations were carried out with stray neutrons from a cyclotron, but a few were carried out at higher dose rates and for shorter times with the neutrons produced by bombardment of a beryllium target. These are indicated in the Tables as 'internal' irradiations.

For most targets the results show a fairly wide scatter, but comparison with the results given in Tables XXI and XXVI shows that there is generally good agreement with the work of other investigators. The most marked feature of Lindner's results is the strong dependence of the chemical state of the radiophosphorus on the presence of hydrogen in the target molecule. Very little non-orthophosphate phosphorus is found in anhydrous non-hydrogenous sulphates and sulphites, but in many cases the amount is increased to 20–40% by the presence of a few molecules of water of crystallization. On the other hand higher hydrates show a wide range of behaviour, amounts of orthophosphate varying from 60 to 95%. Target materials containing

hydrogen bound to nitrogen or in acidic form usually give rise to a considerable amount of radiophosphorus in the lower valency states.

The fact that neither the nature of the carrier solution used in dissolving the target nor post-irradiation treatment such as hydration or dehydration appreciably alters the amount of the reduced forms of phosphorus led Lindner to suggest that most of the recoiling $^{32}P$ atoms attain their final valency state very shortly after the nuclear transformation. The enhancement of the yield of non-orthophosphate phosphorus by the presence of hydrogen in the target molecule was attributed to stabilization of the lower valency states in the target crystal, since P–H bonds are present in phosphite and hypophosphite anions but not in orthophosphate anions. There is, however, a noticeable absence of phosphine in the products of irradiation of sulphates, sulphites, and, surprisingly, the sulphides of sodium and potassium (Table XXIX). On the other hand a considerable fraction of the radiophosphorus in irradiated calcium sulphide is found as phosphine. It was suggested that the absence of phosphine could in many cases be attributed to a preferential formation of P–O bonds, but this cannot be so in the case of potassium sulphide, and the difference in stability between the phosphides of potassium and calcium was invoked to explain the striking differences between the irradiation products of potassium and calcium sulphides.

It was observed that the amount of non-orthophosphate phosphorus in irradiated anhydrous sulphates was reduced considerably if they were heated for a short time in the acid or alkaline carrier solution, but only a very small reduction occurred when a neutral solvent was used. This effect was attributed to the presence of phosphorus compounds (probably thiophosphates) which were not precipitated with the orthophosphate fraction but could be hydrolyzed to give orthophosphate. It is evident from the results of this examination of a large range of sulphur compounds that the final state of the radiophosphorus is in general only slightly influenced by the valency state of the sulphur atoms in the target, and depends largely on other factors such as the presence of hydrogen or oxygen in the molecule.

Some experiments were carried out at liquid air temperature and the products annealed for various times, and these led to the conclusion that some annealing could occur at room temperature. Variations in the extent of annealing could account for much of the scatter observed in the experiments carried out at ambient temperature.

Irradiation of some targets in the form of solutions showed that in these circumstances the presence in solution of reducing species could exert some influence on the state of the radiophosphorus. The results are given in Table XXX.

More recently Lindner[76] has studied the distribution of $^{32}P$ among the valency states +5, +3, and +1, for fast neutron irradiation at −30°C. The results so far obtained, which are given in Table XXX, are however, only of a preliminary nature, and are subject to modification in the light of future work.

Adams and Campbell[62a] have studied the effect of irradiation of sulphur compounds with pile neutrons. For sodium sulphate and sulphite the results obtained were in general agreement with those obtained by Lindner,[62] but as the experiments were carried out at about 40°C. some annealing is likely to have occurred, and storage of irradiated samples at room temperature resulted in little change of valency state of the radiophosphorus. The fraction of $^{32}P$ in the pentavalent state was found to increase with the irradiation dose, indicating that there was considerable annealing

by $\gamma$-radiation. Degassing of potassium thiocyanate crystals before irradiation resulted in a decrease in the amount of pentavalent $^{32}P$, presumably by preventing oxidation of the recoiling fragments by occluded oxygen, although the slight increase in the amount of pentavalent $^{32}P$ resulting from degassing of thiosulphate and sulphite targets does not seem to be consistent with this explanation. Thermal annealing curves for irradiated sulphite and thiocyanate targets showed fast and slow stages similar to those observed for irradiated phosphates,[36–7] indicating that the initial recoil energy has little effect on the subsequent annealing behaviour. The formation of $^{32}P^{5+}$ during the fast stage took place almost entirely at the expense of $^{32}P^{3+}$, and this stage of annealing was thought to be due to the presence of defects or radicals produced in the region near the end of the recoil track.

The irradiation of solutions of carbon disulphide in organic solvents leads to the formation of a number of organophosphorus compounds,[63] details of which are given in Table XXXII. The range of products identified in this investigation was limited by the small number of different carriers used, and the investigators considered that the relatively high yield of triphenylphosphine observed could be attributed to the extraction by benzene, in the course of the separation procedure, of species for which no carriers had been added, and which followed the triphenylphosphine carrier. It was pointed out that the observed products could not be primary products, which might well be species such as $C_6H_5PH_2$ or $C_6H_5PCl_2$, and it was concluded that the mechanism of the primary process leading to the formation of di- and tri-phenyl phosphorus compounds was different from that giving rise to monophenyl compounds. The variation of the yield of monophenylphosphonic acid with the proportions of carbon disulphide and organic solvent in the irradiated mixture is shown in Table XXXIII; the difference in yields for the two solvents was attributed to the greater mass of the chlorobenzene molecule and to the presence in this molecule of an atom of mass close to that of the recoiling phosphorus atom.

## CHEMICAL STATE OF $^{32}$P PRODUCED BY THE $^{35}$Cl($n$, α)$^{32}$P REACTION

The studies which have been carried out on radiophosphorus produced by neutron bombardment of chlorine compounds fall into two broad categories—studies of the valency states of the phosphorus atoms and studies of their diffusion behaviour—and these will be considered separately.

### Irradiation of Inorganic Chlorides

Aten[54] separated the irradiation products of a number of inorganic chlorine compounds into phosphate and phosphite plus hypophosphite fractions, and similar work has been carried out by Korshunov.[61] The results are given in Table XXXIV, from which it can be seen that the amount of pentavalent phosphorus is increased by the presence of water crystallization and is highest for salts containing chlorine in high oxidation states. The difference between the values for magnesium chloride in solution and in the hydrated crystalline form is one for which there does not appear to be a satisfactory explanation.

*Table XXXIV.—The Chemical State of* $^{32}$P *in Irradiated Inorganic Chlorides*

| Target | Form or treatment of target | Percentage of $^{32}$P in valency states below +5[61] or in phosphite plus hypophosphite fraction[54] | Reference |
|---|---|---|---|
| $KClO_4$ | | 1 | 54 |
| $KClO_3$ | | 0 | 54 |
| $MgCl_2$ hydrate | | 7 | 54 |
| $MgCl_2$ hydrate | Dissolved in sulphite solution | 2 | 54 |
| $MgCl_2$ | Soln. (17·4 g. per 100 ml water) | 65 | 61 |
| NaCl | | 62 to 69 | 54 |
| $NH_4Cl$ | Dried in air | 68 | 61 |
| $CaCl_2$ | Dried in air | 47 | 61 |
| $CaCl_2,6H_2O$ | Dried in air | 12 | 61 |

Caillat and Süe observed that about half the radiophosphorus produced by the irradiation of crystalline or fused inorganic chlorides is in pentavalent form, and that the presence of water increases the yield of this form.[64] They also showed that annealing of the *F* centres responsible for the coloration of the irradiated crystals results in a lowering of the proportion of $^{32}$P in pentavalent form[65]; they attributed this to the effect of electrons liberated from the *F* centres during the annealing process. The results of their experiments are summarized in Table XXXV.

*Table XXXV.—Valency States of* $^{32}$P *in Irradiated Inorganic Chlorides*[64–5]

| Target | Form of target | Percentage of $^{32}$P observed(a) | |
|---|---|---|---|
| | | In +5 state | In lower than +5 state |
| LiCl | Fused salt | 51·5 | 43·3 |
| KCl | Fused salt | 49·4 | 50·8 |
| KCl | Satd. soln. | 100 | 0 |
| NaCl | Single crystal | 43 | 57·1 |
| | | 41·5 | 59·6 |
| NaCl | Satd. soln. | 100 | 0 |
| NaCl | Single crystal(b) | 30·5 | 64·7 |

(a) The values given in the table are the mean values from several experiments. For NaCl single crystal they are the mean values from two series of experiments.
(b) Heated to 350°C. for a few minutes after irradiation to remove *F* centres.

It was shown by Carlson and Koski[66] that pre-irradiation treatment of the target, the severity of the irradiation, and exposure to $\gamma$-radiation could all affect the distribution of radiophosphorus amongst the possible valency states. Thorough outgassing of potassium chloride crystals before irradiation by pile neutrons led to a reduction of the yield of pentavalent phosphorus from nearly 100% to 88%, and when a lower neutron dose was used (neutrons being obtained by the reaction $2D \rightarrow T + n$) the change was even more pronounced, the yield of pentavalent phosphorus being 89% for untreated crystals and 40% for outgassed ones. The effect of irradiation conditions is shown in Table XXXVI; the pronounced effect of $\gamma$- or *X*-radiation led the authors to suggest that the high yields of pentavalent phosphorus under severe irradiation conditions could be attributed to the action of the high $\gamma$-radiation also present. Surprisingly, no effect was observed on heating the crystals to 850°C. after irradiation, and this is in direct conflict with the observations of Süe and Caillat.[65]

*Table XXXVI.—Effect of Irradiation Conditions on the Valency Distribution of Radiophosphorus in Potassium Chloride*[66]

| Irradiation conditions | Percentage of $^{32}$P found in the valency states | | | |
|---|---|---|---|---|
| | +5 | < +5 | +1 and +3 | −3 |
| *A* | 95·3 | 4·7 | 2·8 | 1·9 |
| *B* | 36 | 64 | 32 | 32 |
| *C* | 18 | 82 | 43 | 39 |
| *D* | 69 | 31 | | |
| *E* | 62 | 38 | | |

*A* $10^{18}$ n. cm$^{-2}$ by pile irradiation.
*B* $\sim 10^{14}$ n. cm$^{-2}$ from $^{9}$Be($\alpha$, *n*)$^{12}$C reaction.
*C* $5 \times 10^{10}$ n. cm$^{-2}$ from $^{3}$H(*d*, *n*)$^{4}$He reaction.
*D* As *B*, followed by $\sim 10^{6}$ roentgens of 100 KeV. *X*-rays.
*E* As *B*, followed by $2{\cdot}5 \times 10^{6}$ roentgens of $^{60}$Co $\gamma$-rays.

However, the effect of the discharge of *F*-centres has been confirmed by Butterworth and Campbell,[66a] who have shown that during thermal annealing of irradiated potassium chloride crystals there is at one stage a decrease in the proportion of $^{32}$P$^{5+}$, producing a hump in the annealing curve. They have also observed that although considerable annealing occurs on heating pile-irradiated potassium chloride crystals, no significant thermal annealing can be produced when the source of neutrons is the D–T reaction. Cífka[66b] has attributed the oxidation process which occurs during annealing to reaction between the $^{32}$P recoils and *V*-centres. During annealing of crystals doped with cadmium or calcium ions an initial reduction stage was observed, but for pure potassium chloride crystals the reduction stage found by Butterworth and Campbell[66a] was not observed. The yield of pentavalent phosphorus was slightly increased when crystals were outgassed before irradiation. The opposite effect had been observed by Carlson and Koski,[66] but in their experiments the proportion of phosphorus in the pentavalent state was much greater, and since the experiments carried out by Cífka were at dry ice temperature it is possible that the high yields obtained by Carlson and Koski resulted from thermal and radiation annealing in which trapped oxygen played some part.

The results of some experiments carried out by Lindner[62] are given in Table XXXVII. Comparison of these results with those given in Tables XXXIV and XXXV shows that very good agreement is obtained for most target materials, the yields of non-orthophosphate phosphorus being very low for oxyanions and hydrated species, and high for anhydrous crystals. An interesting feature is the variation of the yield from potassium chloride with the form of pre-irradiation treatment, recrystallization increasing the yield of the lower valency forms especially when carried out from an aqueous solution saturated with hydrogen. This was attributed by Lindner to the removal of oxidizing impurities from the crystal. No effect was observed when samples of potassium perchlorate were recrystallized before irradiation, so that the presence of oxygen in the crystal lattice clearly outweighs any impurity effect in this case. Irradiation of sodium perchlorate in 10% solution, however, was found to give rise to 53·7% of the radiophosphorus in non-orthophosphate forms. Some further

results, of a preliminary nature, for the fast neutron irradiation of chlorides at −30°C. are given in Table XXXVIII.

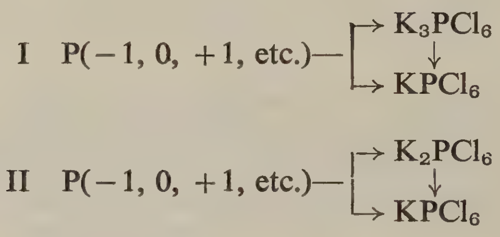
### EFFECT OF ANNEALING

An extensive investigation of the products of irradiation of single crystals of potassium chloride by very high energy protons has recently been carried out[67]; the nuclear reactions which led to the formation of radiophosphorus were ${}_{17}Cl(p, 3p+xn){}^{32}_{15}P$ and ${}_{19}K(p, 5p+xn){}^{32}_{15}P$, and although this section is mainly concerned with $n, \alpha$ reaction it is convenient to consider this spallation reaction at this stage, since the ${}^{32}P$ atoms formed are present as foreign atoms in the potassium chloride lattice. Analyses were carried out for phosphate, phosphite, and hypophosphite, and it was found that 50–60% of the radiophosphorus was in the form of phosphate, but annealing at a high temperature (650°–700°C.) before irradiation reduced this fraction to 10–20%. The crystals used for subsequent experiments were all annealed before irradiation. In one series of experiments phosphine was used as an additional carrier, and an attempt was made to isolate elemental phosphorus, but none could be detected. The results of this series of experiments are given in Table XXXIX. Post-irradiation annealing experiments were carried out at a series of temperatures between 200°C. and 400°C., and these gave results similar to those obtained for the thermal annealing of irradiated phosphates. An initial rapid increase in the phosphate yield was followed by a very slow increase, and at 400°C. the change in phosphate yield took place at the expense of both phosphite and hypophosphite. At 200°C., however, hypophosphite was transformed into nearly equal quantities of phosphate and phosphite, and at intermediate temperatures the yield of phosphite increased rapidly at first and then decreased slowly as the slow stage of the anneal was reached.

*Table XXXIX.—Chemical Forms of* ${}^{32}P$ *in Potassium Chloride Crystals Irradiated by High Energy Protons*[67]

| Experiment No. | Percentage of ${}^{32}P$ found as | | | |
|---|---|---|---|---|
| | Phosphate | Phosphite | Hypophosphite | Phosphine |
| 1 | 14 | 15 | 51 | 20 |
| 2 | 12 | 11 | 49 | 28 |
| 3 | 15 | 17 | 50 | 18 |
| 4 | 13 | 12 | 41 | 35 |
| 5 | 11 | 10 | 41 | 38 |
| 6 | 12 | 9 | 27 | 52 |

The explanation of these phenomena proposed by the authors is based on the formation of Frenkel defects by interaction of the high energy protons with the ions of the lattice and the production of high temperatures in very small regions near the ends of the tracks of the recoiling phosphorus atoms. These high-temperature effects, which promote some annealing of the lattice, are of very short duration, and, taking into account the ionization potentials of all the species involved, the authors considered that the most probable final oxidation states of the phosphorus atoms are the lower ones (−1, 0 and +1). The rapid stage of thermal annealing, during which a considerable degree of order is restored to the lattice, may then be attributed to electronic transfers between atoms and ions, the phosphorus atoms attaining higher valency states and entering cation sites of the lattice. Since a high positive charge must be balanced by neighbouring cation vacancies it is considered that the slow stage of annealing might result from the diffusion of these vacancies, scattered throughout the lattice, to the neighbourhood of the phosphorus ions. The authors point out that the chemical forms observed would be formed by secondary reactions taking place in solution and the parallel increases of the yields of phosphate and phosphite on annealing at 200°C. might possibly result from the hydrolysis of a species such as $PCl_4$. They therefore postulate two possible schemes for the annealing process:



## Irradiation of Carbon Tetrachloride

The chemical form of radiophosphorus produced by neutron irradiation of carbon tetrachloride has been studied.[50, 61, 63] Govaerts[50] found that on simultaneous irradiation and electrolysis of carbon tetrachloride radiophosphorus was deposited on copper electrodes, but deposition was incomplete. Nesmeyanov[63] showed that the yields of radiophosphorus in the form of phenylphosphonic acid from irradiated mixtures of carbon tetrachloride and benzene or chlorobenzene were the same as those from mixtures of carbon disulphide with the aromatic compounds in the same

*Table XL.—Chemical Forms of* $^{32}P$ *Extracted from Irradiated Carbon Tetrachloride by Various Reagents*[61]

| Series of experiments | Extracting reagent | Percentage of $^{32}P$ | | |
|---|---|---|---|---|
| | | In +5 state | In +3 state | Not extractable |

molar proportions. Korshunov[61] investigated the effect of various added compounds on the behaviour of irradiated carbon tetrachloride, and showed that the amount of radiophosphorus which could be extracted from the carbon tetrachloride depended on the reagent used. The amount extracted after the carbon tetrachloride had been refluxed for two hours with an extracting reagent is given in Table XL for various reagents. The distribution of the extractable phosphorus between phosphate and phosphite (the only carriers used) is also given. A small proportion of the radiophosphorus was found to be adsorbed by the containing vessel during the irradiation, and this was increased from a few per cent to 50–80% in the presence of a trace of water, but decreased to zero when an appreciable quantity of water was added before irradiation. The volume of the target material was found to affect the valency state of the radiophosphorus produced, the amount of pentavalent phosphorus increasing with decrease of the target volume. The effect of various added compounds is shown in Table XLI, and the effect of varying the irradiation period in Table XLII. The presence of oxygen dissolved in the target was not found to have an appreciable effect, but high yields of pentavalent phosphorus were observed in the presence of bromine and chlorine, and a marked increase in the amount of pentavalent phosphorus could be brought about by $\gamma$-irradiation. Similar results were obtained for the irradiation of chloroform.

### Diffusion of $^{32}P$ in Crystals

A study of the diffusion of $^{32}P$ in sodium chloride crystals was begun with the object of determining the charge on the phosphorus atoms by comparison of thermal diffusion coefficients with the mobilities in an electric field.[68] This object does not appear to have been achieved, but various aspects of the problem have been investigated. Thin, flat crystals of sodium chloride were irradiated and then heated for periods of up to several hours. The edges of the crystal were trimmed off to eliminate edge effects, and the crystals were then divided into a large number of thin layers

*Table XLI.—Effect of Added Compounds on the Valency State of* $^{32}P$ *in Irradiated Carbon Tetrachloride*[61]

| Compound added | Concentration (ml. per litre of $CCl_4$) | Percentage of $^{32}P$ in pentavalent state |
|---|---|---|
| None | — | 98 |
| $H_2O$ | 0·22 | 86 |
| $H_2O$ | 0·45 | 78 |
| $H_2O$ | 0·7 | 69 |

| Acetone | 10 | 86 |
| $NH_3$ | saturated | 14 |
| $H_2O$ satd. with $Br_2$ | 0·6 | 98 |

*Table XLII.—Effect of Time of Irradiation on the Valency State of* $^{32}P$ *in Irradiated Carbon Tetrachloride*[61]

| Irradiation period (hrs.) | 12 | 24 | 48 | 84 | 96 | 144 |
|---|---|---|---|---|---|---|
| Yield of $^{32}P$ in +5 state(a) | 84 | 89 | 92 | — | 94 | 98 |
| Yield of $^{32}P$ in +5 state(b) | 47 | 50 | 59 | 79 | — | 86 |

(a) Dry $CCl_4$.
(b) $CCl_4$ containing 0·22 ml. of water per litre.

parallel to the original faces. The concentration profiles of $^{32}$P, shown in Fig. 4, were determined by $\beta$-counting the individual layers, which were obtained in the form of powder. The high concentrations observed at the surfaces were thought to result from an irreversible process of escape, the free energy of the crystal being lowest when all the phosphorus had accumulated on the surface. This surface layer could easily be removed by scraping, and the concentration profile in the remainder of the crystal was found to satisfy a diffusion equation when the period of heating was short enough for the concentration in the middle of the crystal to remain unchanged.[69] Values of the diffusion coefficient obtained in this way are given in Table XLIII, and the activation energy ($W$) was found to be 3·30 ev. per atom. The author concluded that diffusion occurs by way of vacant lattice sites, and taking a value of 2·20 ev. for $\varepsilon_0'$, the energy necessary for the formation of a pair of vacancies,[70] calculated the activation energy for the movement of a phosphorus ion ($\varepsilon_0''$) to be 2·2 ev. from the expression $W=\frac{1}{2}\varepsilon_0'+\varepsilon_0''$.

*Table XLIII.—Diffusion Coefficients for* $^{32}$P *in Sodium Chloride Crystals*[69]

| Temperature (°C.) | 610 | 635 | 690 | 727 |
|---|---|---|---|---|
| Diff. coefficient (cm$^2$. sec$^{-1}$) | $3{\cdot}8\times10^{-10}$ | $1{\cdot}16\times10^{-9}$ | $1{\cdot}27\times10^{-8}$ | $5{\cdot}73\times10^{-8}$ |

The accumulation of radiophosphorus on the surface of the crystal suggested the possibility of separation of $^{32}$P and of $^{35}$S (which diffused in a similar way) from the sodium chloride. It was found that the radiosulphur could be removed by passing a stream of hydrogen over the heated crystal. The radiophosphorus was carried to the cooler parts of the apparatus by the very small amounts of sodium chloride which evaporated from the crystal surface,[71] and could be recovered by treating the deposit

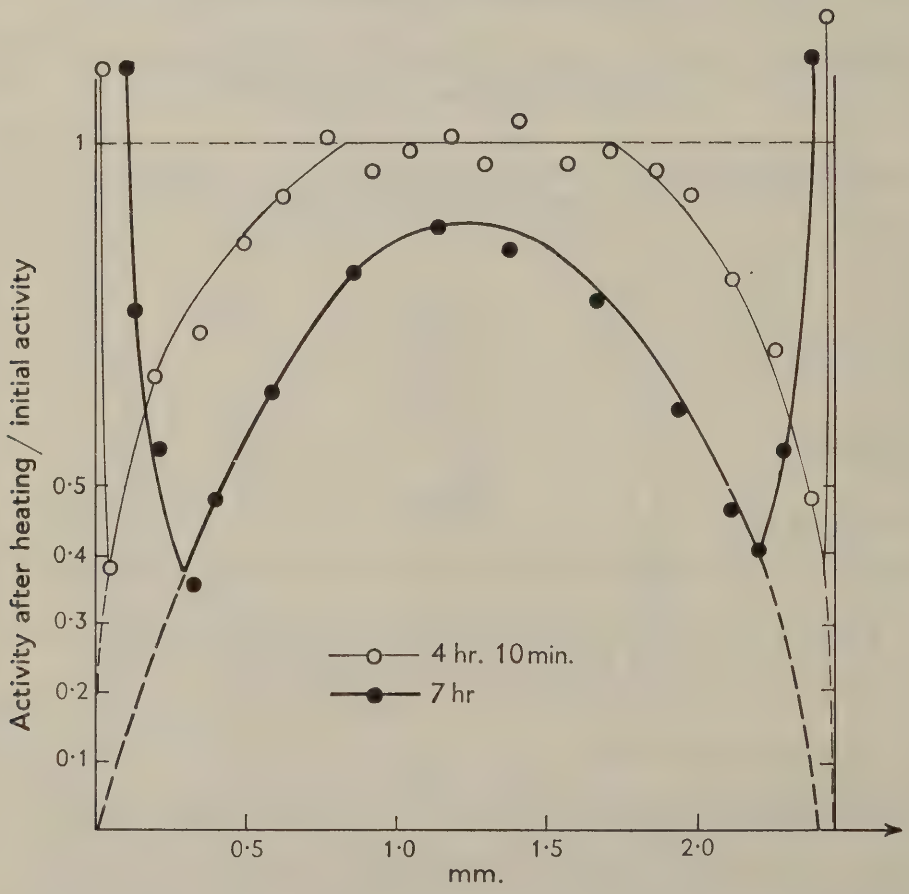

FIG. 4.—Diffusion of $^{32}$P at 660°C. in a sodium chloride crystal for various times

so formed with water. More than half of the radiophosphorus was separated in this way in one experiment. Yields of 85% were obtained by the use of finely powdered sodium chloride; after removal of the radiosulphur, the radiophosphorus was carried by a stream of chlorine into a receiver containing a small quantity of water.[72] Oxygen had to be rigidly excluded from the system, as the presence of trace amounts prevented the escape of phosphorus, presumably by converting it to oxyanions. The whole of this work is summarized and discussed by the author in a later paper.[73]

The problem of determining the charge on the phosphorus atoms has recently been taken up again,[74] the radiophosphorus in this case being produced by the spallation of potassium chloride crystals by 660 Mev. protons. The nuclear reactions involved have already been mentioned in connection with a study of the chemical state of radiophosphorus in potassium chloride crystals.[67] The concentration profiles and diffusion coefficients obtained were similar to those observed by Chemla for neutron-irradiated sodium chloride,[68-9] and the activation energy obtained (3·2 ev. per atom) is very close to that for diffusion in sodium chloride. Measurements of the mobility in an electric field combined with the diffusion data led to a value of 0·191 ± 0·045 electron charge units for the charge on the phosphorus atom, and this small negative effective charge was interpreted as being the result of a strong interaction between phosphorus ions and the anions of the lattice which would cause phosphorus ions to be dragged towards the anode. The authors consider that phosphorus ions occupy potassium sites of the lattice and exist as complexes of the form $[P^{5+}.4K_{\square}^{+}.6Cl^{-}]$, where $K_{\square}^{+}$ represents a vacant potassium ion site (this view is based partly on the results of the annealing experiments already described,[67] which indicated that in annealed crystals a large proportion of the phosphorus is in the +5 state). The presence of large amounts of radiophosphorus on the crystal surfaces was thought to be due to occupation of surface lattice sites by phosphorus ions or to formation of oxides.

## CHEMICAL STATE OF $^{32}$P PRODUCED BY SPALLATION REACTIONS

The chemical state of $^{32}$P produced by spallation of potassium chloride has already been mentioned.[67] Many other spallation reactions led to its production but the chemical form of the radiophosphorus has not usually been investigated. The reaction of $^{14}N^{6+}$ ions with $^{27}$Al has been studied,[75] however, and has given results very different from those obtained by other nuclear processes. When a bombarded aluminium foil was dissolved in sodium hydroxide solution in the absence of air no phosphate could be observed, a third of the radiophosphorus was found in the form of reduced oxyanions, and the remainder as phosphine. The authors tentatively suggested that the radiophosphorus must exist in the target in very low oxidation states or as elemental phosphorus, which would react with water, hydroxyl ions, or the hydrogen produced on dissolution of the aluminium. The yields of the various products would then result from competition between reactions of the type:

$$P + 3H \rightarrow PH_3 \quad \text{and} \quad P + 2H_2O \rightarrow H_3PO_2 + H$$

or

$$P^+ + 4H \rightarrow PH_3 + H^+ \quad \text{and} \quad P^+ + 2H_2O \rightarrow H_3PO_2 + H^+$$

## EXCITED-ATOM CHEMISTRY OF $^{33}$P PRODUCED BY THE $^{33}$S($n$, p)$^{33}$P REACTION

Very little attention has been given to this problem, but Nilsson[56] was unable to find any significant difference between the chemical forms of $^{32}$P and $^{33}$P in irradiated sulphur (Table XXII). Recently some work on this subject has been carried out by Lindner,[62] who irradiated anhydrous sodium sulphite in the thermal columns of JEEP and BEPO. The results obtained from the target irradiated in BEPO (Table XLIV) do not indicate any difference in behaviour between the two isotopes, but a greater proportion of the $^{33}$P than of the $^{32}$P was found in the orthophosphate fraction obtained from targets irradiated in JEEP. The results of the experiments in JEEP are, however, rather uncertain, and subsequent work on the neutron bombardment of a number of sulphates and sulphites at dry ice temperature has failed to reveal any significant difference between the behaviour of $^{32}$P and $^{33}$P.[76]

*Table XLIV.—Comparison of Chemical Forms of* $^{32}$P *and* $^{33}$P *in Irradiated Anhydrous Sodium Sulphite*

| Reactor | Percentage of radiophosphorus in valency states other than +5 | |
|---|---|---|
| | $^{32}$P | $^{33}$P |
| JEEP | 38–44 | 19–25 |
| BEPO | 16·7 | 16·7 |

### SECTION XXXVII

# APPLICATIONS OF RADIOPHOSPHORUS

BY N. R. LARGE

OF the radioactive isotopes of phosphorus only two have long enough half-lives to be of general use, viz., $^{32}P$ with a half-life of about 14 days and $^{33}P$ with a half-life of about 25 days. Although it would appear that $^{33}P$ should be as useful as $^{32}P$, and in certain applications would have advantages in view of its longer half-life and lower $\beta$ energy, the absence of any commercial process for its production has hitherto prevented its use. It has been suggested that the two isotopes could be used for the double labelling of phosphorus compounds,[1] and it has been shown that the relative amounts found in rainwater as a result of cosmic ray bombardment of atmospheric argon can serve as an indicator of the movement of large air masses.[2]

In contrast to $^{33}P$, $^{32}P$ is one of the most widely used radioisotopes, although its chemical applications are very limited, its principal uses being in medicine, biology and biochemistry. A brief outline of its uses will be given here, and the general references given below should be consulted for more detailed information.

## Applications in Medicine, Biology and Biochemistry

The absence of $\gamma$-radiation makes $^{32}P$ particularly suitable for local diagnostic purposes; it is preferentially taken up by malignant tumours, and can therefore be used in the diagnosis of tumours of the eye[3] and breast,[4] and for the accurate location of brain tumours during surgery.[5] The determination of blood volume can readily be carried out by an isotopic dilution technique.[6] $^{32}P$ is used as a therapeutic agent in the treatment of leukaemia and polycythemia vera,[7] and has also been used in the treatment of latent, resistant syphilis.[8] More detailed information can be found in a number of reviews,[9] some of which include extensive bibliographies.

Some of the earliest references to the use of radiophosphorus are in the field of biological research: Hevesy used $^{32}P$ in a study of phosphorus metabolism in rats,[10] and showed that the phosphorus in the leaves of plants is in a mobile state and that interchange between different leaves takes place.[11] Biological applications were developed very rapidly and reviews were published as early as 1938 and 1939.[12] Radiophosphorus has since been widely used in studies of metabolism and in the determination of the structures of complex compounds such as enzymes. The behaviour of insects such as bees and ants has been studied by marking insects by means of radioactive food and then following their distribution among the other members of the community.[13] These biological and biochemical applications have been fully described in a number of books and papers.[14]

## Applications in Agriculture

By the use of $^{32}P$-labelled phosphorus compounds it has been possible to study the behaviour of phosphates in soil and the uptake of phosphates by plants. In particular this technique enables exchange reactions in the soil to be studied.[15] Radiophosphorus has also been used in the evaluation of fertilizers,[16] and in studies of soil erosion.[17] The agricultural applications of radiophosphorus have been described,[18] and a number of papers on this subject are available.[19]

## Industrial Applications

The effect of radiophosphorus on the rate of digestion of sewage has been studied. Several workers have observed no significant effects with carrier-free $^{32}P$ at concentrations of up to 400 mc./l.[20] Grune[21] found that there was a reduction in the rate of gas production with 50 mc./l. incorporated into $KH_2PO_4$, but since inactive $KH_2PO_4$ was found to have a similar effect this behaviour was attributed to chemical toxicity. Radiophosphorus has been used as an indicator in following the course and dilution of sewage,[22] and has also been used to study the possibility of producing potable water by the decontamination of radioactively contaminated surface water.[23]

By the use of radiophosphorus as an indicator the course of many industrial processes can be followed in detail. The movement of the charge in a blast-furnace has been followed by introducing $^{32}P$ into the coke and limestone[24]; it has been observed that the rate of movement is greatest at the top centre of the furnace and that the lime precedes the coke. Introduction of $^{32}P$ through the tuyeres followed by monitoring of the iron showed that there was no significant circulation of iron in the hearth. Other problems in the iron and steel industry which have been tackled with the aid of radiophosphorus include investigations of the process of crystallization in ingots and castings[25] and of the characteristics of a mixer for basic Bessemer pig iron,[26] and the determination of the amount of slag in a basic open-hearth furnace during the period of pure boiling.[27]

Autoradiography with $^{32}P$ has been used to establish the distribution of phosphorus in welds,[28] and to measure the abrasion of rubber on a steel plate.[29] In this case the $^{32}P$ was incorporated in the rubber, and the steel was autoradiographed after the experiment. The degree of mass transfer between steel specimens has been determined by the incorporation of $^{32}P$ in one of the specimens.[30] The behaviour of lubricating oils containing labelled additives has been followed, and information obtained on the stability of the solutions[31] and on the thickness of extreme pressure films.[32]

Other technological applications of radiophosphorus include studies of the flow-time distribution of water in heat exchangers,[33] grain boundary segregation in iron–phosphorus alloys,[34] and the migration of elements in the processing of $Al_2O_3$.[35] The behaviour of protective phosphate coatings on iron, steel, and zinc,[36] and the corrosion of aluminium by alkaline phosphates[37] have been studied, and a method for the detection of dye contamination in the multicolour printing of textiles has been devised.[38] A measure of the deterioration of rubber resulting from the action of organic liquids can be obtained from the uptake of labelled radiophosphorus,[39] and measurement of the back-scattering from glass of $\beta$-particles from radiophosphorus has enabled the amount of lead in the glass to be determined without affecting the glass in any way.[40]

$^{32}P$ can be used in the production of self-luminous materials by mixing it with a zinc sulphide type phosphor and polystyrene,[41] the amount of getter material applied to glow lamps can be checked by mixing $^{32}P$ with the getter,[42] and autoradiographic techniques with $^{32}P$ have even been used to study pearl formation in oysters.[43]

## Applications in Physics

The fact that in the irradiation of sulphur $^{32}P$ is formed only as a result of fast neutron bombardment means that the amount of $^{32}P$ formed can be used as a measure of the fast neutron flux or dose,[44] and this is the principal physical application of $^{32}P$. Since there is a minimum 'threshold' neutron energy, this reaction can be used along with others to obtain information about the neutron energy distribution. The ready availability of $^{32}P$ and the absence of $\gamma$-rays make it an obvious choice when a $\beta$ source is required. It has been used for instance to study the sensitivity of photographic film and plates[45] and in the development of a scintillation counter for $\beta$-radiation dosimetry.[46] The dependence of the Hall mobility of germanium semiconductors on the concentration of phosphorus has been studied with the aid of radiophosphorus.[47]

## Applications in Chemistry

Apart from studies of excited atom chemistry, which are discussed in another section, the chemical applications of radiophosphorus fall into two main groups:—those applications in which the presence of a radioactive atom is of fundamental importance, such as studies of self-diffusion and exchange reactions, and those in which the radioactive atom is used as a tracer so that the amount of phosphorus in a sample or in a particular chemical form can be determined without the need for complete chemical analysis. Occasionally $^{32}P$ is used as a source of $\beta$-radiation, since accurately standardized sources can easily be obtained. For example, it has been used in solution as an internal source for the determination of the radiolytic yield of $Fe^{3+}$ from ferrous ammonium sulphate solution.[48]

The behaviour of a substance in trace quantities is often different from that observed in larger quantities, since it often happens that solubility products are not exceeded, and the tracer may be entrained by precipitates or adsorbed on the walls of vessels. The errors resulting from adsorption on glassware have been studied and it has been shown that these errors can be reduced by pretreatment of the glassware with silicones.[49] Experiments carried out by Yuan[50] indicated that differential adsorption of $^{31}P$ and $^{32}P$ could occur, leading to loss of $^{32}P$ by adsorption on glassware or on soil even in the presence of carriers. This kind of effect is particularly likely to occur if some of the $^{32}P$ is not in the same chemical form as the carrier, and Olsen and Watanabe,[51] using pure materials, were unable to detect any differences between the two isotopes. The effects of temperature, acid concentration, and cupric ion concentration on the entrainment of $^{32}P$ on cupric sulphide precipitates have been studied by Kar and Rangan,[52] and a general description of the behaviour of trace quantities of radioisotopes including $^{32}P$ has been given by Lavrukhina.[53]

## Studies of Isotopic Exchange

Some of the isotopic exchange reactions which have been studied are given in Table I. In most cases no exchange could be detected beyond the limits of experimental error, and where exchange did occur it was not generally attributable to a simple exchange of phosphorus atoms. Thus the exchange between phosphorus tri- and penta-chlorides was attributed[56] to a slowly attained equilibrium $PCl_5 \rightleftharpoons PCl_3 + Cl_2$, and the exchange between disodium orthophosphate and tricalcium orthophosphate was due to exchange of the phosphate anion.[67]

The absence in general of exchange of phosphorus atoms between different compounds of phosphorus is of considerable importance, since it enables $^{32}P$ to be used as a tracer with reasonable confidence.

## Studies of Diffusion by means of $^{32}P$

The diffusion and migration of phosphorus compounds can readily be followed in solution by following the change in activity as a function of time, and in solids by studying the activity profile in the substrate. The self-diffusion of phosphorus in solutions of $NaH_2PO_4$ has been investigated, and the activation energy and dependence on concentration determined.[71] It was found that for concentrations above 0·005 M. the diffusing species was almost entirely the ion $H_2PO_4^-$, but that at much lower concentrations the ion $HPO_4^{2-}$ began to play a significant part. Migration of $H_3PO_4$ through a collodion membrane has been found to be hindered at low concentrations.[72] This hindrance was increased by oxidation of the membrane, but decreased by an increase in ionic strength. The diffusion coefficients of phosphates in gelatin have been found to be dependent on the concentration gradient,[73] and lower values have been obtained in self-diffusion experiments where there is no concentration gradient.[74] Self-diffusion of $H_3PO_4$ in charcoal has also been studied.[75]

The migration of $^{32}P$ in apatite has been found to take place both on the surface and through the bulk of the crystals and does not appear to be a diffusion process.[76]

*Table I.—Isotopic Exchange Reactions of Phosphorus*

| Reactants | Experimental conditions | Remarks | Ref. |
|---|---|---|---|
| $P_4$, $PCl_3$ | $CS_2$ soln. | 4% exchange in a few minutes, 30% exchange in a few days. | 54 |
| Red P, $PCl_3$ | 3 hr. at room temp. | <2% exchange | 55 |
| | 73 hr. at 30°C. plus 62,100 *R X*-rays | <2% exchange | |
| $PCl_3$, $PCl_5$ | $CCl_4$ soln., 0·1°C. | 1st order rate constants $9{\cdot}4\times10^{-4}$ hr.$^{-1}$ | 56 |
| | 25°C. | $1{\cdot}01\times10^{-2}$ hr.$^{-1}$ | |
| | 50°C. | $7{\cdot}9\times10^{-2}$ hr.$^{-1}$ | |
| $PCl_3$, $PSCl_3$ | 2 hr., 163°C. | <2% exchange. | 55 |
| $PCl_3$, $POCl_3$ | 23 days, 250°C., white light. | No detectable exchange. | 57 |
| | Subjected to u.v. light. | Exchange observed; enhanced by hydrolysis products. | |
| | Subjected to $\gamma$-rays. | Exchange rate proportional to dose. | |
| $POCl_3$, $H_3PO_4$ | Up to 150°C. | Half-time of exchange 3 hr. | 58 |
| $PSCl_3$, $H_3PO_4$ | ,, ,, ,, | ,, ,, ,, ,, 36 hr. | 58 |
| $H_3PO_2$, $H_3PO_3$ | Aq. soln., room temp. and 70°C. Also in presence of $I_2$ or $I^-$. | No detectable exchange after several hours. | 59 |
| $KH_2PO_2$, $KH_2PO_3$ | Aq. soln., room temp. and 70°C. Also in presence of $I_2$ or $I^-$. | No detectable exchange after several hours. | 59 |
| $NaH_2PO_2$, $NaH_2PO_4$ | Aq. soln., 80 hr., up to 280°C. | No detectable exchange. | 60 |
| $NaH_2PO_2$, $NaNH_4HPO_4$ | Aq. soln., 10 days at room temp. followed by 1 day at 100°C. | ,, ,, ,, | 61 |
| $NaH_2PO_2$, sodium glycerophosphate | Ditto. | ,, ,, ,, | 61 |
| $(C_2H_5O)_3P$, $C_2H_5PO(OC_2H_5)_2$ | 160 hr. at room temperature, 6 hr. at 100°C. | ,, ,, ,, | 62 |
| $H_3PO_3$, $H_3PO_4$ | Acid and alkaline solns., 20°–100°C., up to 26 days. | ,, ,, ,, | 63 |
| $H_3PO_3$, $H_3PO_4$ | Aq. soln., 80 hr., up to 280°C. | ,, ,, ,, | 60 |
| $Na_2H_2P_2O_6$, $Na_4P_2O_7$ | pH 1–10, 25°–90°C. | ,, ,, ,, | 64 |
| $Na_2H_2P_2O_6$, $NaH_2PO_4$ | ,, ,, ,, | ,, ,, ,, | 64 |
| '$HPO_3$', $H_4P_2O_7$ | pH 2·3, 27°–100°C., 0·5–1·5 min. | ,, ,, ,, | 65 |
| '$HPO_3$', $H_3PO_4$ | pH 2–12·5, 21°–100°C., 2–20 min. | ,, ,, ,, | 65 |
| '$(NaPO_3)_6$', $(NaPO_3)_3$ | pH 2–10, 0°–100°C., 0·17—90 hr. | ,, ,, ,, | 66 |
| '$(NaPO_3)_6$', $NaH_2PO_4$ | 25°C., 25 hr. | ,, ,, ,, | 66 |
| $H_4P_2O_7$, $H_3PO_4$ | pH 2–12·2, 25°–100°C., 1–100 min. | ,, ,, ,, | 65 |
| $Na_2HPO_4$, $Ca_3(PO_4)_2$ | 3 days, 18°C. | 3·1% exchange of $PO_4^{3-}$ | 67 |
| | 180°C. | 8·1% exchange of $PO_4^{3-}$ | |
| $Na_2HPO_4$, $(C_2H_5O)_3PO$ | Dioxan soln., 100°–300°C., 20–30 hr. | No detectable exchange. | 68 |
| $Na_2HPO_4$, $(n\text{-}C_4H_9O)_3PO$ | Dioxan soln., 100°–300°C., 20–30 hr. | ,, ,, ,, | 68 |
| $H_3PO_4$, $(n\text{-}C_4H_9O)_3PO$ | Aq. and org. phases shaken together, acid and alk, solns., 1 min.–1 month. | ,, ,, ,, | 69 |
| $Na_2HPO_4$, $(iso\text{-}C_4H_9O)_3PO$ | Dioxan soln., 100°–300°C., 20–30 hr. | ,, ,, ,, | 68 |
| $Na_2HPO_4$, $(C_6H_{13}O)_3PO$ | Dioxan soln., 100°–300°C., 20–30 hr. | ,, ,, ,, | 68 |
| $H_3PO_4$, $(CH_3C_6H_4O)_3PO$ | Dioxan soln., 100°–300°C., 20–30 hr. | ,, ,, ,, | 68 |
| $Na_3PO_4$, glucose-1-phosphate | pH 8, 37°C., 3 hr. | ,, ,, ,, | 70 |
| $Na_3PO_4$, 2,3-diphosphoglyceric acid | ,, ,, ,, | ,, ,, ,, | 70 |
| $Na_3PO_4$, adenylic acid | ,, ,, ,, | ,, ,, ,, | 70 |
| $Na_3PO_4$, adenosine triphosphate | ,, ,, ,, | ,, ,, ,, | 70 |

Diffusion coefficients have been determined for the migration of phosphate from tricalcium phosphate into calcium oxide[77] and for tritolyl phosphate in polystyrene.[78]

The diffusion of $^{32}P$ in single crystals of sodium chloride has been studied by Chemla[79] and has been more fully discussed in the section on excited atom chemistry (p. 1357). Other problems studied by diffusion methods include the chromatographic separation of iron and zinc by precipitation when their chlorides diffuse into gels containing $K_2HPO_4$,[80] the formation of complex phosphotungstate ions in solution,[81] and the behaviour of phosphates in soils.[82]

## Applications to Analytical Chemistry

Table II lists some of the analytical uses of radiophosphorus. $^{32}P$ is sometimes used in the development of analytical procedures since the relative activities of various samples obtained by the chemical procedure can indicate the distribution of the phosphorus compound under investigation. It has been used in this way in studies of chromatographic methods of analysis of mixtures of phosphorus compounds,[98] in the study of phosphate separations in semi-micro qualitative analysis,[99] in investigations of volumetric methods of determination of phosphorus in ferroniobium[100] and ferrotitanium,[101] and in the development of analytical methods for the determination of small quantities of elements in complex mixtures.[102] The composition of phosphotungstates has been determined by double labelling with radioactive phosphorus and tungsten; the difference between the half-lives enabled the amounts of phosphorus and tungsten to be determined.[103]

*Table II.—Analytical Applications of Radiophosphorus*

| Substance determined | Other substances present | Remarks | Ref. |
|---|---|---|---|
| P | Al alloys or $Al_2O_3$ | Activation analysis. | 83 |
| P | Ge | ,, ,, | 84 |
| P | $I_2$ | ,, ,, | 85 |
| P | Si | ,, ,, | 86 |
| P | Se or Te | ,, ,, | 87 |
| $Na_2HPO_4$ (0·001 M.) | $NH_3$ and $NH_4Cl$ soln. | $PO_4^{3-}$ pptd. with $MgCl_2$. $^{32}P$ used as end-point indicator. | 88 |
| $K_3PO_4$ | $KNO_3$ | Determination of trace impurity in study of zone-melting. | 89 |
| $Na_5P_3O_{10}$<br>$Na_4P_2O_7$ | Other phosphate anions, sulphate, silicate, anionic detergents. | Isotopic dilution. $Na_5P_3O_{10}$ and $Na_4P_2O_7$ pptd. by addition of alcohol to aqueous solution. | 90 |
| Calcium hydroxyapatite | Polystyrene | Higher concn. found in larger beads. | 91 |
| Al, In, La, Ce, Zr. | Other metals. | Determined as phosphates with $Na_2H^{32}PO_4$ or $(NH_4)_2H^{32}PO_4$ after partial chemical separation. | 92 |
| Mg | | Pptd. with $Na_2H^{32}PO_4$. Activity of ppt. determined. | 93 |
| Mg | $NH_3$ and $NH_4Cl$ | Pptd. with $Na_2H^{32}PO_4$. End-point determined by change in activity of solution, or activity of ppt. measured. | 94 |
| Mg and Ca | Portland cement. | Ca and Mg separated in preliminary step. Pptd. with $(NH_4)_2H^{32}PO_4$ soln. Activity of soln. measured before and after pptn. | 95 |
| $MgCl_2$ (0·01 M.) | $NH_3$ and $NH_4Cl$ soln. | Mg pptd. with $Na_2H^{32}PO_4$. Presence of $^{32}P$ in soln. used as end-point indicator. | 88 |
| Uranyl acetate (0·005 M.) | $NH_4$ acetate | U pptd. with $Na_2H^{32}PO_4$. End-point corresponds with minimum activity in soln. | 88 |
| Mn and Zn | | Pptd. with $(NH_4)_2H^{32}PO_4$ soln. Activity of soln. measured before and after pptn. | 96 |
| F | Na, K, Mg, Ca. | Chromatographic technique with $ZrOCl_2$ and $H_3{}^{32}PO_4$. | 97 |

**Refs. p. 1367**

## Other Chemical Applications of $^{32}$P

Radiophosphorus has been used as an indicator in studies of the solubility of mono-, di-, and tri-butyl phosphates[104–5] and of thorium phosphates,[106] in adsorption studies,[107–8] in surface area determination,[109] and in studies of losses of non-volatile substances during freeze-drying.[110] The chemistry of the mono-, di-, and tri-butyl phosphates has been extensively studied with the aid of radiophosphorus. The aspects studied include the hydrolysis[111] of tributyl phosphate, the preparation[112] and separation[113] of the various butyl phosphates, and the distribution of these compounds in various systems.[104, 114]

### SECTION XXXVIII

# THE RADIATION CHEMISTRY OF PHOSPHORUS AND ITS COMPOUNDS

### BY T. FFRANCON WILLIAMS

THIS section reviews the literature concerning the chemical changes which result from the irradiation of phosphorus compounds. Photochemical transformations, as well as the effects of ionizing radiation, are included in this survey, but the discussion of nuclear recoil effects accompanying the formation of radioactive phosphorus atoms is limited to the contribution made by these latter studies to an understanding of the chemistry of radiation-induced changes. These terms of reference enable the topic to be discussed in the widest sense and this approach has been dictated by the fact that much of the available information is scattered and fragmentary. Although only a few concerted and comprehensive studies have been reported hitherto, these are selected for more detailed discussion since they afford a few guiding principles to an appreciation of the chemistry which is involved.

At the outset it seems appropriate to mention some of the physical and physicochemical factors which underlie the absorption of radiation within the range of energy spectrum corresponding to the production of chemical changes. When a quantum of visible or ultra-violet light of wave-length greater than 2000 A. is absorbed by a molecule, an electron is promoted to a higher energy level. The subsequent fate of an excited molecule often involves a variety of competing processes which depend, in general, on the physical state of the absorbing species and on the intimate chemical environment. From a chemical standpoint, an excited molecule may undergo homolytic dissociation to give free radicals or it may react in the excited state; in addition, there is the possibility of the activated molecule undergoing energy transfer with another molecule resulting in the sensitization of the latter. Other processes can lead to the degradation of the initial excitation energy, either by internal transfer to vibrational and rotational degrees of freedom or by light emission from excited levels to the ground state as observed in fluorescence and phosphorescence. In some molecules triplet states may be excited directly or by a transition from a higher singlet state following light absorption; the lifetime of a triplet state measured in terms of the duration of light emission from this excited state, where the absorbing molecule is in the gas phase or in an inert chemical environment, can often extend for $10^{-3}$ sec. By comparison, singlet excited states usually have much shorter lifetimes, *ca.* $10^{-8}$ sec. or less, and consequently the triplet state is more prone to take part directly in chemical reaction. In the case of simple molecules, the primary photochemical act can often be specified unambiguously, but for complex polyatomic molecules, the processes of intra- and intermolecular energy transfer referred to above are far from well understood in their entirety. For a detailed discussion of these topics, the reader is referred to several texts and review articles.[1-8,132]

As the energy of a photon is increased beyond several electron volts, the contribution of photo-ionization to the mechanisms of energy loss becomes of primary importance. The term ionizing radiation is now employed to cover high energy quanta extending from the photo-ionization limit to the highest gamma-ray energies encountered and also includes beams of fast charged particles such as electrons, protons and α-rays. In the case of electromagnetic radiation, the photon energy is passed on to the absorbing medium as energetic electrons derived from photoelectric absorption and Compton scattering with a contribution from pair production at quantum energies exceeding 1 Mev.; the relative importance of these processes as a function of the atomic number of the absorbing material and photon energy is well established.[9] Information from the physics of energy loss by charged particles can be used to derive the spatial distribution of ionization events relative to the path of the primary particle[10]; in this connection it is often convenient to use the term linear energy transfer (LET) to describe the energy loss in units of ev. per A. The passage of heavy charged particles results in the emission of adjacent low-energy secondary electrons with the formation of dense columnar regions of ionization, whereas fast electrons only lose energy at widely separated intervals (*ca.* 1000 A.) in condensed media. A consequence of this different geometrical distribution is that the possibility of interaction between the primary products of chemical change is much more likely at a high rate of LET.[10] Thus it is found that for aqueous solutions, the quantitative chemistry is highly dependent on the energy of the incident particle,[11] although it should be noted that this behaviour is not universal and, for the case of organic systems, only aromatic compounds have hitherto been found to display a dependence of chemical yield on ion density.[12] In addition to the ionization of molecules, there is evidence that direct excitation also represents an important mode of energy loss from the charged particles to the medium. Measurements of $W$, the mean energy required to form an ion pair in irradiated gases, give values[13] in considerable excess of the ionization potential and, although part of this difference must be attributed to the excitation of the ion, it is generally assumed that direct excitation and ionization events are comparable in magnitude.

The electronic processes referred to above occur with extreme rapidity (*ca.* $10^{-16}$ sec.); the subsequent behaviour of the positive parent ions, excited molecules and thermalized electrons (or negative ions) determines the overall chemistry of any system. The effect of physical state is clearly of paramount importance since the neutralization time of an ion in a gas at atmospheric pressure is about $10^{-3}$ sec., whereas the corresponding interval in the liquid phase is usually estimated[14] at about $10^{-12}$–$10^{-13}$ sec. Consequently ion-dissociation processes must be extremely fast to compete with neutralization in the liquid state and these are probably limited to exothermic reactions.[15] On the other hand the fragmentation of gaseous ions can be appreciable, even for endothermic dissociation, in a time of $10^{-10}$ sec. which corresponds to the interval between collisions at atmospheric pressure.[16] Apart from undergoing dissociation, parent ions may also react in ion-molecule processes which in some instances have been shown to occur on every collision in the mass spectrometer.[17] The importance of ions in the radiation chemistry of gases was originally emphasized by Lind.[18] Both ion-molecule and ion-dissociation processes can therefore make important contributions to the formation of free radicals and molecular products, particularly for gaseous systems, and there is now a substantial body of experimental evidence to support this contention.[19-20] One particular advantage which accrues from the evaluation of ionic processes is that the reactions of a polyatomic molecule-ion can often be specified with some degree of certainty. In considering the behaviour of excited polyatomic molecules, it is rarely possible to predict the nature of the reactivity unless a well-defined (e.g. triplet) state is concerned. The neutralization of an ion has often been represented unequivocally as leading to the formation of another excited molecule. An alternative process is the elimination of a proton from the prevailing ion in the case where the latter contains hydrogen,[13, 21] leading to hydrogen atom formation:

$$t.\mathrm{C_4H_9}^+ + e^- \rightarrow iso\mathrm{C_4H_8} + \mathrm{H}$$

It is also conceivable that in the presence of substances with high electron affinity, electron capture may occur with negative ion formation before neutralization.[22-4] In summary, we note that the processes following (or attendant upon) ionization, excitation, electron capture and neutralization lead to a wide spectrum of possible intermediate and molecular products. The transient chemical species are undoubtedly radicals and ions, but their nature and relative importance are largely determined by the chemical structure and physical state of the system. This chemical effect of ionizing radiations is expressed in terms of an energy yield or 'G unit', defined as the number of molecules produced or decomposed for each 100 ev. of energy absorbed from the radiations.

The chemical effects of thermal neutron capture are of special interest in the case of phosphorus, but this is a more specialized branch of radiation chemistry since the emphasis is placed mainly on the chemical fate of the radioactive atom. Nevertheless, it is important to consider the effect of energy dissipation during nuclear recoil since both the dense concentration of chemical decomposition products and, possibly, the transient high temperatures generated along the track would be expected to affect the ultimate result; these aspects are referred to below.

Although it is something of a misnomer to write of the radiation *chemistry* of phosphorus, it is appropriate to begin by noting the effects of radiation on the different allotropic and physical states of the element. Phosphorus vapour is known[25] from electron diffraction studies to be made up of $P_4$ molecules as regular tetrahedra, but above 800°C. the $P_4$ thermally dissociates to give $P_2$ molecules. Robinson[26] determined the ionization potential of neutral phosphorus to be less than 10·9 ev. by an optical spectroscopic investigation of the discharge emitted by a Geissler tube containing phosphorus vapour. It was noted in this work that the yellow phosphorus vapour quickly polymerized in the discharge tube to give a more stable brownish yellow substance of low vapour pressure. By the same technique, the second ionization potential of phosphorus was calculated to be 19·56 ev. In a second investigation of phosphorus spectra, using a hot spark discharge between beryllium electrodes containing red phosphorus, it was further established[27] that the ionization potentials corresponding to the formation of $P^{3+}$, $P^{4+}$ and $P^{5+}$ are 30·012 ev., 51·016 ev. and 64·698 ev., respectively. A more recent determination[28] of the first and second ionization potentials gives respective values of 10·48 ev. and 19·72 ev. which are in good accord with the previous data. Kerwin[29] has studied the mass spectrum of phosphorus; the element was evaporated from a hot filament and bombarded with electrons. No appearance potential measurements at low voltages were carried out. With 70 volt electrons, the mass spectrum showed the following relative ion yields: $P_1$ 16; $P_2$ 50; $P_3$ 6; $P_4$ 100; $P_5$, $P_6$ and $P_7$ none; $P_8$ 0·5; and the element was found to be largely monoisotopic. The observation of $P_8$ units in this work is interpreted as supporting the theory put forward by Pauling and Simonetta[30] for the mechanism of formation of red phosphorus from white phosphorus. According to this view one of the bonds of tetrahedral white phosphorus breaks open and the open tetrahedra then join in long chains forming amorphous red phosphorus; such chains are thought, however, to be unstable and to break down readily to give molecules made up of multiples of $P_4$ so that a low percentage of $P_8$ molecules would be expected in red phosphorus. The presence of appreciable amounts of $P_2^+$ ions in the mass spectrum suggests that the dissociation of the parent ion, $P_4^+$, occurs readily:

$$P_4^+ \rightarrow P_2^+ + P_2$$

There are several reports[31] which indicate that ultra-violet radiation catalyses the thermal conversion of white phosphorus to red phosphorus; the latter process[32] is ordinarily a first order reaction in the temperature range 250°–350°C. with an activation energy of 38 kg.-cal./mole. Rathenau[33] has studied the photochemical precipitation of red phosphorus from a solution of white phosphorus in carbon disulphide; the reaction velocity is again first order in concentration of white phosphorus and it has been suggested that the mechanism involves the dissociation of $P_4$:

$$P_4 \rightarrow 2P_2$$

the $P_2$ molecules recombining to form red phosphorus. Some observations[34] on the effect of pile irradiation on white phosphorus also indicate that conversion to red phosphorus occurs.

A modification of the chemical properties of red phosphorus after irradiation with neutrons in a reactor has been described[35] in which it was found that an irradiated sample was more easily oxidized by atmospheric oxygen than the inactive material. Thus about 1·0–1·5% of the total mass of an irradiated sample dissolved in an aerated aqueous solution to yield several oxy-acids of phosphorus. However, if the dissolution was attempted in the absence of air, only a small mass of the active phosphorus was found in solution. Evidence that the radioactive atoms dissolved more readily, in the presence of oxygen, than inactive material is suggested by the higher specific activity of the aqueous extract relative to insoluble phosphorus. The irradiation of orthorhombic black phosphorus[36] in a reactor for one month resulted in 0·03% expansion of the *c* axis as evidenced[37] by measurements on the broadening of the (00*l*) *X*-ray diffraction peaks. It is interesting that the same irradiation dose did not affect the lattice parameters of close-packed metallic crystals. The authors suggest[37] that the expansion is the result of the displacement of phosphorus atoms from the layers into interstitial lattice positions, and that (since the *c* direction is thought to be highly elastic under strain) even small disturbances between the planes would be sufficient to cause the observed effect. It was also noted that the *X*-ray diffraction pattern of the irradiated black phosphorus revealed a number of new lines which could partly be assigned to one of the several known forms of red phosphorus.[38] Although this finding suggests that black phosphorus can revert to the less stable red phosphorus under neutron bombardment, this conclusion must still be regarded as tentative since some characteristic lines of red phosphorus were not observed.

At this point it seems pertinent to mention that phosphorus atoms born in nuclear reactions do not appear in the form of elementary phosphorus. This conclusion rests on the study by Carlson and Koski[39] of the phosphorus products arising from the nuclear reaction $^{35}$Cl $(n, \alpha)^{32}$P in neutron-irradiated potassium chloride crystals. The effect of pre-irradiation treatment, particularly the out-gassing of the sample, affected the distribution of $^{32}$P in the various 'oxidation states' as determined by the use of phosphine, hypophosphite, phosphite and phosphate as carriers. The use of the term 'oxidation state' to denote the nature of phosphorus combination with other elements has been criticized by Van Wazer.[40] In any case, it appears to be a doubtful assumption that the valence state of phosphorus in the potassium chloride crystal necessarily corresponds to the final 'oxidation state' of the element after dissolution and, presumably, reaction has occurred in the carrier solution. Exposure of the crystal to low neutron doses after thorough de-gassing resulted in a high yield of radioactive phosphine, hypophosphite and phosphite on subsequent carrier analysis. It is claimed that this result accords with the theoretical expectation that, since the recoil energy of the phosphorus atom is too low for self-ionization to occur except at very high neutron energies, the phosphorus atom formed from the chloride ion would carry a $-3$ charge after the nuclear event. At high neutron doses, or if the sample was exposed to gamma radiation subsequent to pile irradiation, the proportion of radioactive phosphate in the products increased; this result is construed to indicate that the gamma component of the reactor irradiation is responsible for the conversion of phosphorus from the $-3$ to the $+5$ state as reflected in the product distribution. Additional experiments showed that the phosphorus activity could not be removed as the pentachloride, even by heating the crystal as high as 850°C., and this annealing treatment did not appreciably affect the amount of phosphate measured in solution. The last result appears to contradict the previous work of Süe and Caillat.[41] The range of $^{32}$P recoil in sodium chloride has been determined as $0{\cdot}5 \pm 0{\cdot}2\ \mu$ by Süe.[42]

It is convenient to divide the remaining discussion into parts dealing separately with inorganic and organic compounds of phosphorus.

## INORGANIC COMPOUNDS

### Phosphine

Electron impact measurements on phosphine in a mass spectrometer[43] have shown that $PH_3^+$, $PH_2^+$, $PH^+$ and $P^+$ ions can all be formed in varying abundance, depending on the ionizing energy of the electrons. The ionization potential of phosphine was determined to be $10{\cdot}0 \pm 0{\cdot}2$ ev. and the appearance potential of $PH_2^+$ corresponding to the dissociation process:

$$PH_3^+ \rightarrow PH_2^+ + H$$

was found to occur at $13{\cdot}9 \pm 0{\cdot}3$ ev. In the same investigation[43] two appearance potentials were observed for $PH^+$; the first at $12{\cdot}0 \pm 0{\cdot}3$ ev. corresponding to the dissociation:

$$PH_3^+ \rightarrow PH^+ + H_2$$

and a second located at 14·2 ev. is thought to arise from the more endothermic process:

$$PH_3^+ \rightarrow PH^+ + 2H$$

Some recent measurements by Stevenson[16] substantiate the ionization potential of phosphine as 10·1 ev., but the difference between this latter value and the appearance potential of $PH^+$ is given as 2·7 ev. which does not accord with the values quoted above. The appearance potential of the $P^+$ ion from phosphine was measured at $16{\cdot}7 \pm 1{\cdot}0$ ev. by Neuert and Clasen[44] and is thought to arise from the dissociation of the parent ion in the process:

$$PH_3^+ \rightarrow P^+ + H_2 + H$$

Stevenson[16] has discussed the use of mass spectrometric data to calculate the fragmentation pattern of parent ions for time intervals which are outside the range of observation, i.e., for less than $10^{-5}$ sec. after initial ionization, but which are of interest in radiation chemistry. By a treatment based on the quasi-equilibrium rate theory[45] of the origin of mass spectra, Stevenson has calculated[16] that the fraction of phosphine parent ions, $f_p$, which do not decompose to give $PH^+ + H_2$ after $10^{-10}$ sec. is 0·87. This calculation is valid for that region of ionizing electron energy (usually greater than 40 ev.) where $f_p$ is essentially constant. By comparison, the experimentally observed $f_p$ corresponding to a time of $10^{-5}$ sec. after initial ionization of phosphine is 0·38. Thus the usual mass spectrum pattern is not truly indicative of the ion distribution corresponding to the time before ion-molecule and collisional deactivation processes begin to intervene in the radiation chemistry of gases at appreciable pressures. Further aspects of this problem have recently been examined by Futrell for the case of propane.[46] It should be pointed out, however, that the statistical rate theory[45] in its present form appears to have distinct limitations in accounting for many aspects of ion-dissociation kinetics,[47] although it remains the only approach which has hitherto been developed. For the case of phosphine and small molecules, the theory[45] may be particularly unsuitable since the excited levels of $PH_3^+$ could well be discrete with low probabilities for rapid energy randomization as required by the model.

The only report[34] dealing with the macroscopic radiation chemistry of phosphine suggests that decomposition by reactor or gamma radiation occurs according to the overall equation:

$$PH_3 \rightarrow P + \tfrac{3}{2}H_2$$

There was no evidence for diphosphine, $P_2H_4$, or a polymer of the form $(PH)_x$ in the irradiation products. Attempts[34] to initiate the formation of phosphine by the irradiation of phosphorus and hydrogen gas were unsuccessful. In contrast to the dearth of experimental information on the mechanism of phosphine decomposition by radiolysis, the photochemical reaction has received detailed attention. Melville[48-9] studied the direct photolysis and found a quantum yield of 0·5 which increased with the diameter of the reaction vessel; additional experiments on the photosensitized reaction showed that the decomposition could be inhibited by atomic, but not by molecular, hydrogen. In conformity with these results, the following mechanism was formulated:

$$\text{(a)}\qquad \begin{array}{l} PH_3 + h\nu \rightarrow PH_2 + H \\ PH_2 + H + \text{wall} \rightarrow PH_3 \\ H + H + \text{wall} \rightarrow H_2 \\ PH_2 + PH_2 \rightarrow P_2 + 2H_2 \end{array}$$

In a similar investigation,[50] the quantum yield for the decomposition of trideuterophosphine was shown to be 1·1 times that for phosphine and this difference was attributed to a change in the relative frequencies of the secondary reactions. As a supplement to this earlier and classical approach some recent work by Norrish and Oldershaw,[51] using the techniques of flash photolysis[6,52] and kinetic spectroscopy, has led to the direct spectroscopic identification of $PH_2$, PH, and $P_2$ as reaction intermediates and provides new insight into the detailed mechanism of the decomposition. This latter work is an elegant example of the use of modern methods to demonstrate the unequivocal existence of transient chemical species such as free radicals. The overall stoicheiometry of the reaction induced by flash photolysis agrees with the equation:

$$PH_3 \rightarrow P\,(\text{red}) + \tfrac{3}{2}H_2$$

Immediately after the discharge of a flash, a high concentration of radicals is generated in the reaction vessel and this results in the secondary reactions occurring homogeneously, whereas with conventional light sources the secondary reactions are probably heterogeneous in character. Following the primary act, two possible processes can be written to account for the formation of the PH radical:

$$\text{(b)}\qquad PH_2 + PH_2 \rightarrow PH_3 + PH$$

or

$$H + PH_2 \rightarrow H_2 + PH$$

If the latter reaction is predominant, the quantum yield would be expected to show no temperature dependence since the hydrogen atoms would be eliminated from the system before the secondary abstraction reaction:

$$H + PH_3 \rightarrow H_2 + PH_2$$

could occur. However, it was found that the yield of the reaction was reduced if phosphine was flash-irradiated in the presence of an inert diluent; these conditions correspond to a lower effective temperature for the above secondary reactions. Hence the reaction between $PH_2$ radicals is assumed to give PH, and the increase in yield with rising temperature is attributed to the reaction of H with $PH_3$. It is consistent with the above scheme that a reaction between two radicals would be expected to have a lower activation energy than a radical-molecule interaction. A mechanism for the homogeneous photolysis of phosphine at low temperatures is therefore represented adequately by the following reactions:

$$\begin{array}{ll} & PH_3 + h\nu \rightarrow PH_2 + H \\ \text{(b)} & 2PH_2 \rightarrow PH + PH_3 \\ \text{(c)} & 2PH \rightarrow P_2 + H_2 \\ & H + H + M\ (\text{or wall}) \rightarrow H_2 \end{array}$$

The quantum yield of 0·5 for the above sequence is identical with the value observed by Melville, but the mechanism differs from that proposed for the direct photolysis in the form of the reaction between $PH_2$ radicals; reaction (*b*) is conceptually much simpler than (*a*) and is thought to be more important in the gas phase although it is conceded that (*a*) may well occur on the walls and could therefore be important under the conditions used by Melville. The absence of $P_2H_4$ formation suggests that combination of $PH_2$ radicals does not occur as an alternative to (*b*). In the flash photolysis,[51] $P_2$ was produced in a vibrationally excited state ($\nu''=7$) with up to 15 kg.-cal. excess energy, but it is uncertain whether this excitation is produced in the chemical reaction (*c*) or by absorption from the 'tail' of the photoflash followed by fluorescence back to the upper vibrational levels of the ground state. Deactivation of the $P_2$ molecule from the upper levels is fairly rapid and the lifetime of $\nu''=0$ level of $P_2$ is estimated between 1 and 2 msec., indicating that several thousand collisions take place before dimerization occurs to form $P_4$ molecules. If inert gas is present, the phosphorus remains suspended in the gas phase for several minutes before the particles grow large enough to sediment as a deposit of red phosphorus on the bottom of the flask. When ammonia was present with phosphine during flash photolysis, the absorption spectrum of PN was subsequently observed. This result indicates that the probable reaction:

$$(d) \qquad PH + NH \rightarrow PN + H_2$$

must have an activation energy comparable with process (*c*); it follows that, since the N–H bond dissociation energy exceeds that of P–H, both reactions (*c*) and (*d*) occur with very low activation energy.

The oxidation of phosphine is a branched-chain reaction which occurs spontaneously with explosion between certain pressure limits. However, the reaction can be induced photochemically outside these limits and followed quantitatively.[50,53] By flash photolysis[54] the radicals $PH_2$, PH, OH and PO were identified in the reaction mixture and the decay of their absorption spectra with time was followed. The results of this work[54] suggest that $PH_2$ and OH act as chain carriers in the straight propagation reactions:

$$PH_2 + O_2 \rightarrow HPO + OH$$

followed by:

$$OH + PH_3 \rightarrow H_2O + PH_2$$

The radical PH is assumed to be generated less frequently by the reaction:

$$PH_2 + O_2 \rightarrow PH + HO_2$$

and to react subsequently with an oxygen molecule to form an oxygen atom:

$$PH + O_2 \rightarrow HPO + O$$

The oxygen atom is then responsible for chain branching according to the process:

$$PH_3 + O \rightarrow PH_2 + OH$$

According to this plausible scheme,[54] termination is effected at low pressures by the reaction of oxygen atoms with other free radicals at the wall and at high pressures by the loss of oxygen atoms due to combination with molecular oxygen to form ozone. The previous mechanisms[50,55] postulated for this reaction stressed the importance of HPO as the intermediate involved in chain branching.

## Phosphorus Halides

The distribution of ions formed by electron impact on phosphorus trichloride is known from the work of Kusch, Hustrulid and Tate[56]; their values for the appearance potentials of the fragment ions and relative ion intensities at an electron ionizing of 120 volts are tabulated below:

| Ions | Abundance (120 volts) | Appearance potential (ev.) |
|---|---|---|
| $PCl_3^+$ | 100 | 12·2 |
| $PCl_2^+$ | 182 | 12·5 |
| $PCl^+$ | 38 | 17·5 |
| $P^+$ | 36 | 22·1 |
| $PCl_2^{++}$ | 2·4 | |
| $PCl^{++}$ | 0·4 | |

Since the appearance potential of $PCl_2^+$ is only slightly greater than the ionization potential for $PCl_3$, the high intensity of $PCl_2^+$ in the above fragmentation pattern can be attributed to a low activation energy for the dissociation process:

$$PCl_3^+ \rightarrow PCl_2^+ + Cl$$

This evidence would appear to suggest that chlorine atoms may be readily formed in the gas-phase radiolysis of phosphorus trichloride.

A study[57] of the labelled chemical species formed by neutron irradiation of phosphorus trichloride indicated that 88% of the total $^{32}P$ was present as $^{32}PCl_3$, irrespective of the total neutron dose, irradiation temperature or physical state (liquid or gas) of the compound. This conclusion [57] was revised according to a later study [58] which showed that for shorter irradiation exposures of liquid phosphorus trichloride, the proportion of $^{32}P$ in combination as $^{32}PCl_3$ was significantly lower than the above result and increased with time of irradiation from 60 to 90%. This latter growth is postulated to be caused by a radiation-induced conversion of radioactive $P_2Cl_4$ to form $PCl_3$. According to this scheme, the $P_2Cl_4$ is presumably formed by the combination of $PCl_2$ fragments remaining after P–Cl bond rupture in the recoil of the $^{32}P$. No visual decomposition was noted after irradiation and the residual fraction of the $^{32}P$ activity was probably present as phosphorus oxychloride.

A corresponding study[59] of reactor-irradiated phosphorus oxychloride showed that the $^{32}P$ fraction of activity present as $PCl_3$ decreased from 60% at low doses to a value of less than 10% for long irradiation exposure. Concurrently, the activity formed as $POCl_3$ increased over the same dose interval from 30 to greater than 80%. The possibility of phosphorus exchange in the $POCl_3$–$PCl_3$ system was shown to be negligible under the prevailing distillation conditions. It was further established that the *G* values for a gamma-ray induced phosphorus exchange were about 2·4 and 1·5 for respective concentrations of 3·7 and 1·4% $PCl_3$ in $POCl_3$, but this contribution could not account for the amount of $^{32}PCl_3$ present in the irradiated $POCl_3$. The authors[59] conclude that the high fraction of $^{32}PCl_3$ formed initially in the sample implies that a minimum number of three atoms must, on average, be split away in the recoil process following the $^{31}P(n, \gamma)^{32}P$ reaction; they further suggest that a secondary radiation-induced reaction involving recoil processes from $Cl(n, \gamma)$ reactions is responsible for the conversion of $^{32}PCl_3$ to give $^{32}POCl_3$ as well as a high-boiling component, presumably $PCl_5$, which is also assumed to be subsequently transformed to $POCl_3$. It is clear from the foregoing account that further work is required to clarify the many uncertainties with regard to the individual processes that occur in the neutron irradiation of phosphorus chlorides.

The kinetics of the gamma radiation-induced exchange of phosphorus in the $PCl_3$–$POCl_3$ system[60] have been shown to be adequately represented by the equation:

$$M = k'bD + k''abD$$

where *M* refers to the concentration of phosphorus exchanged while *a* and *b* are the respective concentrations of $PCl_3$ and $POCl_3$, all in units of millimoles per gram of solution, and *D* is the absorbed dose. The constants $k'$ and $k''$ were found to be $3{\cdot}19 \times 10^{-10}$ rad$^{-1}$ and $4{\cdot}24 \times 10^{-11}$ gram m.-mole$^{-1}$ rad$^{-1}$, respectively (1 rad $= 6{\cdot}24 \times 10^{13}$ ev. g.$^{-1}$). The first term of the above equation is independent of the $PCl_3$ concentration and is thought to correspond to a mechanism involving an exchange process in which the $POCl_3$ undergoes P–O bond rupture and the oxygen atoms then recombine with a molecule of $PCl_3$. The second term describes a second-order reaction which is presumed to involve either an induced transfer of oxygen between weakly coupled $PCl_3$–$POCl_3$ dipoles or else the exchange of oxygen during a collision process between the two component molecules when one of them is excited. Neglecting the second term in the above equation, i.e., for low concentrations of $PCl_3$, the $G$ value for phosphorus exchange at low conversion is deduced to be *ca.* 2·0 in agreement with earlier observations.[59]

It is reported[61–2] that a mixture of dry hydrogen and $PCl_3$ when subjected to a silent electric discharge results in the formation of $P_2Cl_4$, together with a small yield of red phosphorus contaminated with white phosphorus. If a copper cathode is used in the discharge tube, copper phosphide, $Cu_3P$, is apparently deposited on the electrode. By exposing $PCl_3$ alone to the effect of a high voltage discharge between mercury electrodes,[63] $P_2Cl_4$ is again produced. As part of a study of the irradiation effects of high energy electrons on mixtures containing an inorganic halide and a hydrocarbon, Henglein[64] found that the major products from the use of $PCl_3$ and $POCl_3$ are organic phosphorus dichlorides and organic derivatives of dichlorophosphine oxides, respectively. The overall process can be represented by the elimination of hydrochloric acid from the reactants:

$$PCl_3 + RH \rightarrow RPCl_2 + HCl$$

It appears that this simple process accounts for up to half of the total amount of initial material which undergoes reaction, and that conversions of 20–30% can be attained at high irradiation dosage. This method of radiation synthesis is recommended as a convenient route to several compounds which have not been prepared by conventional methods. It is postulated[64] that these reactions involve the intermediate formation of 'hot' hydrogen and chlorine atoms, but chain processes are ruled out by the magnitude of the yields. Since we have already indicated that the loss of chlorine atoms from ionized $PCl_3$ molecules would be expected to occur with relative ease, it is reasonable to suppose that a chlorine atom then undergoes a hydrogen-atom abstraction reaction with the hydrocarbon leaving an organic free radical to couple with the $PCl_2$ fragment. The amounts of $P_2Cl_4$ and hydrocarbon dimers in the products were generally much less than the yield of $RPCl_2$ and it is concluded[64] that the reaction between $R\cdot$ and $PCl_2\cdot$ is favoured over the combination or disproportionation of identical radicals. The irradiation of pure $PCl_3$ does not produce a yellow product, presumably phosphorus, which is usually found in the irradiated halide–hydrocarbon mixture. It is suggested that the phosphorus is formed from the secondary decomposition of the $P_2Cl_4$. A mixture of *n*-heptane and $PCl_3$ was found to give a number of isomers corresponding to the formula $C_7H_{15}PCl_2$. *cyclo*Hexene reacts with $PCl_3$ under these conditions to form a mixture of 3- and 4-*cyclo*hexenyl phosphorus dichlorides, the 3-isomer predominating; this result accords with the view that these reactions are of a free-radical character since a chlorine atom would be expected to abstract a hydrogen atom preferentially from the allylic 3-position in *cyclo*hexene.

Another interesting application of the use of radiation for synthetic purposes is in the preparation of phosphonitrilic chloride derivatives. Spitsyn[65] and co-workers have irradiated the tetramer of phosphonitrilic chloride as a 5% solution in absolute butyl alcohol; after exposure to 0·06 Mev. electrons for an integral dose of $1{\cdot}5 \times 10^{22}$ ev. ml.$^{-1}$, the yield of butyl phosphonitrilic ester remaining after removal of the *n*-butyl alcohol was found to be equivalent to the conversion of 45% of the initial phosphonitrilic chloride. This yield corresponds to a $G$ value of 1·6 for the replacement of chlorine atoms, based on total energy absorption. Thus it appears that the substitution of chlorine atoms by organic radicals is a reaction of some generality in the irradiation of phosphorus halides with organic compounds. The radiation stabilities of some of the lower homologues of phosphonitrilic chloride have been examined[66] by measuring the amount of insoluble polymer and gaseous products formed on bombardment with 4 Mev. electrons. On exposure of the solid (m.p. 113·5°C.) cyclic trimer $(PNCl_2)_3$ to a dose of $10^9$ rad, the yields of insoluble product were 2·62% and 5·19% for irradiations carried out *in vacuo* and under 1 atmosphere of oxygen, respectively. The addition of 10% benzoquinone increased the polymer yield, for the same dose, to 27% for irradiation at −78°C., although the same concentration of additive had little effect at room temperature; it is suggested that benzoquinone may act by accelerating a radiation-induced ionic polymerization at low temperature. Whereas the insoluble polymer formed in the presence of oxygen had the properties of a rubber, a waxy solid was produced when benzoquinone was added. A mixture of cyclic polymers of mean mol. wt. corresponding to $(PNCl_2)_{12}$ showed a steady increase in viscosity up to $5 \times 10^8$ rad, but the linear $(PNCl_2)_n,PCl_5$ polymer gave insoluble rubbers for doses below $2{\cdot}5 \times 10^8$ rad. The yields of chlorine gas obtained also indicate that the linear material is more susceptible to radiation decomposition than the cyclic compounds. Only a small amount of nitrogen was produced in comparison with chlorine, except in the case of the cyclic $(PNCl_2)_{12}$ where the measured nitrogen yield was almost twice that due to chlorine. The infrared spectra of the irradiated $(PNCl_2)_{12}$ showed no change in the bands attributable to P–Cl and P=N, but some absorptions indicative of P–O–P and $\rangle$P–OH linkages were observed for the material irradiated in oxygen. These authors[66] attribute the greater radiation stability of the cyclic phosphonitrilic chlorides over the linear polymers to the aromatic character of the former class[67]; however, this view may have to be modified in the light of a recent conclusion[68] that the resonance stabilization of the phosphonitrilic chlorides is due primarily to localized three-centre $\pi$-bonds involving a discontinuity in overlap at each phosphorus atom because of the use of two separate *d*-orbitals by phosphorus in $\pi$-bonding.

## Phosphorus Oxyacids

The oxyacids of phosphorus have been the subject of many irradiation studies, particularly concerning the effects accompanying $^{32}P$ recoil in solid crystalline salts exposed to thermal neutrons. On the latter subject, the results obtained by different workers are often in marked disagreement, and it is suspected that some, at least, of the discrepancies are due to variations in the techniques employed for the preparation of samples and in the handling and subsequent analysis after irradiation. The early work of Libby[69] indicated that for neutron-irradiated inorganic orthophosphates, approximately half of the $^{32}P$ remains in the pentavalent state with the remainder as trivalent phosphorus and that the immediate chemical environment does not affect this ratio. A series of similar investigations[70–6] have reported hypophosphite, phosphite, hypophosphate and pyrophosphate as radioactive products in addition to the retention of $^{32}P$ as orthophosphate, but most of this work refers to samples irradiated in the presence of air and often containing water of crystallization. By contrast, Sellers, Sato and Strain[34] claim that the main radioactive product from the irradiation of anhydrous $Na_2HPO_4$ in vacuum is orthophosphate with only traces of elementary phosphorus and some unidentified products. In addition, it has been shown that the effect of $3 \times 10^8$ roentgen of gamma radiation produces a negligible effect on the distribution of radioactive products. In a further study of phosphoric acid and a large number of its salts,[77] it has been confirmed that only traces of reduced radioactive products can be detected according to the electro-chromatographic method of separation and that the bulk of the activity is due to orthophosphate. A small amount of active material that migrated more slowly than the orthophosphate was claimed to be a condensed phosphate with similar properties to an irradiation product derived[75] from $KH_2PO_4$; this same product was also detected in samples which had been irradiated with gamma rays alone to high doses. The formation of pyrophosphate from the neutron irradiation of $Na_2HPO_4$ in 'boron-free' glass containers has been shown[78] to be an artefact due to the overall heating of the container during irradiation; the latter effect was found to be proportional to the boron content of the containers and therefore is attributed to energy release in the $^{10}B(n, \alpha)^7Li$ nuclear reaction. Samples irradiated under the same conditions in polyethylene or quartz tubes did not yield pyrophosphate. In some ancillary experiments,[78] the thermal conversion of disodium acid phosphate to pyrophosphate was followed by the technique of differential thermal analysis and an endothermic reaction was observed to occur between 325° and 390°C. The absence of pyrophosphate in the neutron-irradiated phosphate is presented as evidence[77] that the energy dissipation in $^{32}P$ recoil is unable to heat the activated molecule, or those in its immediate environment, to the necessary reaction temperature for a sufficient period of time to enable condensation to proceed. It has been argued[79] that the tracks of recoiling atoms do in fact correspond to localized zones of transient high temperature, and thus it would be interesting to investigate other systems where thermal effects of this type could perhaps be of greater importance. A second conclusion adduced by Sato *et al.*[77] from their results is either that P–O bonds are not disrupted or that they recombine after disruption in a manner identical with their disposition in the original material. The latter explanation is considered unlikely since samples of various condensed phosphates, including pyrophosphates and metaphosphates, were all shown to produce radioactive forms identical with the starting material regardless of physical state, degree of condensation or molecular size.

Despite the evidence reviewed above, there have been some recent suggestions[80-1] that the absence of reduced products and pyrophosphates as revealed by the experiments of Sato *et al.*[34, 77-8] may have been due to annealing processes arising in the pile from thermal effects and the concomitant gamma radiation, or from the heating of the sample during separation by electrophoresis. Claridge and Maddock[80] report that the products of neutron irradiated ammonium and potassium dihydrogen phosphates can undergo appreciable annealing by a thermal treatment at about 100°C. and by ultra-violet or electron irradiation, with a substantial increase in the percentage of activity retained in both total phosphate and orthophosphate fractions. Yoshihara and Yokoshima[81] irradiated a wide variety of orthophosphates and found large amounts of activity as phosphite, hypophosphite, pyrophosphate and higher condensed phosphates. The retention of activity in the parent phosphate appears to be greater, while the fraction of activity in the form of combined phosphite and hypophosphite is generally smaller, for hydrated relative to anhydrous salts. In contrast to the conclusions mentioned earlier, the latter authors suggest that local high temperatures are produced during $^{32}P$ recoil[79] and that this explains the formation of radioactive pyrophosphate and higher polyphosphates, including polymetaphosphates, $(MPO_3)_n$. It is clear that the points in dispute regarding $^{32}P$ recoil effects in organic phosphates can be resolved only by additional experiments designed to eliminate the uncertainties in regard to irradiation conditions and methods of analysis.

The neutron irradiation of disodium hydrogen phosphite and sodium dihydrogen hypophosphite under anhydrous conditions *in vacuo* has been shown[34] to result in about 50% retention of the $^{32}P$ in the original salt. Both hypophosphite and phosphate are formed from phosphite, and phosphite together with phosphate are products from hypophosphite. From the results on these salts using pile and gamma radiation separately, it appears that gamma rays alone induce similar chemical changes to those encountered in the formation of the $^{32}P$ recoil products. However, the gamma component of pile radiation cannot solely account for the changes in chemical constitution of the radioactive products.

Although there is a conflict of evidence on the chemical stability of solid inorganic phosphates subjected to the effects of thermal neutron capture, the extensive work of Cottin, Haïssinsky and Lefort[82-5] on the gamma- and alpha-ray irradiation of the inorganic phosphite–phosphate system in aqueous solution leaves little doubt that the phosphate ion is not reduced in either aerated or deaerated systems. It should also be mentioned that the use of relatively large concentrations of phosphate ions in the preparation of aqueous buffer solutions for the irradiation of solute systems has been practised[86] without, apparently, affecting the primary radiolysis of water to any significant extent. In this respect, the behaviour of phosphate appears to parallel that

**Refs. p. 1389**

of sulphate, and it would appear that these anions are highly stable both to the direct absorption of energy[87] and to the radiolysis products of water. A general description of the radiation chemistry of aqueous solutions[88-9] is outside the scope of this section, but it is pertinent to discuss the main features of the radiation-induced oxidation of phosphite ion in dilute solution,[82-5] Cottin[85] has established that phosphite ions are completely oxidized to phosphate under all irradiation conditions, both in the presence and in the absence of oxygen in solution. Thus there is no evidence for a radiation-induced equilibrium between phosphite and phosphate ions. In irradiations with 10 Kev. *X*-rays or $^{60}$Co gamma-rays the oxidation yield in evacuated solutions is equivalent to the hydrogen gas evolved, but the magnitude of this yield depends both on the pH of the solution and the initial phosphite concentration. For a concentration of $10^{-3}$ M. phosphite, the oxidation yield ($G$) is 3·15 at a pH of 0·1 but declines to 1·8 at a pH of 7·7. The oxidation yield at constant pH appears to reach the maximum value at a concentration of $2 \times 10^{-3}$ M. phosphite with a $G$ yield of 3·75 in 0·8 N. $H_2SO_4$ solution (pH$\simeq$0·1). The last oxidation yield cannot be attributed solely to the effect of the OH radical, since two OH species must be involved in the oxidation of a single phosphite ion according to the overall equation:

$$H_2PO_3^- + 2OH \rightarrow H_2PO_4^- + H_2O$$

and this process alone would imply the formation of 7·5 OH radicals per 100 ev., which is more than twice the known value of $G(OH) \simeq 3{\cdot}2$. Hence it is inferred that H atoms are also able to oxidize phosphite according to the equation:

$$H + H_2PO_3^- \rightarrow H_2 + HPO_3^-$$

this represents an exothermic process since the bond dissociation energy of H–H (103 kg.-cal./mole) exceeds that of P–H (63 kg.-cal./mole). A combination of oxidation steps provided by OH radicals and H atoms can therefore account for the equivalence of hydrogen gas to the oxidation yield, and the mechanism is postulated to proceed through a single tetravalent intermediate ($H_2PO_3$, $HPO_3^-$ or $PO_3^{2-}$):

$$\begin{gathered} H_2PO_3^- + OH \rightarrow HPO_3^- + H_2O \\ H_2PO_3^- + H \rightarrow HPO_3^- + H_2 \\ 2HPO_3^- + H_2O \rightarrow H_2PO_3^- + H_2PO_4^- \end{gathered}$$

In the presence of added hydrogen peroxide, the phosphate yield is enhanced owing to the reaction:

$$HPO_3^- + H_2O_2 \rightarrow H_2PO_4^- + OH$$

When oxygen is present, the initial oxidation yield ($G$) reaches a maximum at pH 3·0 and is about 30 at pH 2·15 for $10^{-3}$ M. phosphorous acid. The consumption of 1 molecule of oxygen corresponds, at high phosphite ion concentration, to the oxidation of two phosphite ions. A mechanism consistent with the results involves the following reactions:

$$\begin{array}{ll} & H_2O \xrightarrow{O_2} HO_2 + OH \\ & H_3PO_3 \rightleftharpoons H_2PO_3^- + H^+ \\ (1) & H_2PO_3^- + OH \rightarrow HPO_3^- + H_2O \\ (2) & HPO_3^- + O_2 \rightarrow HPO_3 + O_2^- \\ (3) & HPO_3 + H_2O \rightarrow H_3PO_4 \rightleftharpoons H_2PO_4^- + H^+ \\ (4) & H^+ + O_2^- \rightleftharpoons HO_2 \\ (5) & H_2PO_3^- + HO_2 \rightarrow H_2PO_4^- + OH \end{array}$$

The propagation steps in this chain oxidation involve the electron transfer reaction (2) followed by (4) and (5); termination is assumed to occur by inter-radical reactions as in (6) and (7).

$$\begin{array}{ll} (6) & HPO_3^- + OH \rightarrow H_2PO_4^- \\ (7) & OH + HO_2 \rightarrow H_2O + O_2 \end{array}$$

The dependence of the yield on pH is explained qualitatively in terms of the ionization equilibria involving $H_3PO_3$ and $HO_2$; both these latter species are largely dissociated in neutral solution where reaction (5) takes the form:

$$H_2PO_3^- + O_2^- \rightarrow HPO_4^{2-} + OH$$

and would involve strong electrostatic repulsion between the reacting entities. Thus chain propagation by this route is impeded and a lower yield obtains. At low phosphite concentration the relationship of one oxygen molecule consumed per two phosphite ions oxidized breaks down and this is explained in terms of the increased importance of inter-radical reactions (6) and (7) over radical-solute processes (1) and (5). The action of polonium α-rays on this system results in much lower $G$ yields for phosphite oxidation relative to the values obtained for gamma irradiation under corresponding conditions. In deaerated solution the sum of $G_{(\text{phosphate})} + G_{H_2O_2} + 2G_{O_2}$, corresponding to a total oxidation yield for the system, is constant (*ca.* 1·7) and agrees with $G_{H_2}$ over the entire concentration range from $10^{-4}$ to $10^{-1}$ M. phosphite ion in 0·8 N. $H_2SO_4$. While $G_{O_2}$ assumes a mean value of 0·45 almost independent of phosphite concentration, $G_{H_2O_2}$ (0·47) exceeds $G_{(\text{phosphate})}$ (0·19) at $2 \times 10^{-4}$ M. phosphite but at a higher solute concentration, ($5 \times 10^{-3}$ M.), $G_{H_2O_2}$ is reduced to zero and $G_{(\text{phosphate})}$ becomes 0·79. When 0·8 N. $H_2SO_4$ is irradiated in the absence of phosphite, $G_{H_2} = G_{H_2O_2} + 2G_{O_2} = 1{\cdot}75$.

These findings are interpreted[90] to mean that intra-track OH radical reactions yielding $O_2$ are unaffected even at high phosphite ion concentrations. The increase in $G_{(\text{phosphate})}$ with solute concentration would appear to be due to an increased efficiency of the scavenging reaction:

$$H_2PO_3^- + OH \rightarrow HPO_3^- + H_2O$$

augmented by the attack of $HPO_3^-$ on the 'molecular yield' of $H_2O_2$ according to the process:

$$HPO_3^- + H_2O_2 \rightarrow H_2PO_4^- + OH$$

Confirmation of the latter step is afforded by the observation of an enhanced phosphate yield ($G = 1{\cdot}6$) and complete removal of $H_2O_2$ on the irradiation of a $5 \times 10^{-3}$ M. phosphite solution containing added $3 \times 10^{-4}$ M. $H_2O_2$. In the presence of oxygen, phosphite concentrations exceeding $10^{-2}$ M. are necessary to attain oxidation yields indicative of a chain mechanism. This result is attributed to the effect of the high OH radical concentration in the α-ray track favouring the reaction of OH with $HPO_3^-$ immediately after formation of the latter:

$$OH + HPO_3^- \rightarrow H_2PO_4^-$$

thus decreasing the probability of the electron transfer step:

$$HPO_3^- + O_2 \rightarrow HPO_3 + O_2^-$$

previously postulated as the initial reaction in the gamma-induced chain oxidation.

The irradiation of aqueous phosphoric acid at 77°K. results in the formation of trapped atomic hydrogen which has been identified by electron spin resonance.[91] By comparison, atomic hydrogen is produced in irradiated ice[92] only at much lower temperatures, *ca.* 4°K., and disappears on warming much below 77°K. Thus it is evident that solid aqueous phosphoric acid constitutes a better stabilizing medium for atomic hydrogen than ice; aqueous perchloric and sulphuric acids behave similarly to phosphoric acid in this respect. It is also found [93] that the yields of atomic hydrogen are greater when the aqueous acid is irradiated in the glassy as compared with the crystalline state over the entire range of acid composition. The amount of molecular hydrogen evolved on warming the crystalline aqueous $H_3PO_4$ to the melting point is in good agreement with the yield of atomic hydrogen as determined by the paramagnetic resonance method; for the irradiated glass, the yield of atomic hydrogen exceeds that due to liberated hydrogen. The maximum initial yields for aqueous phosphoric acid are attained at a mole fraction of $H_3PO_4 \simeq 0{\cdot}2$; $G$(H) values of 0·6 and 1·0 are recorded for the crystalline and glassy states respectively whereas $G(H_2)$ is about 0·30, almost independent of state. An important conclusion derived from this work is that atomic hydrogen reacts preferentially by atomic combination in these systems rather than with the other paramagnetic species present; this is confirmed by the observed persistence of paramagnetic resonance after the characteristic spectrum of atomic H has disappeared on warming the sample to a temperature still considerably below the melting point.

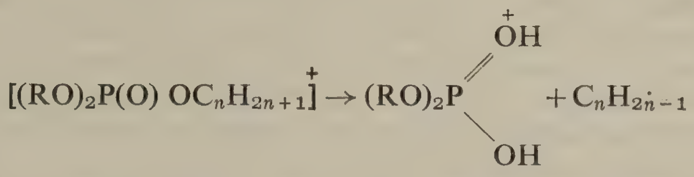
## ORGANIC PHOSPHORUS COMPOUNDS

Numerous studies of the irradiation of organophosphorus compounds have been motivated by the technological needs of the nuclear energy industry. One compound which has been studied repeatedly is tri-*n*-butyl phosphate (TBP) since it finds application as a solvent for the processing of nuclear fuels. There is a general consensus of agreement that *di-* and *mono-n*-butyl phosphoric acids are formed together with gaseous and polymeric products; the yields recorded by different investigators are shown in Table I.

*Table I.—G-values for Radiolysis of Tri-n-butyl Phosphate*

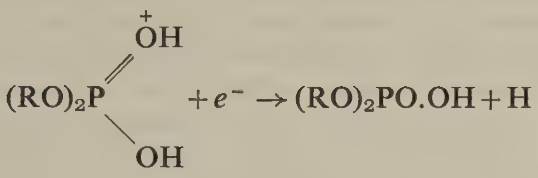
| Author | Radiation used | Dibutyl phosphate DBP | Monobutyl phosphate MBP | $H_2$ | $CH_4$ | $C_2$ | $C_3+C_4$ |
|---|---|---|---|---|---|---|---|
| Williams, Wilkinson and Rigg[94]<br>Wilkinson and Williams[95] | 1·25 Mev. electrons | 1·52 | 0·12 | 1·11 | 0·05 | 0·24 | 0·45 |
| Burger and McClanahan[96] | Co–60 gamma | 1·7–1·8 | 0·3 | | | | |
| Wagner, Kinderman, and Towle[97] | 1 Mev. electrons | 2·25–1·37 | 0·39–0·03 | 1·59 | 0·07 | 0·13 | 0·75 |
| Burr[98] | 1·66 Mev. electrons | 2·44 | 0·14 | 1·73 | 0·07 | 0·18 | 0·65 |

Burger and McClanahan[96] claim that in addition to the products listed, *n*-butyl alcohol is formed, but it could not be detected as an irradiation product from the radiolysis of TBP saturated with water.[94] It is interesting that the presence of water in the TBP reduces the yield of acidic products,[94, 96] and there is no evidence that the mechanism of decomposition by radiolysis is related to the mode of hydrolysis. In this respect, it is pertinent to mention that studies[99] of the chemical stability of TBP in nitrate and chloride solutions indicate that the acid-catalyzed reaction is not a hydrolysis but involves dealkylation; similarly, the thermal decomposition[100] occurs with olefin elimination and is catalyzed by acids. Burr has suggested[98] that the mechanism of TBP radiolysis can be interpreted on parallel lines to the radiation chemistry of ethanol[101] and other alcohols, according to which the primary process would be the rupture of a C–H bond at one of the carbon atoms linked to the oxygen in the phosphate group. Another view[95] is based on recent mass-spectral work[102–3] which has demonstrated that parent organic phosphate ions, in the gas phase, can undergo facile rearrangement with the fragmentation of one, two or all three alkyl chains. An extrapolation of the last results to account for the radiolysis products in the liquid phase requires the fragmentation pattern to be modified so that only primary decomposition processes involving the rupture of one alkyl chain are predominant; it has been argued[95] that this is a reasonable assumption and that the criterion of exothermicity determines whether parent ions can undergo dissociation in the liquid phase before neutralization[15]:



$$[(RO)_2P(O)\,OC_nH_{2n+1}]^{+} \rightarrow (RO)_2P(\overset{+}{O}H)(OH) + C_nH_{2\dot{n}-1}$$

The neutralization of the fragment ion is considered to proceed by removal of a proton with the formation of a dialkyl phosphate molecule and a hydrogen atom:



$$(RO)_2P(\overset{+}{O}H)(OH) + e^{-} \rightarrow (RO)_2PO.OH + H$$

Because of the short lifetime, *ca.* $10^{-13}$ sec., of an ion in the liquid phase, the diffusion distance of the radical $C_nH_{2n-1}$ in the interval between rearrangement and neutralization would be small so that both $C_nH_{2n-1}$ and H are formed in close proximity according to this model, thus favouring their combination. Hence the products of the above reactions may be amended to dialkyl phosphate and olefin. In an extended study[95] the *G* yields of dialkyl phosphoric acids have been shown to decrease in the series trimethyl to tripentyl phosphate, whereas *G* for hydrogen gas formation increases with molecular weight. These results are interpreted[95] on the premise that the parent ion can either undergo dissociation and rearrangement as indicated above or else react with a neighbouring molecule to form a dimer by loss of molecular hydrogen. Since the dimerization or cross-linking reaction is well known in the radiation chemistry of linear alkanes, it is reasoned that this type of process would be expected to attain greater importance as the alkyl groups increase in size. It should be added that neither oxygen gas nor pyrophosphates have been found as products of the gamma- or fast electron-radiolysis of these organic esters of orthophosphoric acids; this lends further support to the view that the phosphate group is inherently stable to irradiation.

It is interesting to compare the above information with some results which have been obtained for the distribution of $^{32}P$ in TBP samples exposed to neutron irradiation.[104] At low neutron beam intensities, it appears that only a small amount (5·5%) of the total activity remains in the parent molecule and appreciable fractions are due to DBP (22–28%), MBP (33%), and inorganic phosphorus compounds (26–36%) soluble in water; the last fraction consists mainly of orthophosphate and orthophosphite. This proportion of $^{32}P$ activity in the aqueous phase is similar to that observed in the neutron irradiation of triphenyl phosphate in benzene[105] where 40% of the induced activity dissolved in water. On the other hand, when TBP is irradiated at high neutron fluxes[104] the $^{32}P$ is retained preferentially (59%) as radioactive TBP with considerably smaller fractions in the form of MBP and in the aqueous extract, although the DBP fraction remains appreciably similar (24%) to that encountered at lower neutron intensities. The possibility that isotopic exchange affects the distribution of yields is ruled out on account of previous work. Some calculations[104] based on a stochastic procedure[106] for determining the probability of escape by a recoiling atom from the parent molecule suggest that only 3% of $^{32}P$ atoms remain as originally bound. Hence, it is concluded that the high yield of $TB^{32}P$ must be the result of recombination processes involving radical fragments and is not due to primary retention; the results are held to be inconsistent with the 'billiard-ball' mechanism advanced by Libby.[107]

The chemical state of $^{32}P$ in neutron-irradiated phosphorus compounds has been explored in a number of other systems,[108-10] but it is almost impossible to obtain definitive evidence in condensed systems to decide between the alternatives of primary retention or recombination to explain the occurrence of activity in the parent molecule. However, a recent study by Halmann[111] has succeeded in clarifying the processes following thermal neutron capture in gaseous trimethylphosphine. Irradiation at pressures of about 100 mm. was shown to result in the formation of *ca.* 3% $^{32}P(CH_3)_3$ compared to 13·7% $^{32}PH_3$, 4·9% $^{32}PH_2(CH_3)$, and 0·8% $^{32}PH(CH_3)_2$; the remainder (77·7%) of the $^{32}P$ was deposited on the walls of the vessel. As the initial pressure was decreased in these experiments, the fraction of $^{32}P$ appearing in the parent compound was reduced still further until it represented less than 0·4% of the total activity at a pressure of 1·8 mm. In order to decide whether this effect is the result of a decrease in the probability of recombination at lower pressures or is due to a greater likelihood of disruption owing to the greater mean free path of the recoiling molecule, further experiments were performed with low partial pressures of trimethylphosphine in the presence of 50 mm. of added argon. The results indicated negligible retention, which suggests that moderation of the activated molecule by energy transfer in collisions is a negligible factor. Thus this evidence supports the recombination theory to explain retention in gaseous systems.

In addition to TBP, many other organophosphorus compounds have been examined as possible extraction solvents for the processing of radioactive materials, and an overall assessment of their potential value must include some consideration of radiation stability. In this connection, it has been shown[97, 112] that di-*sec*-butyl phenyl phosphonate and tri-*n*-octylphosphine oxide are slightly more resistant to fast electron radiation than TBP as judged by criteria of gas and acid production. It has been reported[113] that, in the presence of air, tri-*iso*propyl phosphite labelled with $^{32}P$ undergoes appreciable oxidation, whereas unlabelled material is unaffected under the same conditions. Some mass spectroscopic data have been recorded[114] for the cyclic dimethylphosphino-borine trimer, $((CH_3)_2PBH_2)_3$. It is interesting that the most abundant ion in the 70-volt spectrum is $B(CH_3)_2^+$ which must be formed by a rather extensive rearrangement process. This ion has the high appearance potential of 20 ev., so it is somewhat surprising to find it present in such high intensity even at an electron ionizing energy of 70 ev. The thermal decomposition of the trimer at 510°C. also results in the migration of methyl groups to boron with the eventual formation of methyl substituted boranes and of elementary phosphorus.

Considerable effort has been devoted over the past decade to the study of irradiation effects on biologically important substances, many of which contain phosphorus in the molecular structure. In particular, the nucleic acids have been widely investigated under varying conditions of irradiation exposure. A recent review[115] summarizes much of the information which has been obtained. It is worthy of mention that the use of physical methods has contributed greatly to the general understanding of irradiation effects on macromolecules, and an elegant example is the deduction[116] from viscosity and light-scattering measurements that two irradiation-induced breaks must occur close together in deoxyribonucleic acid (DNA) to effect scission; this finding concurs with the Watson–Crick model for DNA involving a two-stranded polynucleotide structure. The complementary investigations of chemical changes have been centred mainly on aqueous solutions where the effects are 'indirect' and proceed through the radical products from the radiolysis of water. Scholes, Weiss and their collaborators[117] have presented evidence for reactivity at various positions in the nucleic acid structure leading to breakage of the nucleotide chain, hydroperoxide formation in the presence of oxygen, deamination of the base, and ring fission. Inorganic phosphate is reported to be produced in low yield both directly during irradiation and in a subsequent post-irradiation reaction. It is clear that for such a complex molecule, the mechanism of radical attack is non-selective and that the overall process is one of great chemical complexity. Since the diester from phosphoric acid and sugar hydroxyl groups constitutes the essential linkage in the nucleic acid chain, it is of related interest to examine the irradiation of simpler phosphate esters and a few investigations have been reported along these lines. Butler and

Conway[118] have studied the kinetics of inorganic phosphate formation in the photolysis of aqueous solutions of mono-, di- and tri-ethyl phosphates containing hydrogen peroxide. The yield of inorganic phosphate from mono-ethyl phosphate varies linearly with time of irradiation, but the corresponding curves for di- and tri-ethyl phosphate show much smaller yields per unit time which increase slowly as the irradiation proceeds. These results are explicable on the postulate that the reaction is due to a cleavage of the alkyl chain at the carbon atom linked to the phosphate group, which in the case of the mono-alkyl ester leads to direct phosphate ejection. The liberation of free phosphate from the di- and tri-esters is represented as the net result of two and three consecutive processes, respectively. Acetaldehyde and formaldehyde are formed from mono-ethyl phosphate, but there is no evidence for labile esters which degrade subsequent to the irradiation. All the facts are consistent with a simple scheme whereby some of the primarily formed OH radicals abstract hydrogen atoms from the alkyl group(s) to produce organic radicals, and the latter combine with more OH species to form an unstable product which breaks down readily to give an aldehyde and inorganic phosphate:

$$CH_3CH_2OPO_3H_2 + OH \rightarrow CH_3\dot{C}HOPO_3H_2 + H_2O$$
$$CH_3\dot{C}HOPO_3H_2 + OH \rightarrow CH_3CH(OH)OPO_3H_2 \rightarrow CH_3CHO + H_3PO_4$$

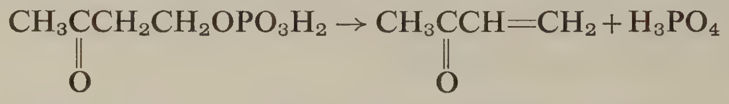
Concerning the effects of ionizing radiation on aqueous solutions of organic solutes, it is generally found that the presence of oxygen in the solution during irradiation modifies the results both quantitatively and qualitatively. This behaviour is particularly evident for the esters of phosphoric acid, and can be attributed to the combination of molecular oxygen with organic radicals $R\cdot$ to form peroxy-intermediates $RO\cdot_2$ which undergo subsequent reactions (*vide infra*). Thus Scholes and Weiss[119] have shown that acetyl phosphate is formed from the irradiation of mono-ethyl phosphate solutions containing oxygen, but only inorganic phosphate is produced *in vacuo*.[119–120] Further work[120–1] on the irradiation of aqueous solutions of the mono-alkyl phosphoric acids in the series from methyl to *n*-pentyl has contributed information as to the distribution of radical attack on an extended alkyl chain. In the absence of oxygen, only inorganic phosphate is formed from each of the esters examined, and the *G* values for irradiation at pH 8 decrease from 1·1 for the methyl ester to 0·3 for both *n*-butyl and *n*-pentyl phosphate. These results were found to be less reproducible than those obtained in oxygenated solution and also showed some dependence on dose rate.[121] The yields obtained at pH 8 in the presence of oxygen[120–1] are given in Table II; these values are independent of solute concentration above $10^{-3}$ molar.

*Table II.—Product Yields from the Irradiation of Monoalkyl Phosphates*
($10^{-3}$ M. solutions at pH 8)

| Solute | *G* Inorganic phosphate | *G* Acyl phosphate | *G* Labile phosphate(a) | *G* Acid | *G* Aldehyde | $G_i$ Total hydro-peroxide | $G_i$ $H_2O_2$ |
|---|---|---|---|---|---|---|---|
| Methyl | 2·8 | 0 | 0 | 2·4(b) | 0·4 | 3·3 | 3·3 |
| Ethyl | 1·0 | 1·3 | 0 | — | 0·85 | 2·9 | 2·9 |
| *n*-Propyl | 1·0 | 0·35 | 0·2 | — | 0·8 | 2·8 | 1·6 |
| *n*-Butyl | 1·0 | 0·15 | 0·7 | — | 0·8 | 2·8 | 1·4 |
| *n*-Pentyl | 0·9 | *ca.* 0·1 | 0·2 | — | 0·75 | 2·7 | 1·2 |

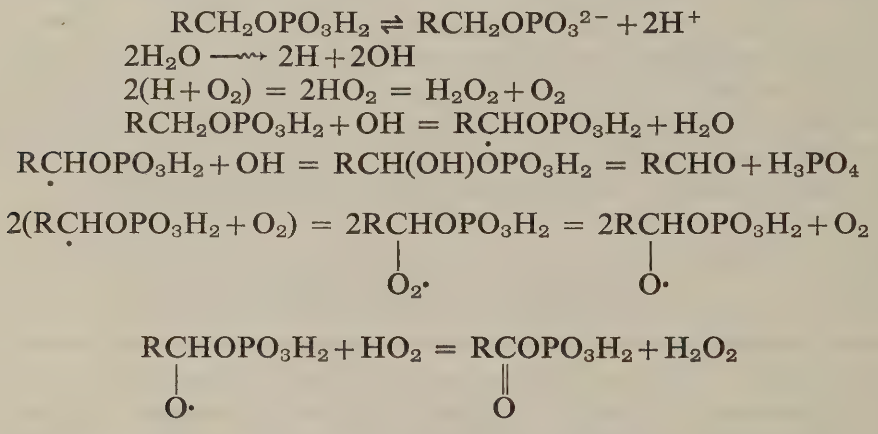
*i* Refers to initial yields.
(a) Refers to inorganic phosphate liberated after irradiation.
(b) Refers to formic acid.

The results for methyl phosphate appear anomalous in regard to the absence of acyl phosphate, but no compound corresponding to formyl phosphate appears to be known and in view of the increase in lability of acyl phosphates with decreasing length of alkyl chain, it is inferred that such a product would hydrolyze rapidly under the mildest conditions. A high yield of formic acid supports this contention. Except for methyl phosphate, the yields of inorganic phosphate and aldehyde appear to be comparable for each solute. The aldehyde was identified as having the same number of carbon atoms as the alkyl group from which it was derived, and it is reasonable to suppose that aldehyde and inorganic phosphate are formed in a common process through an intermediate similar to that postulated to account for the reaction of OH radicals with ethyl phosphate.[118] The yield of labile phosphate is taken to represent the subsequent breakdown of ketophosphates formed by radical attack at $\beta$- or $\gamma$-carbon atoms. Evidence on this point is provided by the marked catalysis of the post-irradiation effect for butyl phosphate by added alkali, which indicates that the process is mainly an elimination reaction rather than a hydrolysis[121]:



$$CH_3\underset{\underset{O}{\|}}{C}CH_2CH_2OPO_3H_2 \rightarrow CH_3\underset{\underset{O}{\|}}{C}CH{=}CH_2 + H_3PO_4$$

Since no after-effect of any type was observed for irradiated ethyl phosphate, it is surmised that initial radical attack occurs predominantly at the $\alpha$-carbon atom leading to acetyl phosphate and inorganic phosphate. It is also consistent that the $G$ values for inorganic + acyl phosphate derived from methyl and ethyl phosphate are not appreciably less than $G_R$ (radical yield) = *ca.* 3·2. In the case of the larger alkyl groups, application of the same criteria as above leads to the conclusion that $\rangle CH_2$ groups remote from the phosphate group are attacked by the primary radicals in irradiated water. The tabulated results refer to the natural pH (7·8) of a solution of the sodium or barium salt; variation of pH showed that maximum yields were attained at this latter value except for the case of ethyl phosphate where higher yields were observed in acid solutions. A mechanism reasonably consistent with the results for methyl and ethyl phosphate is given by the following scheme of reactions[121]:



$$RCH_2OPO_3H_2 \rightleftharpoons RCH_2OPO_3^{2-} + 2H^+$$
$$2H_2O \rightsquigarrow 2H + 2OH$$
$$2(H + O_2) = 2HO_2 = H_2O_2 + O_2$$
$$RCH_2OPO_3H_2 + OH = R\underset{\bullet}{C}HOPO_3H_2 + H_2O$$
$$R\underset{\bullet}{C}HOPO_3H_2 + OH = RCH(OH)OPO_3H_2 = RCHO + H_3PO_4$$
$$2(R\underset{\bullet}{C}HOPO_3H_2 + O_2) = 2R\underset{\underset{O_2\cdot}{|}}{C}HOPO_3H_2 = 2R\underset{\underset{O\cdot}{|}}{C}HOPO_3H_2 + O_2$$
$$R\underset{\underset{O\cdot}{|}}{C}HOPO_3H_2 + HO_2 = R\underset{\underset{O}{\|}}{C}OPO_3H_2 + H_2O_2$$

An interesting effect[122] has been observed on irradiation of oxygenated solutions of methyl or ethyl phosphoric acid containing added *ca.* $10^{-3}$ M. hydrogen peroxide. At pH 8 and below, the yield of total phosphate (inorganic + acyl) liberated is enhanced over the value given in the absence of $H_2O_2$, but at pH 12 the opposite result is found. While the increase in yield can be readily explained in terms of a contribution due to reactions of the form:

$$R\underset{\bullet}{C}HOPO_3H_2 + H_2O_2 = RCH(OH)OPO_3H_2 + OH$$

the reduced yield at high pH can only be rationalized on the basis of a competition between $H_2O_2$ and the alkyl phosphate for OH radicals. Since there is evidence[123] that OH is largely dissociated to $O^-$ at a pH exceeding 10, it is suggested that electrostatic repulsion between $O^-$ and the ionized alkyl phosphate anion hinders the process of hydrogen abstraction in this instance, thus allowing other reactions of $O^-$ radicals to compete more favourably, e.g.,

$$O^- + H_2O_2 \rightarrow H_2O + O_2^-$$
$$(\text{cf. } OH + H_2O_2 \rightarrow H_2O + HO_2)$$

The action of 200 kv. *X*-rays on aqueous solutions of α- and β-glycerophosphates has also been shown[124] to result in attack by OH radicals on the carbon atom linked to the phosphate and on neighbouring carbon atoms. In this case the $\rangle CH(OH)$ group is susceptible to oxidation by OH radicals and $\rangle C{=}O$ groups are formed even in the absence of oxygen. As a result, dihydroxyacetone phosphate is formed in addition to inorganic phosphate from α-glycerophosphate and although the presence of oxygen is not essential, higher yields of dihydroxyacetone phosphate obtain in aerated solution. Dihydroxyacetone phosphate is labile in alkaline solution and this is attributed to an elimination rather than a hydrolytic reaction. One of the main products from the irradiation of β-glycerophosphate is a phosphate ester labile to acid hydrolysis at high temperature. Organic hydroperoxides were not detected and therefore must be unstable if they are formed. The yields of the various products depend on solute concentration and pH. It is clear that the radiation chemistry of phosphorus oxyacids and their derivatives in aqueous solution is much influenced by the ionic form of the solute.

This section is concluded with a brief reference to the role of phosphorus compounds in photosynthesis. While it has long been recognized that esters of phosphoric acid participate as essential intermediates in many biological processes,[125] considerable interest is attached to the recent discovery by Arnon and co-workers[126] and by Frenkel[127] of the cyclic photosynthetic phosphorylation of adenosine-diphosphate(ADP) using isolated chloroplasts. Among the catalytic substances necessary for the reaction to proceed are magnesium ions and a suitable redox co-factor:

$$ADP^{3-} + HPO_4^{2-} + H^+ \xrightarrow[\text{chloroplasts}]{h\nu} ATP^{4-} + H_2O$$

It is thought that this reaction yields the ATP necessary to provide the 'driving force' for the reduction of carbon dioxide in the photosynthetic process, and it could therefore be regarded as the primary chemical reaction in photosynthesis.[128] Recent observations also indicate that a relation exists between photophosphorylation and the Hill reaction.[129] This refers to the process whereby oxygen gas is evolved from the irradiation of isolated chloroplasts in solutions containing a suitable oxidant which can function as a hydrogen atom or electron acceptor, e.g.,

$$2H_2O + 4Fe(CN)_6^{3-} \rightarrow O_2 + 4H^+ + 4Fe(CN)_6^{4-}$$

It has been claimed that the rate of the Hill reaction for isolated chloroplasts is stimulated by concomitant photophosphorylation but there is some dispute as to the findings.[130] The effect of β-radiation on chloroplasts has been shown[131] to affect their efficiency in both photophosphorylation and Hill reactions. A dose of 130,000 rad resulted in a 50% reduction of the rate of photophosphorylation, but a higher dose (530,000 rad) was necessary to effect the same decrease in the rate of the Hill reaction.

## SECTION XXXIX

# BIOLOGICAL ASPECTS OF PHOSPHORUS

BY F. CALL

## INTRODUCTION

PHOSPHORUS is an element which appears to be essential to life. The element has been found in all forms of life in which it has been sought and it is believed that the life processes which occur on this earth would be impossible without phosphorus. The overriding importance of phosphorus appears to be its function as a key element in energy processes in living cells. Thus in all living cells which have been investigated phosphorus compounds have been found to be connected with the formation, conversion, transfer and storage of chemical energy. By simple structural changes in phosphorus esters carried out at normal temperatures by enzymes certain C–OP bonds become converted into 'high energy' bonds which are able to be transferred to other carbon compounds for synthetic or other purposes or to still other compounds which are able to store the 'energy rich' bond as a reserve until required. Much of this fascinating aspect of biochemistry is unfortunately beyond the scope of this review.

The very large number of literature references necessitates rigorous selection and only a representative sample can be discussed here, sufficient, however, to underline the important role that phosphorus plays in life processes.

The subject is reviewed under the following headings:

1. Phosphorus and Food.
2. Phosphorus and Micro-organisms.
3. Phosphorus and Plant Growth.
    - (i) Occurrence and Distribution of Phosphorus in Soils.
    - (ii) Availability of Phosphorus in Soils.
    - (iii) Phosphorus as a Fertilizer.
    - (iv) Deficiency of Phosphorus in Plants.
    - (v) Uptake of Phosphorus by Plants.
    - (vi) Metabolism of Phosphorus.
4. Phosphorus and Aquatic organisms.
5. Phosphorus and Invertebrates.
    - (i) Insects.
    - (ii) Helminths.
6. Phosphorus and Vertebrates.
    - (i) Occurrence and Distribution.
    - (ii) Growth requirements.
    - (iii) Distribution and Exchange.
    - (iv) Excretion.
    - (v) Metabolism.
        - (*a*) General.
        - (*b*) Use of radioactive phosphorus for diagnostic and therapeutic purposes.
7. Phosphorus and Proteins and Enzymes.

## PHOSPHORUS AND FOOD

Wide variations have been found to occur in the normal phosphorus content of foodstuffs.[1] The content of lean meat is greater than that of fat,[1a] while that of fish is twice that found in beef.[2] The mean phosphorus content of egg yolk (expressed as $P_2O_5$) is 1·42% but only 0·035% in the white.[3] The total phosphorus content of 53 French wheat samples varied between 0·80 and 1·41%, but 0·59–0·69% for Syrian wheat,[4] while that of Australian wheat was only 50% of that found in English wheat.[5] The phosphorus content of the flour prepared from these wheats was, however, only 20–25% of that of the whole grain.[4,6] Because of the great nutritional value of phosphorus, determinations have been made of the normal contents in typical foods occurring in the average diets of many countries, including Puerto Rico,[7] Belgium,[8] Brazil,[9] China[10] and the Philippines.[11]

The phosphorus content of human milk (0·22 g./l.) is much less than that of cow's milk (0·93 g./l.)[12] and the latter may range up to 2·73 g./l. or higher.[13] About 38% of the original phosphorus of milk is retained in cheese.[14–5] Only about 40% of milk phosphorus is dialysable[16] or removed by ion exchange resins[17] and the existence of several independent forms of phosphorus has been demonstrated by these means.[18] Techniques have been developed for separating the phosphatides of milk.[19] About 50% of the phosphorus of cereals is in the form of phytin[20–1] but the percentage of this form is increased in flour.[22] The phosphorus of potato flour is present largely in the form of polyose phosphates.[23] Many foods lose considerable amounts of phosphorus during preparation by steeping or cooking[24]; the phytin phosphorus of rice, for example, decreases from 0·435 to 0·116% on boiling.[25] Such losses tend to be greater for boiling than for steaming[26] but are not invariably high.[27] The loss of phosphorus on milling rice parallels the loss of thiamine.[28] There is a greater loss of phosphorus than of nitrogen during storage of orange juice.[29] Since spoilage of many foods is also accompanied by losses of phosphorus, determination of this element has been suggested as an index of quality,[30] though the ratio of phosphorus to calcium appears to be a better estimate of the suitability of peas for canning.[31] Exposure of foodstuffs to very intense radiation has not been found to induce radioactivity of the phosphorus contained in the food.[32] Vitamin *D* has been determined by bioassay following the parenteral use of $^{32}$P. The method has a wide range and is more sensitive than the normal assay.[33–4]

It has been shown that the improvement of human diet following the addition of milk and green foods is due largely to the additional calcium and phosphorus.[35] The feeding of milk labelled with $^{32}$P to dogs indicates that the milk proteins contain a bound form of phosphorus which contributes to the nutrition of young animals[36] and is assimilated more efficiently than calcium phosphate.[37] Cow's milk treated by base-exchange resins still contains adequate calcium and phosphorus for the nutrition of infants.[38] A higher phosphorus utilization by young children was obtained by feeding evaporated milk instead of pasteurized milk.[39] Inorganic phosphate has a curative effect on rickets and may lead to a false diagnosis in Vitamin *D* assays.[40] At the same time Vitamin *D* and calcium affect the availability to animals of the phosphorus of phytic acid.[41] Provided that the ratio of calcium to phosphorus in the diet is the same as that in which they are laid down in bone, Vitamin *D* does not appear to be essential for health.[42] Vitamin *D* may in fact depress the utilization of phosphorus in some cases.[43] The rate of calcification in young animals may be increased by raising the calcium and phosphorus contents of an already adequate diet.[44] There may be some advantage in varying the proportion of calcium to phosphorus in the diet as different body weights are reached.[45] Slightly better phosphorus assimilation occurs in rats in which the phosphorus source is $CaHPO_4,2H_2O$ than with $Ca_3(PO_4)_2$,[46] while the addition of $K_2HPO_4$ to the diet increases still further the growth of rats receiving calcium lactate, but not when administered alone.[47] More phosphorus is retained but less calcium is utilized by subjects on a diet of unpolished rice although the same amount of phytate phosphorus is available.[48]

The nutrition of cattle has received much attention because of its economic

**Refs. p. 1395**

importance. The phosphorus content of many cattle foodstuffs has been determined[49] and there have been several studies of the effects of cultivation on the content of pastures.[50-2] Calves require 10–16 g. of phosphorus per day up to 1 year.[53-4] Cows fed on alfalfa alone may receive inadequate supplies of phosphorus[55] and show signs of phosphorus deficiency.[56] This can readily be diagnosed by determinations of the blood serum phosphate content.[57] Phosphorus deficiency leads to a reduction in the milk yield of dairy cows.[58] An excess of phosphorus in the diet of cattle causes high serum phosphate values but no apparent adverse symptoms.[59] Serious cases of phosphorus deficiency are characterized by the chewing of wood and bones, the condition being readily cured by the addition of bone meal to the diet.[60] Calcium hydrogen phosphate,[61] sodium dihydrogen phosphate[62] and disodium hydrogen phosphate[62-3] appear to be utilized more efficiently by cattle than is bone meal. The availability to rats of the phosphorus of hay is less when the phosphorus content is low, possibly because of increased excretion in the faeces.[64-5]

## PHOSPHORUS AND MICRO-ORGANISMS

The phosphorus content of many species of micro-organisms grown under standard conditions is fairly constant and reproducible and determination of the phosphorus content of a medium has frequently been used as a measure of the total number of organisms present in the medium.[1–3] Organisms grown in a medium containing radioactive phosphorus readily become labelled and determination of their specific activity is then a convenient means of estimating their number or dry weight.[3–5] Different species of micro-organisms may differ considerably in their normal phosphorus contents. Thus, among the yeasts, *Tortula utilis* has 36% more phosphorus than *Saccharomyces cerevisiæ*.[6] A virulent strain of the tuberculosis bacillus, *Mycobacterium phlei* had a normal phosphorus content three times as great as, and required a much more abundant supply of phosphorus in the medium than a non-virulent strain of the same species.[7]

Labelling of micro-organisms by the radioactive isotope, $^{32}$P, has proved of great value for tracing their fate during various transformations. Thus when labelled tubercle bacilli are injected into rabbits $^{32}$P is detected in the liver, lungs and kidneys.[8] Many fungicides have been shown to have a direct effect on the permeability of the fungal cell wall, permitting labelled phosphorus compounds to leak out.[9] The progeny of a single cell of *Micrococcus cryophilus* has been followed through eight generations and useful information obtained on the organization of the DNA of the cell.[10] Similarly labelled bacteriophage $T_2r+$ has been carried through two successive cycles of reproduction in bacteria and found to transfer 30% of the phosphorus at each cycle.[11] Bacteria and yeasts are very efficient in removing $^{32}$P but not iso-

**Refs. p. 1398**

topes of the alkali metals from laundry waste water.[12] Higher specific activities are required to label bacteria for radioautography and satisfactory results are obtained with a content of $10^{-8}$ microcuries per cell, i.e., about 1000 phosphorus atoms per bacterium.[13] Although repeated passage of *Escherichia coli* through a medium containing $^{32}P$ had no apparent effect,[14] exposure of many species to an activity exceeding 5–10 μC./μg. of phosphorus causes growth inhibition.[13,15] The inhibitory and lethal effects of $^{32}P$ on many micro-organisms appears to be due to transmutation to $^{32}S$ rather than to the radiation.[13,16] It has been claimed that the inactivation of bacterial cells is due to those disintegrations which occur in the DNA[17] and a diminished capacity to transmit generic characters may be caused by $^{32}P$.[18] Addition of the isotope above a minimum of 0·02 μC. per culture to a *Staphylococcus* culture modified the pigmentation and virulence.[19] From the lethal effects of $^{32}P$ the diameter of the sensitive volume of *Escherichia coli* cells is estimated at 0·15 μ, which is larger than that estimated for *X*-rays (0·11 μ).[20]

Although labelled crown gall bacteria release much $^{32}P$ when transferred to a non-radioactive medium,[13] there is little exchange between cell and medium in the case of soil bacteria[21] and *Acetabularia*,[22] while the phosphorus of tobacco mosaic virus cannot be removed by dialysis.[23] The phosphorus taken up by *Escherichia coli* is rapidly incorporated into nucleoproteins and phospholipids.[24] *Micrococcus halodenitrificans* may later release a fraction of the labelled nucleoprotein as extracellular material when the external ionic atmosphere is changed.[25] Phosphorus is incorporated more rapidly into RNA than into DNA and there is no appreciable exchange of phosphorus between the two.[26] The phosphorus taken up by fowl cholera virus is partitioned in the ratio: 21% in the RNA and 65% in the phospholipids.[27] During the logarithmic growth phase of a culture, phosphate uptake is also logarithmic and both growth and uptake are independent of the external phosphate concentration down to $10^{-6}$ M. During the lag phase, however, organic phosphorus compounds are synthesized whilst the organic phosphorus content declines during the stationary phase.[28] The rate of turnover of all organic phosphorus compounds is increased by raising the supply of ammonia–nitrogen.[29] More than 97% of the phosphate taken up appears almost immediately in four simple sugar phosphates (adenosine triphosphate is the first compound to accumulate), and these then undergo further synthetic reactions.[30] The metabolism of many species of micro-organisms has been shown to involve oxidative phosphorylation, not only for the oxidation of simple metabolites[31–2] but also for the reduction of nitrate[33] and sulphate.[34] An enzyme has been isolated from *Escherichia coli* which causes polymerization of adenosine phosphate.[35] Antibiotics exhibit variable effects on phosphorus uptake and metabolism. Thus, penicillin causes the accumulation of phosphorus compounds in *Staphylococcus aureus*[36] but has no effect on the uptake of $^{32}P$ by *Micrococcus pyogenes*.[37] *p*-Aminosalicylic acid and *iso*nicotinoyl hydrazide increase the absorption of phosphorus by *Mycobacterium saprophyticum* and *M. smegmatis*[38] whereas streptomycin increases absorption by *M. avium*[39] and oxytetracycline has no effect on that of *Micrococcus pyogenes*.[40]

The permeability of the bacterial cell wall increases greatly on the death of the cell and the rate of loss of $^{32}P$ from cells to the medium approximates to the mortality rate.[41] The rates of loss were similar whether the bacteria were killed by heat, by phenol or by chlorination.[42] Cells of *M. pyogenes* are osmotically impermeable to phosphates and transport of this ion into the cell appears to be an enzyme-linked reaction.[43] Uptake of phosphate by *Amœba proteus* seems to be very dependent on the activity of the nucleus.[44] During the early stages of growth phosphate ions may accompany alkali cations into cells of *Basterium lactis aerogenes*.[45] The transport of labelled phosphate into *Escherichia coli* is largely via fructose phosphates to which the cell wall is highly permeable.[46] Azide ion markedly stimulates the uptake of phosphate by *Azotobacter vinelandii* at low concentrations but inhibits at higher concentrations.[47] The toxic silver ion increases the rate of loss of $^{32}P$ from fungal spores.[48] It has been found that orthophosphite does not interfere with enzyme reactions involving phosphate and can thus be used in buffers in many cases, but this

**Refs. p. 1398**

finding does not hold for *A. vinelandii* the respiration of which is inhibited by orthophosphite.[49]

Infection of the cells of *Escherichia coli* by single virus of T1 or T2 bacteriophage causes a rapid loss of intracellular phosphate.[50] Polyhedral virus infecting silkworm larvæ behaves like a genuine parasite and appropriates the phosphate of the host cells.[51] The phosphate taken by T2 bacteriophage from the bacterial cell is, however, limited to that most recently absorbed by the bacterium from the medium, within two minutes of infection, and thus the host cell nucleoprotein is not utilized by the virus.[52] A fowl virus infecting *Amœba proteus* also took up only a very small fraction of the host phosphate.[53] Almost all the phosphate assimilated by the virus enters the nucleic acid fraction and there is no significant exchange of $^{32}$P between the combined and inorganic phosphate.[54] Studies using virus labelled with $^{32}$P show that 80% of the parent virus DNA is broken down to smaller fragments during reproduction.[55–6] There is some inactivation of bacteriophage by the disintegration of $^{32}$P and the rate of inactivation is reduced at low temperatures.[57–8] The lethal effect is again due not to the radiation but to the transmutation.[59]

## PHOSPHORUS COMPOUNDS AND PLANT GROWTH

### Occurrence and Distribution of Phosphorus in Soils

Since phosphorus is an essential plant nutrient it is present in all soils which support plant growth. In unfertilized soils phosphorus largely arises from the decomposition of animal and vegetable matter, although rain has been shown to cause increases in soil phosphorus of the order of 0·55 kg./ha.[1] Phosphate ion applied as fertilizer is normally found in the upper 15–30 cm. of the soil, although the presence of vegetation can cause a gradual penetration into the deeper layers.[2–3] Thus, after 28 years of cropping with citrus the total phosphorus of a soil increased at all depths up to 36 inches,[4] but a grass cover caused the phosphorus to remain in the surface layers.[5] There is general agreement that the B horizons absorb and fix more phosphorus than either the A or C horizons[6–8] and the proportions of acid-, neutral- and alkali-soluble phosphorus differ in the three horizons.[9] Acid-soluble phosphorus in deep soil may first decrease to a minimum in the A horizon and then rise to a maximum in the C horizon.[10] Repeated annual fertilization has been found to increase the soil phosphorus content as much as fivefold,[11] this increase being confined to the upper few centimetres of the soil.[12] Mixing to greater depths may then be necessary to ensure the correct nutrition of deeper rooted trees.[13] The proportion of phosphorus in the organic form decreases with depth.[14–5]

The ratio of organic carbon to organic phosphorus varies so widely that there appears to be no relationship between the two, contrary to expectations.[16–8] In the surface layers about $33\frac{1}{3}\%$ of the total phosphorus is in the organic form, iron and aluminium phosphates accounting for another 50%, the remainder being absorbed. The corresponding figures for sub-soils are 20, 67 and 5% respectively.[19] In acid soils phosphorus tends to accumulate in alkali-soluble forms and in neutral or calcareous soils in acid-soluble forms.[20] About 45% of the organic phosphorus occurs in decomposable organic matter, the remainder being in the more resistant humus.[21] The

**Refs. p. 1403**

effects of a number of physical factors on the synthesis of organic phosphorus have been studied in a variety of soils. The rate of synthesis is high initially but soon decreases. Alternate wetting and drying of the soil increases synthesis.[22] The organic phosphorus content of soil is increased by fertilization.[23] The reverse process of mineralization depends on the intensity of metabolism and is thus measured by the respiration of the soil.[24] By means of the radioactive isotope $^{32}P$ it has been shown that there may be a rapid turnover of phosphorus in certain phosphorus compounds and this lends support to the concept of a 'metabolic pool' of phosphorus from which bacteria and plants are supplied with assimilable phosphorus.[25] Recent work on the use of $^{32}P$ to study phosphorus transformations in the soil has been reviewed.[26] The seasonal variation of phosphorus in a cropped soil and a bare peat soil followed exactly opposite courses, the cropped soil restoring its reserves in winter and spring. This restoration was correlated with the metabolic activity of the soil.[27]

## Availability of Phosphorus in Soils

Many soils have the ability to convert phosphorus into a form not readily available to plants, the process being known as fixation.[28] Since the fixed phosphorus is soluble in acids only with difficulty, methods of determining the available phosphorus are often based on extraction of the soil with very dilute acids.[29] In some soils 70% of the added superphosphate fertilizer is fixed in the upper 4–6 inches.[30] It has been suggested that in acid soils at least the formation of iron and aluminium phosphates may be responsible for fixation[31–2] and this process almost certainly occurs in lateritic soils.[33] Although ferric oxide and alumina gels fix phosphate in an insoluble form, plants are able to utilize this phosphate during growth.[34] There is the possibility that in some cases the phosphate may be occluded in the iron oxide coatings of colloidal silicates.[35] There is a significant correlation between the amount of phosphate fixed and the soil colloid content.[36] Phosphate is fixed in the clay minerals by reaction with aluminium and iron originating from the exchange sites or from dissociation of the mineral.[37] In some cases a new solid phase has been observed to form on the surface of the mineral particles.[38] Calcium ions may stabilize the iron and aluminium phosphates[39] and fixation is in fact observed to increase with increasing calcium saturation.[40] In general, however, phosphate fixation is reduced as the degree of base saturation increases.[41] The predominant anion also appears to have an important influence on fixation.[42] Apparatus has been developed for determining the exchangeable phosphate in soil.[43] The percentage of phosphate firmly absorbed varies greatly with different soils.[44] The formation of separate phase crystals of phosphates by kaolinite and greenalite has been made the basis of a unified theory of phosphate fixation in soils.[45]

In some soils phosphate is rapidly leached[46] and carried into deeper strata.[47] Such leaching losses may be very important in mountainous districts.[48] There is little evidence for lateral movement of phosphate.[49] Leaching is fairly rapid in light sandy soils,[50] but normally the phosphate is fixed in the upper horizons unless the soil is degraded by water-logging, etc.[51] Phosphate added as the ammonium, sodium or potassium salt moves downwards much more rapidly than that applied as superphosphate,[52] as might be expected from solubility considerations. Simultaneous addition of ammonium sulphite or sodium nitrite accelerates the penetration of rock phosphate.[53] Phosphate is more mobile at lower pH values.[54] Trials show that there is little danger of serious loss of phosphate through leaching following autumn application.[55]

Recent work on the availability to plants of soil and fertilizer phosphate has been reviewed.[56] Organic phosphate appears to be largely unavailable to plants and must be first mineralized by bacterial action.[23, 57] Superphosphate and ammonium phosphate are equally available.[58–9] Addition of sulphur to soil containing rock phosphate increases both the growth and the phosphorus content of oats and clover.[60] Where fixation takes place considerable additions of fertilizers may be required to increase the phosphorus content of crops and the increase may not occur in the edible portion.[61] A multiple regression equation has been derived for non-calcareous soils indicating the relationship between available phosphorus, inorganic phosphate and organic phosphate.[22] An excess of available phosphorus may cause symptoms of toxicity in some crops and the amount of superphosphate required to produce such symptoms varies between 5 tons/acre in clay soils and 4 cwt./acre in sands.[62] Similarly the growth of apple trees has been found to be adversely affected by fertilization with apatite, iron or aluminium phosphates but not by magnesium pyrophosphate.[63] Cultivation of a brown forest soil tends to increase the organic phosphate and to decrease the soluble portion.[64] Amounts of phosphate taken up by grasses are related to the degree of saturation of the base exchange of the soil.[65] Nitrogen fertilization was found to increase the phosphorus availability of soils,[66] possibly through an effect on the pH value.[67] There appears to be an optimum ratio of nitrogen to phosphorus for maximum uptake by crops.[68] Sterilization of soils by ethylene oxide increases the available phosphorus.[69] Although oats could not utilize the phosphorus of undecomposed phytin,[70] the intact roots of some crop plants are able to absorb this form of phosphorus (without mineralization) owing to the presence of the enzyme phosphatase in the root cap.[71] In general plant residues decompose and give up their phosphorus gradually over a period of some months.[72] Carbon dioxide may be an active agent in causing the release of available phosphorus from minerals.[73] The solubility of soil phosphorus is decreased by storage of the soil in either a dry[74] or a moist state[75] but is considerably increased by alternate moistening and drying. There are conflicting reports of the action of calcium on the availability of phosphorus[76]; in some cases liming increased the amount of phosphate absorbed by plants,[77] in other cases the opposite resulted.[78] The action is probably complex but part of the effect is a result of pH changes.[79] Thus the water-soluble phosphate decreased from 20 to 4 mg./100 g. of soil as the pH was increased from 4·3 to 6·7 by liming.[80] Significantly the various calcium phosphates are stable in the following pH ranges: monobasic pH 3·0–5·0, dibasic pH 5·0–6·4 and tribasic above pH 6·4.[81]

### DETERMINATION OF AVAILABLE PHOSPHORUS

A great deal of attention has been focused on the problem of determining the amount of phosphorus in soils actually available to plants. The most direct method is a biological one in which plants are grown in the soil under closely defined conditions and the phosphorus content of the plant is determined at harvest. Analysis of a crop plant by Mitscherlich's method[82] is occasionally used but is regarded in general as too time-consuming. More rapid methods have thus been evolved including the use of bacteria[83] and fungi such as *Aspergillus niger*,[84,86] or *Cunninghamella sp.*,[85] but the most widely used of these methods is that of Neubauer in which test seedlings are grown under controlled conditions.[87-9] Tests using fungi often give conflicting results.[90-1] The time and labour required for these biological tests have stimulated interest in the development of a rapid chemical method for determining available phosphorus. The phosphorus present in soils may be classified as difficultly-soluble, acid-soluble and water-soluble; only the last is readily available to plants. Acid-soluble phosphorus is available to a limited degree but may first require conversion into an easily-soluble form.[92] The difficulty in the determination is thus that of devising a method of extraction which removes the available phosphorus only; determination of the phosphorus in this extract is done by a colorimetric method such as a modification of the Denigès or Fiske–Subberow method.[93-5] Extraction methods include the use of 0·002 N. sulphuric acid (Truog),[96] 0·03 N. ammonium fluoride plus 0·025 N. or 0·1 N. hydrochloric acid (Bray),[97] 1% acetic or critic acid (Dyer),[98] sodium bicarbonate,[99] lactic acid (Egner)[100] or a mixture of sulphuric and acetic acids.[101] Careful comparison of the chemical with the biological methods indicates that no one chemical method is satisfactory for all soils.[102] The Truog method appears to be the most useful for soils of low fixing capacity and the Bray method for those of high capacity.[103] A study of the solubility of phosphates in sulphuric acid solution indicates the value of solutions as strong as 0·2 N.,[104-5] but the

**Refs. p. 1403**

standard Truog method may dissolve more phosphorus than is available to plants.[106] The Bray method using ammonium fluoride plus hydrochloric acid gives results agreeing with the sodium bicarbonate method and with the crop yield on calcareous soils[107-8] but gives high results with volcanic soils containing much alumina.[109] Other workers have obtained good results with the Egner method[110] but the acetic acid[111] and citric acid[110,112] methods appear unsatisfactory. The correlation between crop yield and chemical method varies with the crop,[113] but determination of the total soil phosphorus is superior to any extraction method.[114] Good correlation has been obtained between crop response and the amount of phosphorus removed from the soil by electrodialysis.[115] Among the biological methods, the *Aspergillus niger* method agrees with most chemical methods.[116] The Neubauer method tends to give slightly lower values of available phosphorus than the Truog method.[117] The Mitscherlich method did not agree with the Egner or Neubauer methods.[118] The influence of soil pH on the absorption of phosphorus in the Neubauer test has been investigated.[119] This test indicates that a soil is deficient in phosphorus at levels of 8 mg./100 g., or less in 75% of cases examined, the corresponding Egner values being about double this content.[120] Foliar analysis gives excellent correlations with soil analysis of some soils but not all.[121-2] Analysis of sugar beet petioles appears to be a very efficient method of determining the available phosphate of a soil.[123] Evaluation of available phosphorus by comparing the slopes of biological responses may not always be valid.[124] Although in general organic phosphorus does not contribute to the available phosphorus, this may not be true at high soil temperatures when the rate of mineralization of such phosphorus is greatly increased.[125-7] Determination of soil organic phosphorus is usually based on determination of the phosphorus liberated by oxidation with hydrogen peroxide.[128-9]

### THE PHOSPHORUS CYCLE IN SOIL

There is a well-defined cycle of phosphorus in soil and the citrate-soluble phosphorus content of soil is directly related to the bacterial and mould populations.[130] The phosphorus and nitrogen cycles appear to be interdependent[131-2] and phosphorus not only stimulates the assimilation of nitrate–nitrogen but also prevents its leaching.[133] Phosphorus also stimulates the nitrogen-fixing capacity of *Azotobacter*.[134] A group of organisms classed as *Nucleobacter* are able to split off inorganic phosphate from nucleoproteins in soil,[135] while *Bacillus megatherium* var. *phosphaticum* actively produces soluble phosphorus compounds.[136] Many moulds assimilate soluble phosphorus and one has been found to solubilize insoluble phosphorus.[137-8]

### EFFECTS OF PHOSPHATE FERTILIZERS

The use of the radioactive isotope $^{32}P$ has thrown new light on many of the problems of the uptake of phosphorus from fertilizers and their use has recently been reviewed.[139-40] All rates of application of phosphate fertilizers increase crop yield except when manure is used[141] and the uptake by the plants is correlated with the decrease of available phosphorus.[142] Careful application of the Mitscherlich equation enables differentiation to be made between the phosphorus taken up from the soil and from applied fertilizer.[143] The phosphorus of superphosphate is much more available to plants than that of rock phosphate[144] and the uptake from the former is independent of pH whereas the uptake from the latter fertilizer is inversely related to the pH.[145] Assimilation of phosphorus from a series of phosphates was greatest from magnesium hydrogen phosphate[146] but in other trials ammonium phosphate was best.[147] The most efficient fertilization is achieved when a source of readily available phosphorus is applied in the early stages of growth[148-9] and uptake by young plants has been observed within 1 hr. of application. As might be expected, uptake depends to a great degree on the distribution of fertilizer in the vicinity of the seed,[151] although all phosphate ions in the soil have the same probability of being absorbed.[152] All the inorganic phosphate ions in soil undergo exchange with

**Refs. p. 1403**

added phosphates[153] and prolonged fertilization is found to increase greatly the amount of exchangeable phosphorus in the soil.[154] There is often rapid disappearance of added phosphorus which may be partly taken up by bacteria[155] and absorption of phosphorus by plants from superphosphate proceeds more rapidly when the phosphate is no longer in an easily water-soluble form.[156] There is also a good correlation between the precipitation and movement of phosphorus in the soil.[157] The uptake of phosphorus by plants is more rapid from granular fertilizers than from powders.[158]

Studies of the diffusion of phosphate ions in soil suggest that the passage of phosphate from soil to solution is more complex than a simple solution of a definite chemical form[159] and is dependent on the water:soil ratio.[160] Only a small fraction of the total phosphorus is easily diffusible.[161] The distribution of ions at the soil–water boundary may represent a Donnan equilibrium.[162] The diffusion of phosphate ions from soil particles has been demonstrated in agar gels containing molybdate reagent and shown to be dependent on the particular-size distribution in a sandy soil.[163] Kinetic exchange studies in soils show the presence of two points of inflection which are not due to either ferric or aluminium phosphate.[164–5] Phosphate ions may be very firmly absorbed by some soils,[166] the isotherms being of the Langmuir type.[167] Although absorption is greater in acid than in alkaline soils this is probably of little importance for the fixation of phosphorus.[168]

## Phosphorus as a Fertilizer

In some cases phosphate fertilizers have been shown to be very long-acting, crop responses being obtained 50 years after application.[1] The actual concentration of phosphate ion in the soil water required for plant growth may be as low as 0·05–2 p.p.m.[2–3] The optimum nutrition of crop plants depends in general on a balanced fertilization of nitrogen, phosphorus and potassium, the so-called N–P–K ratio. A decrease in the optimum supply of any one of these may lead to increased or decreased absorption of the other two depending on the particular crop.[4–5] The effect of nitrogen and potassium on phosphorus uptake appears to vary at different stages in the growth of rice,[6] while only in the early growth stages of wheat did phosphorus fertilization affect the phosphorus content of the crop; otherwise the nitrogen supply alone controlled the phosphorus content.[7] The relationship between nitrogen and phosphorus fertilization is complex. Thus an increase in nitrogen supply did not affect the phosphorus uptake by coffee, whereas application of phosphorus fertilizer

**Refs. p. 1412**

decreased the nitrogen content of sugar cane or sorghum.[8] Nitrogen fertilization may double the rate of uptake of phosphorus by wheat and oats when the phosphorus supply is low.[9] A reciprocal relationship appears to exist between phosphorus and nitrogen in oranges, and a high nitrogen supply is essential for the synthesis of organic phosphate.[10] Ammonium salts increase utilization of phosphorus more than do nitrates,[11-2] and conversely an adequate supply of phosphate is necessary for the utilization of nitrate.[13] Orange trees take up more phosphorus when treated with organic nitrogenous manures than with quick-acting fertilizers such as ammonium sulphate.[14] Basic phosphate and calcium hydrogen phosphate tend to favour the uptake of nitrogen by grape vines, while superphosphate favours uptake of potassium.[15] An increase of phosphorus fertilization decreases the calcium content of the chlorophyll of sugar-cane leaves but increases the magnesium content.[16] Conversely, phosphorus utilization by barley is increased by the addition of magnesium.[17] Little work has been done on the effect of anions on phosphorus utilization. Chloride increases the phosphorus uptake of potatoes,[18] while addition of elemental sulphur to neutral or alkaline soils increases the availability of phosphorus from less efficient fertilizers such as dicalcium phosphate.[19] Silicate tends to enhance the uptake of phosphorus by wheat,[20-1] while nickel ions reduce the uptake of phosphate by tomatoes.[22]

Green manuring is an efficient means of supplying phosphate[23] and a relatively greater amount of phosphorus is utilized by plants from compost than from non-composted plant material.[24] Green manures supply more of the available forms of phosphorus than do mineral fertilizers.[25] During composting much of the phosphorus may be fixed in bacterial cells and be subsequently liberated on the death of the micro-organisms.[26]

### FOLIAR ANALYSIS

The necessity for a rapid chemical test of the nutritional status of a particular soil for a specific crop has led to the development of foliar analysis in which selected leaf samples are ashed and assayed for total phosphorus content.[27-8] The definite establishment of a simple minimum phosphorus content is usually impossible since the requirement closely depends on the nitrogen content of the leaves,[29-30] and some workers have attempted to lay down minimum[28] or optimum[31] leaf compositions in terms of a complete analysis of potassium, nitrogen, phosphorus, etc. The uptake of phosphorus by apple trees is strongly dependent on the magnesium and potassium contents of the leaves.[32] Variation in phosphorus contents is found among leaves taken at different levels along the stalk[33] and at different positions on the tree.[34] The percentage of phosphorus decreases with the age of the leaf owing to translocation into the younger developing regions.[35-8] There may, however, be some relationship between leaf phosphorus content and availability of phosphorus in the soil during the early part of the growing season.[39] No general relationship could be deduced between the phosphorus content of barley and the type of fertilizer used.[40] In spite of the lack of correlation between total soil phosphorus and leaf phosphorus content, the latter is closely related to fruit quality.[41] There is a close relationship between the amount of phosphorus found in the leaves of red oak, chestnut and red maple and the amount of phosphorus applied as fertilizer,[42] but the actual amount found in the leaves varies widely with the genus but not with the species.[43]

### FOLIAR FEEDING

It has been found that phosphate ion can be absorbed through the leaves of plants and this has led to the development of 'foliar feeding'. Studies with the radioactive isotope $^{32}P$ show that in some species of plant considerable quantities of phosphorus are absorbed through the leaves and translocated to the roots,[44] though there is also a tendency for the ion to accumulate in the rapidly growing aerial parts.[45-6] The

**Refs. p. 1412**

younger leaves absorb phosphate much more readily and both absorption and translocation tend to decrease with the age of the plant.[48] The rate of entry into apple trees is greatly increased through damaged bark.[49] Upper leaf surfaces had a greater rate of absorption than lower surfaces in spite of the smaller number of stomata.[50] Absorption is enhanced by light[50] and temperature.[50-1] Soya-bean leaves absorb 15% of the phosphate applied to the leaves within the first two hours,[52] and a large percentage of that absorbed is rapidly taken into the metabolic cycle as sugar phosphates.[50, 52] Three-year trials suggest that the technique of foliar feeding may be most effective when applied at the time of flowering.[53] Phosphorus is utilized 20 times more efficiently by foliar feeding than by soil application.[54] A considerable percentage of the absorbed phosphate content has been observed to pass out of the plant again through the roots.[55] When sprayed in admixture with $^{32}PO_4'''$, insecticides have no effect on the rate of absorption but calcium salts are definitely inhibitive.[56] Foliarly applied phosphate tends to reduce the leaf contents of nitrate,[57] calcium[58] and magnesium.[58]

## Deficiency of Phosphorus in Plants

A restricted supply of phosphorus below 0·2 p.p.m. in culture solutions leads to deficiency symptoms in citrus[59] while the growth of *Chlorella pyreoidnosa* ceases below a content of $10^{-7}$ μg. of phosphate per cell.[60] The unicellular marine plant *Nitzschia closterium* after growth in light under phosphorus-deficient conditions incurs a 'phosphorus debt' which is repaid by increased absorption of phosphorus in the dark.[61] Among higher plants such as maize, deficiency symptoms do not often appear during slow growth with restricted total nutrient supply, but only when the balance of nutrients is upset by additional supplies of nitrogen.[62] Phosphorus deficiency symptoms appear in citrus when the phosphorus content of the leaves is below 0·05%.[63] The first symptom in orange trees appears as a loss of quality in the fruit and only when deficiency is more acute are the foliage and growth affected.[64-5] Phosphorus deficiency symptoms have been described in many crop plants.[66] In tobacco deficiency of phosphorus leads to an abnormally dark green immature plant which fails to ripen satisfactorily[67-9]; in sugar cane retarded growth, absence of tillering, abnormally large root systems and narrow leaves[70]; in rice restricted root growth[71]; in potatoes a reduction in crop.[72] Phosphorus deficiency in other plants is associated with unusual pigmentation such as a red-purple discoloration of pine needles[73] and in many instances coloured spots appear resembling those caused by disease.[74-5] In some cases phosphorus deficiency may render a plant more susceptible to attack by a fungus such as the *Pythium* root rot in cereals.[76] The *Myitpo* disease of rice paddy in Burma is not strictly a deficiency disease since the roots contain an abnormal amount of phosphorus which the plant is unable to utilize.[77] Excessive supplies of phosphorus may prove toxic to plants, by producing copper deficiency in citrus for example,[78] or by producing physiological disturbances in cereals.[79-80]

## Uptake of Phosphorus by Plants

Studies with nutrient solution suggest that the absolute concentration of phosphate in the solution is the most important single factor controlling the uptake of the ion by the plant.[81] There is, however, evidence that in some soils direct root–soil contact is necessary.[82] The number and character of the secondary roots are certainly important factors and the rate of uptake is not related simply to the concentration of the ion in the soil solution.[83] Attempts have been made by using the Mitscherlich equation to calculate the contribution to plant nutrition of three forms of phosphate: the direct fertilizer, the absorbed phase and the soluble phase. It is concluded in the case of wheat that the absorbed phase is more important than the soluble form.[84] Phosphate ions may be adsorbed on to ion-exchange resins without loss of biological activity.[85] The amount of phosphorus absorbed depends on the amount already present inside the plant tissues.[86] Attention has been directed to the variations in uptake of phosphorus in different regions of the same plant.[87] The rate of assimilation of phosphorus varies with the age of the plant. Thus rye sprouts exhibit a minimum rate at 5·3 days after sowing and the greater part of the phosphorus is taken up in 6–15 days.[88] The rate of uptake by *Andropogon ischæmum* undergoes two maxima within the first six weeks of growth,[89] but in sugar cane[90] and pineapple[91] the rate of uptake is essentially constant during the first year. The uptake of phosphorus is greater through shallow lateral roots than through the deeper root system,[92–3] and the absorbed phosphorus tends to accumulate in the lateral roots prior to movement into the plant stem.[94]

Uptake by non-mycorrhizal plants tends to occur in two phases, first as initial rapid uptake, the rate of which is inversely related to the phosphorus content of the plant, followed by a second slower, uptake, whereas mycorrhizal plants have a more constant and higher rate which is independent of phosphorus content.[95] It seems to be well established that mycorrhizal growth results in increased uptake of phosphorus by many species,[96–8] but this does not appear to be due to greater utilization of organic forms of phosphorus.[99] The rhizosphere bacteria may play a part in the absorption of phosphorus by converting the element into a form more readily absorbed by the plant.[100] The rate of uptake of phosphorus increases with the rate of transpiration.[101] A small percentage, about 1%, of the absorbed phosphorus may be excreted by the roots.[102] The effect of temperature on phosphorus uptake appears to depend to a great degree on the plant. Thus absorption by millet is little affected by temperatures up to 40° whereas with winter wheat the rate of absorption is highest over the range 1–10°.[103] Uptake of phosphorus by cereals increases with the amount of applied irrigation water,[104] although roots preconditioned at low moisture conditions absorb more phosphorus than those conditioned at higher water levels.[105] Similarly roots absorbed most phosphorus from solutions of the same pH as that to which they had been conditioned.[106] The influence of pH on uptake is more marked in dilute than in concentrated nutrient solutions.[107] The presence of iron in solution resulted in a minimum rate of absorption at pH 5·0 owing to the lowered solubility of ferric phosphate at this pH.[108] Absorption of phosphate by many plants is reduced at low oxygen concentrations in the soil, but this effect may depend largely on the translocation from the roots.[109] In general uptake is little affected until the oxygen concentration falls below 10%, but uptake is stimulated by 5% of carbon dioxide.[110] Uptake of phosphorus by rice is strongly inhibited by hydrogen sulphide in the soil.[111] Addition of silicic acid to the soil increases the absorption of phosphorus by plants.[112] Aluminium oxide and humic acids behave similarly.[113]

The radioactive isotope $^{32}P$ has proved very useful for the study of plant nutrition.[114] The isotope must of course be used at such a level that radiation damage to the plant is minimized.[115–6] Movement of the isotope through the plant may be followed by autoradiography[117] or with the aid of a Geiger counter.[118] When superphosphate is applied to sugar cane 80–90% of the leaf phosphorus comes from the fertilizer.[119] Phosphorus is taken up more readily from calcium dihydrogen phosphate and from magnesium hydrogen phosphate than from tricalcium phosphate[120] and is absorbed as the orthophosphate ion,[121] although organic phosphates are readily assimilated.[122] The absorbed phosphate is very rapidly converted into organic phosphate.[123] Over 90% of the phosphate present in a solution was taken up by wheat grain and seedlings in 13 days[124] and equilibrium between absorption and translocation occurred after about 20 days.[125] The percentage of initial phosphorus absorbed plotted against concentration shows a well-defined maximum.[126] Phosphate absorbed by *Nitella* appears to be located almost entirely in the protoplasm.[127] The mycorrhizal fungus *Cortinarius glaucopus* after exposure to $^{32}P$ and subsequent inoculation onto the roots of pine seedlings is able to transfer this isotope to these seedlings.[128] Phosphate may be absorbed through the stems and branches of many woody plants,[129] but as might be expected damaged leaves absorb more rapidly than intact ones.[130]

## TRANSPORT OF PHOSPHORUS IN PLANTS

Phosphorus is translocated in plants at rates of 1·2–1·4 m./hr. in roots,[131] 64 cm./hr. in stems[132] and 2·4 cm./hr. in leaves.[125] There appears to be a slow continuous interchange of phosphorus between different leaves.[133] Phosphorus is largely taken up into the various parts of the plant during active growth and subsequent exchanges are slow.[134] The phosphorus of seed is transferred to the developing plant even in the dark.[135] The highest and thus usually the youngest leaves take up most phosphorus.[136] The content of phosphorus decreases from the base to the tip of the leaves.[137] Translocation in winter is very sluggish in many woody plants such as the white oak or alder, but not in conifers such as pines or red cedar.[138] In spring almost half of the phosphorus of stems and roots of woody plants migrates to the leaves[139] and flower buds.[140] The phosphorus content of the leaves of deciduous species continues to increase so long as they remain green, but in autumn as the leaves yellow a large percentage of the phosphorus is returned to the stem and shoots.[141] The total loss of phosphorus in fallen leaves at leaf fall varies between 35 and 90% of that originally present depending on the species.[142] A similar movement occurs in grain.[143] Movement of the phosphorus inside the plant may depend on concentration gradients resulting from the interconversion between soluble and insoluble forms.[144] In self-rooted plants phosphorus absorbed by one root is translocated to one group of branches only, whereas in grafted plants each root feeds all the branches.[145-6] Although there is little lateral movement of phosphorus in the conducting vessels of cacao trees,[147] many conifers and foliate trees exhibit free horizontal movement in the trunk.[148] Translocation is slow in the bark but rapid in the xylem and there is rapid lateral transfer between bark and wood when these are in contact.[149] The isotope $^{32}P$ appears in the xylem only after considerable accumulation in the roots and the main upward movement is due to transpiration.[150] Injury to the sap wood does not prevent upward translocation.[151] Very little phosphate penetrates the bark unless this is injured.[152-3] More phosphate is carried by the outer layer of the stem of *Pelargonium* than by the vascular system.[154] The greatest transport is through the phlœm of willow where $^{32}PO'''$ and $^{14}CO_2$ move in opposite directions.[155] The accumulation of phosphorus in leaves depends on illumination and is clearly dependent on carbohydrate metabolism.[156-7] Uptake and transport of phosphate increase with transpiration[158] and the transpiration rate of rape is higher for phosphorus-deficient plants.[159] Uptake of $^{32}P$ is reduced during the wilting of tomato plants and phosphate is transferred from leaves to stem.[160] Translocation of phosphate is dependent on the concentration in the plant of calcium,[161] boron[162] and iron[163] and is reduced by certain herbicides, fungicides and insecticides[164-5] and by soil fumigation.[166] After foliar application, $^{32}PO_4'''$ is translocated out through the roots into the soil and may be taken up by neighbouring plants.[167-9] There is also some loss from leaves by direct leaching.[170-1]

## DISTRIBUTION OF PHOSPHORUS

The normal phosphorus contents of different plants grown on the same soil vary widely with the species, from 0·163% for celery to 0·952% for tomato.[172] In general weeds are found to be richer in phosphorus than wild grasses,[173] while legumes are still richer.[174] The phosphorus content of castor bean hulls varied little with varieties but varied widely with years and locations,[175] whereas there was considerable variation among hybrids of sugar beet and mangel-wurzels.[176] The distribution of $^{32}PO_4'''$ in various tissues and organs has been followed by autoradiographic[177] and Geiger counting techniques.[178] The content of wheat varies widely from 0·328% in flour to 1·485% in the bran.[179] The distribution in grain crops depends on the point in the growth cycle at which the phosphate is added. Thus if added at the earing stage, phosphorus accumulates in the roots and is never translocated to the ears.[180] The total phosphorus content of germinating acorns and soya-beans remains constant, the phosphorus being transferred from cotyledons to embryo.[181] The distribution in tomato plants is affected by the growth promoters heteroauxin and 1-naphthylacetic acid.[182] During growth complex changes take place in the forms in which phosphorus occurs in the growing plant[183] and in the leaves during autumn yellowing.[184] Techniques have been developed for determining the various organic forms of phosphorus by means of radioactive phosphorus.[185] Approximately 75% of the phosphorus is in a soluble form in winter wheat up to the time of heading; this form then decreases to 50% or less.[186] In wheat bran 86% of the total phosphorus is in the phytin and only 17% occurs as phospholipid, whereas the germ contains 48% as phytin and the endosperm has very little phytin.[187] The structure of the phosphohexoses and phosphotetroses produced from potato starch by $\alpha$-amylase degradation has been determined by end-group analysis.[188] The major phosphate ester of plant sap has been identified as phosphorylcholine. Its zwitterion structure and solubility properties suggest its importance as a carrier for the penetration of phosphate through plant membranes.[189] $\alpha\alpha'$-diglycerophosphate is present in high concentration in *Scenedesmus*.[190] Inhibition studies indicate that the enzyme system responsible for the uptake of phosphate by loblolly pine roots has azide- and fluoride-sensitive components[191] and that mycorrhizal roots differ physiologically from non-mycorrhizal.[192] Cyanide ion is an inhibitor of phosphorus uptake by potato tuber slices.[193]

### Metabolism of Phosphorus

During the ripening of seed, phosphorus is continuously transformed to phytin, nucleic acid and lipid forms which slowly break down on storage of the seed with liberation of inorganic phosphorus.[194] Light has no effect on the pattern of distribution of phosphorus compounds in wheat during vernalization but does have an effect during later growth.[195] Oxidative phosphorylation has been shown to occur in homogenates of seedlings of *Phaseolus*.[196] A light-sensitive phosphorylation occurs in chlorophyll-free cells of barley and in yeast cells.[197] Intact chloroplasts transform light energy into adenosine triphosphate (ATP) by a photosynthetic phosphorylation which does not require oxygen[198] although phosphorylation is higher in aerobic conditions.[199] A positive correlation has been demonstrated between photosynthetic activity and the phosphorus content of cells.[200–1] Radioactive phosphorus has proved a useful technical aid for the study of the intermediate reactions of photosynthesis and detailed techniques have been developed for isolation of the intermediate products.[202–3] The initial conversion of soluble phosphate into an insoluble form is very rapid and carbon dioxide is necessary.[204] The concentration of phosphorylated metabolites changes when plants are transferred from light to darkness.[205] Phosphorus is also required for the photoreduction of carbon dioxide.[206]

In tomatoes on a deficient phosphorus supply, nitrate reductase activity decreases and nitrate thus accumulates.[207] An inadequate phosphorus supply affects the reproductive more than the vegetative tissues of cotton[208] and also appears to limit protein synthesis in wheat.[209] The chromosome volume in root tips supplied with an excess of phosphorus is usually nearly twice that of roots deprived of phosphorus.[210] Obligate parasites such as rusts and mildew cause an accumulation of $^{32}PO_4'''$ at the site of infection.[211]

The growth of pollen tubes may be followed by labelling the pollen with $^{32}PO_4'''$.[212] Autoradiography shows that phosphorus is directly incorporated into nucleic acids during formation[213] but the shoot cannot synthesize sufficient nucleic acid for its requirements and migration of nucleic acid from the root makes good the deficit.[214] Labelled phosphorus is taken up and incorporated into the nucleic acids of tobacco mosaic virus infected tomato leaves, but the virus does not affect the normal phosphorus metabolism processes of the leaves.[215] In crown gall tumours, owing to infection of *Pelargonium* by *Agrobacterium tumefaciens*, $^{32}P$ accumulates markedly.[216] The herbicide 2,4-D (2,4-dichlorophenoxyacetic acid) greatly reduces the upward movement of phosphate to the leaves,[217–9] and causes an increase in total phosphorus in the stem.[220] This herbicide and its analogues cause blockage of metabolic processes so that the total phosphate content of the leaves declines, although the ratio of organic to inorganic phosphorus in the leaves may increase.[221–3] Radioactive phosphorus has been used to study the uptake, translocation and metabolism in plants of systemic organophosphorus insecticides such as Systox,[224] Schradan[225–6] and many experimental compounds.[227] Insecticides of this type do not appear to affect the biochemical reactions of plants to the same degree as 2,4-D.[228]

Care must be taken when working with the radioactive isotope $^{32}$P lest radiation injury be caused to the plants sufficiently to obscure or vitiate the experimental results. Although radiation injury to barley is apparent at a specific activity in the plant tissue[229] of 5·6 mC./g. of $^{32}$P, the effects produced by doses as high as 30 mC. of $^{32}$P per gram of inactive $^{31}$P are slight and not objectionable in nutrition experiments.[230] The damage is caused mainly by radiation dosage due to phosphorus inside the cells and not that in solution outside the tissues.[229] The most consistent symptoms of low doses are an increase in the absorbed phosphorus translocated to the roots and a reduction of root weight due primarily to an interference with metabolic processes.[231] Low doses of *X*-rays cause a rapid decrease in the amount of phosphorus taken up and a reduction in synthesis of nucleic acids.[232] Cell division may cease due to direct action on meristems at higher doses, the shoot being more sensitive than the root tips.[223] Very low doses of $^{32}$P cause a slight decrease in the number of mitoses, but as the dose increases there is a sharp decline.[234] Doses of $^{32}PO_4'''$ of 2·7–10·8 μC. per seed for 3–9 days produced mutants in tomato seeds.[235]

## PHOSPHORUS AND AQUATIC ORGANISMS

Most natural waters have a low phosphorus content[1] except streams draining through phosphate mineral areas.[2] The abundance of many marine organisms, notably plankton and diatoms, has been shown to be directly dependent on the phosphate content of the water.[3] The normal ratio of nitrate to phosphate in the sea is about 9:1 by weight.[4] By means of the radioactive isotope $^{32}P$ it has been shown that ionic exchange between lake mud and water is an important cause of the observed seasonal variation in phosphate content.[5] Much of the variation may also be attributed to the activity of micro-organisms, notably bacteria.[6] The concentration of phosphate in estuarine waters was found to reach a maximum in August and to

**Refs. p. 1418**

decline sharply in early September. There was also a decrease during the hours of darkness.[7] Variations of phosphorus content in the sea cannot be correlated with changes in salinity.[8] Inorganic phosphate is converted to organic forms by photosynthesis in phytoplankton in the upper layers of water. The plankton then sinks before decomposing to release the phosphorus.[9] Analysis of plankton in the Western Atlantic showed a phosphate content of 1·35% with a carbon to phosphorus ratio of 1:0·0273. The annual dissolved phosphate requirement for photosynthesis is estimated to be $75{\cdot}6 \times 10^{-5}$ g./sq. cm. of surface.[10] Most of the phosphorus associated with plankton is liberated within 24 hr. of its death.[11] Inorganic phosphate undergoes a cycle of bacterial assimilation and regeneration in the sea in which the phosphate is removed from solution for short periods.[12] In lakes and freshwater reservoirs the great bulk of the total phosphorus is in the form of insoluble compounds in the bottom sediments and this fraction is rendered soluble by the action of bacteria.[13] The limiting factor controlling the growth of plankton is the amount of assimilable phosphorus available[14] and the population peaks occurring throughout the year are closely correlated with available phosphorus.[15] The ratio of dissolved nitrogen to phosphorus is also important, the optimum ratio being about 10 parts of nitrate nitrogen to 1 part of phosphate phosphorus, although phytoplankton prefers ammonia as a nitrogen source.[16] There have been many attempts to use artificial fertilizers in fish ponds and lakes[17] and, although marine algæ respond to addition phosphate at 0·02 g./l. of $Na_2HPO_4,12H_2O$,[18] concentrations 4 times as large do not stimulate the growth of phytoplankton and still higher concentrations suppress growth.[19] It has been suggested that algæ growing in a lake with less than 1 μg./l. of phosphate obtain their supplies directly from suspended colloidal clay rather than through the intermediary of soluble phosphate.[20] The possibility of controlling the growth of algæ in freshwater lakes by reducing the concentration of nitrate and phosphate has been discussed.[21]

Determinations have been made of the phosphorus content of 322 species of marine invertebrates,[22] 20 species of fish[23–4] and many species of marine algæ.[25–6] The phosphorus content of the blood of fish is usually very high, approximately 3–4 times that of beef blood,[27] but the electric eel has a particularly low blood phosphorus content.[28] Analyses made for calcium and phosphorus in trout at all stages of life show that initially phosphorus is predominant but calcium soon reaches equivalent proportions.[29] The calcium–phosphorus ratio varies widely in different species from 0·42–0·73 in herrings to 1·57–0·65 in *Scomber scombrus*.[30–1] The phosphorus content of different organs and muscles has been determined for the pearl oyster[32] and for *Balanus physalus*.[33] Unusually high contents occur in minnow eggs[34] and in the starfish.[35] The blood-phosphorus of the crab *Maia squinado* rises to a maximum during the moult but falls again thereafter.[36] The phosphate content of a number of species of mollusc shells fluctuates considerably at different times of the year and in different localities.[37] Molluscs take up the isotope $^{32}P$ and its distribution in different tissues has been studied with a view to elucidating the mechanism of shell formation.[38–40] Similarities are noted between shell formation and calcification of mammalian teeth.[41] Labelled phosphate in solution is rapidly taken up by carp and distributed throughout the organs and tissues.[42] The freshwater mollusc *Helisoma duryi* concentrates the absorbed phosphate largely in the liver and pancreas.[43] The uptake of phosphate ions by crustacea may be under hormonal control, for removal of the eyestalks in *Hemigrapsus nudus* markedly affects uptake, the direction of the change depending on the stage of the moult cycle.[44] Pretreatment of *Xenopus blastulæ* with solutions of lithium and sodium salts increased subsequent uptake of $^{32}P$ very greatly.[45–6] Uptake of $^{32}P$ by the sea urchin *Strongylocentrotus purpuratus* is greatly increased during cleavage and blastulation but decreases in later stages.[47] The cephalopod *Sepia* contains the phosphagen arginine phosphate,[48] while creatine phosphate has been identified in the muscle of several species of freshwater fish.[49] Arginine phosphate appears to play an important part in the metabolism of lobster and crab nerves.[50] The percolating filters used for water purification have a definite requirement of inorganic phosphate to ensure satisfactory functioning.[51–2]

**Refs. p. 1418**

The isotope $^{32}P$ has no significant effect on the rate of biological oxidation in such filters[53] and they may be used safely for the removal of radioactive contamination from waste water.[54]

## PHOSPHORUS AND INVERTEBRATES

### Insects

Insects contain the same organic phosphorus compounds as do other animals; adenosine triphosphate, for example, occurs in the muscles of flies as well as in those of frogs and rats.[1-2] There is a general increase in inorganic phosphate derived from organic combination during the metamorphosis of many insects, during nymphosis in *Lepidoptera*[3] and pupation in silkworms.[4] During emergence females of the butterfly *Deilephila euphorbiæ* excrete three times as much phosphate as males.[5] The total phosphorus content of grasshopper eggs remains constant during development, but pyrophosphate is high initially and inorganic phosphate increases.[6] The time of pupation of the flour beetle, *Tribolium confusum*, is proportional to the amount of phosphate in the food ration although this does not affect the total phosphorus content of the pupæ.[7] Phosphates may have an important rôle as buffer in the blood of insects.[8] Infestation of plants by insects, mites, aphids, etc., has in some cases been shown to be dependent on the mineral nutrition of the plant. Thus absorption of phosphorus by tomatoes is positively correlated with population of the mite *Tetranychus bimaculatus* infesting the plants,[9] while phosphorus deficiency of garden peas led to a reduction in the number of aphid progeny although deficient plants succumbed more readily.[10] A low supply of phosphorus to lemon seedlings did not, however, affect the red scale *Aonidiella aurantii.*[11] Administration of compounds of the radioactive isotope $^{32}$P to insects has proved a very efficient method of 'tagging' or labelling them for studies of subsequent movements.[12] Insects fed on sugar solution containing active phosphate show higher activity than larvæ reared in media or solution containing $^{32}$P.[13-4] When larvæ of the mosquito *Culex fatigans* were tagged by this method, the subsequent female adults were three times as active as the males.[15] The root maggot fly *Hylemya* sp. has been successfully tagged by applying a solution containing $^{32}PO_4$ to the soil around turnip plants.[16] Radioactive phosphorus is not suitable for labelling the plum curculio *Conotrochelus* owing to its short biochemical and radioactive half-life.[17] Phosphorus metabolism has been studied in the spider mite *Tetranychus bimaculatus* by means of $^{32}$P.[18] Treatment of insects with large doses of radioactive phosphorus may have adverse effects. Thus the fertility of houseflies is reduced by large doses of the order of 70–100 mC.,[19] while egg production is reduced in the wasp *Habrobracon juglandis* by doses above 50 μC./g.[20] and 28% of the resulting progeny are abnormal as compared with 1–2% in controls.[21] This effect on egg production is correlated with the number of $\beta$-particles received by the wasp during the first day after ingestion.[22] Sterility is produced in adult *Drosophila* treated with doses exceeding 5 μC./g.[23] Calculations show that $^{32}$P is 2·3 times as effective as *X*-irradiation in producing lethal mutations in this species, 18·8 mrd. (approx. 0·54 μC.) of $^{32}$P in the food of the larvæ being equivalent to 1000 r. of *X*-rays applied to the immature sperm.[24-5] The biological half-life of $^{32}$P in houseflies is about 0·8 day and in the cockroach *Blattella germanica* about 9 days for males and 14 days for females.[26] The jassid *Orosius* became labelled when fed on plants containing the isotope and 65% of the ingested $^{32}$P was excreted within 30 min. of the commencement of the feeding.[27] Radioactive phosphorus has been incorporated by synthesis into a number of organophosphorus insecticides which have then been used to study the absorption, translocation and distribution of the insecticide inside the insect body. These studies

**Refs. p. 1420**

include parathion[28-9] and dimethyl-2,2-dichlorovinyl phosphate (DDVP).[30] Several studies have been of disturbances of phosphorus metabolism caused by insecticides with a view to elucidating their mode of action.[31] A refinement is the study of the distribution of radioactive phosphate in various metabolic intermediates in normal and poisoned insects.[31-4] Similar studies have been made on strains of flies susceptible and resistant to insecticides.[35] A correlation has been found between cholinesterase inhibition in insects and lability of the P–O aromatic bond in a series of 24 substituted phenyl phosphates.[36] Phosphorus metabolism has been studied during growth and metamorphosis of the wax moth *Galleria mellonella*.[37] Adenosine triphosphate acts as an intermediate in the activation of luciferin in fireflies.[38]

## Helminths

Infective larvæ of *Wuchereria bancrofti* have been labelled with $^{32}P$ by feeding the tagged host *Culex fatigans* on parasitized blood.[39] Similarly *Trypanosoma equiperdum* assimilated isotopic phosphorus from rats,[40] and the plant parasitic nematodes *Heterodera rostochiensis* and *Meloidogyne hapla* from tomato plants. Injury to the plants was not caused by interference with phosphorus metabolism in the latter case.[41]

## PHOSPHORUS AND VERTEBRATES

### Occurrence and Distribution

Total phosphorus content is usually determined by the phosphomolybdate reaction after first destroying organic matter by oxidation.[1–4] Inorganic phosphorus is extractable by water. Schemes which have been developed for determination of the phosphorylated intermediates occurring in metabolizing tissue are based on the determination of phosphorus after fractionation of the tissue extract by various agents, and after acid hydrolysis for various times.[5]

It is difficult to give a precise value for the normal phosphorus content of animal tissues owing to great variations not only among individuals but also in the same individual at different times and under different environmental conditions. Provided a sufficiently large sample of normal individuals is tested a mean figure can, however, usually be obtained. Table I gives the normal phosphorus content of various animal organs, Table II that of human organs and tissues. In Table I the P values quoted for blood and other body fluids are for inorganic phosphorus, but for solid tissues total phosphorus data are given.

Phosphorus has been found to accumulate regularly in the human fœtus during gestation.[72] The rate of increase of phosphorus in the pig fœtus was 0·002 g./day during the first 2 months of gestation, rising to 0·0278 g./day during the 4th month.[73] In most mammals including man phosphorus tends to increase from birth[74] to a maximum at maturity and then to decline steadily to some constant value for the remainder of adult life.[6,8,57] Daily determination of the phosphorus content of muscle shows a rhythmic variation in the values with periods of 9 and 22 days.[75] It has been claimed that some of these variations are due to changes in the external environment such as the weather.[76] The total phosphorus of frog brain is three times as high in the summer as in the winter,[8] whereas that of rabbit muscle is lowest in summer.[76] Determination of the phosphorus content of blood taken from various vessels indicates that the highest concentration is in the portal vein and lowest in the renal vein.[77] The skeleton of the cow contains 83·57% of the total body phosphorus[78] and the calcium:phosphorus ratio of 1·7–1·8 is approximately the same for a number of species.[79] There seems to be no biologically significant concentration of calcium phosphate in the blood,[80] and although some workers have failed to demonstrate a relationship between calcium and phosphorus concentration in serum,[81] others claim some interdependence. Thus the average concentration product $\text{Ca} \times \text{P}$ is stated to be 25 in adult women[82] and 43·7 in children under 3 years.[56] The relationship between calcium, phosphorus and protein is stated to follow the equation: $\text{Ca} = -0{\cdot}255\ \text{P} + 0{\cdot}566\ \text{protein} + 7$ in nephritics.[83] A highly significant correlation is found between serum phosphorus and lecithin.[84] During the healing of fractures serum-phosphorus is observed to increase from 0·0037 to 0·005% in man[85] and from 0·003 to 0·004% in dogs.[86] A similar rise occurs, however, after surgery and is probably the result of shock.[87] The normal serum phosphate content is lowered in many diseases,[89–90] and increased by about 34% during epileptic seizures.[91]

## Growth Requirements of Phosphorus

Much attention has been paid to the normal requirements of phosphorus for adequate growth and maintenance of health in man and animals and much of this earlier work has been reviewed.[92–4] The estimated daily requirements of phosphorus are: for man[95] 0·88 g./70 kg.; pigs[96] 6·5 g./100 lb. for body weight at 50 lb. weight falling to 4 g./100 lb. at 200 lb. body weight; sheep[97] 2·5 g./100 lb.; chickens[98] 0·5% of ration; dairy cattle[99–100] 10–12 g./100 lb. live weight. As important as, if not more important than, the phosphorus intake is the ratio of calcium to phosphorus in the diet. Thus the optimum ratio Ca:P for growth of pigs,[101] of man[102] and of chickens[103] is between 1 and 2. Administration over a long period of diets with a ratio outside these limits may result in severe rickets.[104–5] With a high Ca:P ratio, greater than 2·5, blood phosphorus may increase and tetany result, while a low ratio below 0·4 causes blood-phosphorus to fall and rickets to develop.[106] An excess of calcium in the diet tends to impair the retention of phosphorus in the body.[107] A retention of 40 mg. of calcium and 20–25 mg. of phosphorus per kg. per day is desirable for artificially fed infants, but for older children retentions of 10 mg. of calcium and 10 mg. of phosphorus are satisfactory.[108] A higher percentage of ingested phosphorus is retained by infants receiving human milk than by those on cow's milk.[109] There appears to be no difference in effects on reproduction, calcification and teeth formation if the calcium and phosphorus are supplied as inorganic salts rather than as milk and green vegetables[110] and the retention is equally good.[111] Retention of phosphorus is almost 100% from disodium hydrogen phosphate but is less from bone meal.[112-3] Dicalcium phosphate is superior to tricalcium phosphate as regards calcification when administered to poultry.[114] An excess of dietary phosphorus is regarded as the principal cause of 'slipped tendon' in chickens.[115] Rickets appears to be due to an unsuitable ratio of calcium to phosphorus in the diet in addition to a deficiency of vitamin *D*.[116] Vitamin *D* does not appear to have a direct action on the absorption in the intestines of phosphorus,[117] but it influences phosphorus retention through its action on the absorption of calcium.[118-9] It is of interest that irradiation of pigs with a carbon arc lamp increases both the calcium and the phosphorus retention.[120] Addition of phosphorus to the diet enhances the potency of vitamin D in assays.[121] Seasonal variations have been observed in the absorption and excretion of phosphorus.[122] Studies of the rate of absorption of phosphorus by rats using $^{32}P$ show that only 60% of the ingested phosphorus is absorbed and 20–30% of that absorbed is re-excreted within 8 hr.[123]

Diets containing an unsatisfactory Ca:P ratio can interfere with sexual maturation and cause irregularities in the reproductive cycle of rats.[124-5] The ratio of the two elements has a greater influence on calcification than have the absolute levels of either.[126-7] Inorganic phosphate is more important for calcification than organic forms such as phytic acid.[128] Although no direct connection can be demonstrated between dental caries and dietary levels of calcium and phosphorus, the incidence of caries is correlated with lowering of retention of both calcium and phosphorus.[129-30] An increase of sucrose in the diet of rats tends to raise the calcium and phosphorus contents of the enamel and dentine of the incisors.[131] A reduction in the intake of phosphorus causes an immediate fall in the blood phosphate content,[132] but this can be restored by supplementing the diet with inorganic phosphates.[133] An inverse relationship exists between calcium and phosphorus concentration in the blood[134] so that the product of the two concentrations tends to constancy.[56, 82, 135] The main factor controlling the absorption of calcium and phosphorus appears to be the acidity of the gastric juices.[136] Phytin labelled with $^{32}P$ appears to exchange its phosphorus readily after ingestion by turkeys without enzymic hydrolysis.[137] Large doses of iron salts increase the excretion of phosphorus in the intestines,[138] while ingested ferric phosphate is absorbed very poorly by the body compared with calcium dihydrogen phosphate.[139] Administration of disodium phosphate so as to maintain high blood phosphorus levels reduces the concentration of lead ions in the blood following lead poisoning.[140]

Early work on phosphorus deficiency in cattle has been reviewed.[141] An unmistakable symptom is a depraved appetite for wood, bones etc.[142-4] Growth and utilization of food are impaired[145] and after a considerable time the bones become soft owing to losses of phosphorus and calcium.[146-8] There may be an increased output of urinary nitrogen.[149] During recovery from a condition of phosphorus deficiency the turnover rate of phosphorus in the femurs of rats is very greatly increased.[150] The ash content of the teeth increases much more slowly than that of the bones.[151]

## Distribution and Exchange

The radioactive isotope $^{32}P$ has proved invaluable for studies of the distribution of phosphorus in animal bodies following administration by various routes. There is invariably a rapid rise in the phosphorus content of the blood plasma, but within 8 hr. this begins to fall as phosphorus is transferred to other cells and tissues.[152] Lower levels of plasma phosphorus occur in febrile patients owing to increased partition with cells.[153-4] The order of decreasing rate of uptake of circulating phosphate from the blood is liver, kidney, heart, spleen, lung, muscle, brain.[155] About 90% of the administered dose appears in the bones[156] although the specific activity is lowest owing to the greater phosphorus content.[152] The biological half-life of phosphorus in the human body is about 30 days.[157-8] The mean turnover rates of $^{32}P$ labelled phospholipids from the blood stream of dogs was 0·15 millimole/hr.,[159] and the half-life of phosphorus in the blood stream was 8 ± 1 days.[158] Such turnover studies have been used to deduce the mean life of leucocytes in patients with various blood diseases.[160]

The rate of transfer of phosphate through the red blood cell membrane is calculated to be 8·49 micromoles/min./l. of plasma;[161] this rate falls off rapidly with decreasing temperature.[162] The exchange has been attributed to slow diffusion[161] but active transport linked with metabolic processes also plays an important rôle.[163] This is shown by the partial inhibition of transfer after treatment with enzyme inhibitors such as iodoacetate and fluoride ions.[164] The rate of transfer of phosphate through the cell wall is also depressed by sodium oxalate,[165] and *X*-irradiation.[166] Red blood cells may be able to utilize adenosine in place of glucose for transporting phosphate through the cell wall.[167] Cerebrospinal fluid contains 60% of the diffusible calcium and 26% of the diffusible phosphorus of blood serum and cannot therefore be simply a plasma-ultra-filtrate.[168] The transfer coefficient of $^{32}PO_4$ through the capillary walls is $20 \times 10^{-3}$ in normal persons and is almost doubled in ascitic patients.[169] Adrenaline increases the rate of transfer of phosphorus from blood plasma to tissues.[170] The rate of uptake by skeletal muscles decreases during activity and increases during the recovery period.[171] Transfer of phosphate from blood stream to nerve cells is very slow,[172] equilibrium requiring some 10 days to become established.[173] The rate of equilibration throughout hen's eggs is, on the contrary, rapid.[174] Excised eye lenses rapidly take up $^{32}PO_4'''$ from solution,[175] the rate being the same in light or in darkness.[176] There is no evidence of a posterior–anterior concentration gradient through the lens but rather a 100-fold excess accumulates in the epithelium.[177] This difference disappears in cases of radiation cataract.[178] Equilibrium between blood stream and cornea is slow, requiring some 7 days, whereas penetration into the aqueous humor is due to simple diffusion and is much more rapid.[179] A complete exchange of phosphorus between blood stream and ocular tissues is calculated to require some 2000 days.[180] Penetration of phosphate ion through intact skin follows an exponential law with a half-period of about 2 hr.,[181] but the rate of penetration is greatly increased by irradiation or application of lanolin.[182] Although the attainment of equilibrium between the phosphate contents of the blood and the cerebrospinal fluid is rapid (1–3 hr.), some 5 days are required for cerebral tissues to come into equilibrium with the blood plasma[183] and the rate of entry of the $^{32}PO_4'''$ ion appears to be the limiting factor.[184] Applications to the brain tissue of electrical pulses cause a conversion of acid-soluble phosphate into an acid-insoluble form.[185] The uptake of phosphorus by bone is largely in the more recent, poorly mineralized regions, the epiphyses.[186–8]

Phosphorus atoms present in the teeth are readily exchangeable with those of the blood stream, even in those parts of the teeth remote from the pulp.[189] The exchange of $^{32}P$ atoms in the dentine is largely with the blood stream but enamel exchanges with saliva.[190] Exchange is more rapid in functioning teeth which are regularly used for chewing.[191] The dentine may be rendered impermeable to $^{32}P$ by the formation of a precipitated layer of calcium fluoride.[192] Autoradiographic localization of the phosphorus in the rat intestine after administration of $^{32}PO_4'''$ shows that a little is present as deoxyribosenucleic acid but the bulk appears to be free inorganic phosphate.[193] The ratio of the radioactivity of pleural effusion to that of blood plasma after injection of solutions containing $^{32}PO_4'''$ ions varies widely with different lung diseases.[194] Two minutes after the intravenous injection into rabbits of lipovitellin labelled with $^{32}P$ at least 25% is found in the lungs.[195] The maximum excretion of $^{32}P$ in bull semen, however, occurs about 14 days after injection.[196] The distribution of radioactive phosphate in frog embryos at different ages has been studied after inoculation of the egg with the isotope.[197] Phosphorus is largely present at the surface of the shells of eggs laid by hens fed with rations containing $^{32}P$.[198]

## Excretion of Phosphorus

There is a daily rhythm in the excretion of phosphorus by sheep[199] and by man.[200] In dogs[201] and man[202] about 10% of an orally administered dose of $^{32}PO_4'''$ is excreted in the first 24–48 hr. Starvation may increase the rate of excretion by rats more than 60 times the normal rate.[203] During work, after a preliminary rise, excretion practically ceases and is resumed only during recovery from work.[204] Between 40 and 60% of the phosphorus eliminated is excreted via the kidneys, the remainder via the fæces.[205-6] The correlation coefficient between the concentration of inorganic phosphate in the blood and the rate of excretion of the same form in the urine is $0{\cdot}416 \pm 0{\cdot}071$.[207] Studies of the relative specific radioactivities of the urine and blood after ingestion of a dose of $^{32}PO_4'''$ suggest that most of the inorganic phosphate of the blood plasma exists in a simple filterable state.[208] Elimination ceases when the blood-phosphate falls below a certain level, this threshold being changed by phlorizin, by uranium salts and by varying the ionic product $Ca \times P$ in the blood.[209] There is reabsorption of phosphate in the glomeruli; the mean value was $91{\cdot}3 \pm 3{\cdot}3\%$. Administration of hormone of parathyroid gland or enhanced activity of the parathyroid reduces this reabsorption and hence increases the rate of elimination.[210-2] Serum-phosphate remains at the normal level until the glomerular filtration rate falls below a certain value, when it begins to increase once more. Although the concentration of fæcal phosphate varies directly with fæcal calcium content, the urinary phosphate varies inversely with fæcal calcium and the phosphate of the milk.[214] All segments of the intestinal tract, but particularly the jejunum, appear to be important for the excretion of phosphorus.[215-6] Excretion *via* both kidneys and intestine is reduced when the diet contains copper and molybdenum ion in amounts of approx. 40–80 p.p.m.[217]

## Phosphorus Metabolism

### GENERAL

There have been recent reviews of present knowledge of the metabolism of phosphorus in man,[218] in animals[219] and in the eye.[220] There is some evidence that the adrenocorticotropic hormone (ACTH) controls the systems responsible for the transport of phosphorus across cell boundaries,[221] this action of ACTH being potentiated by ascorbic acid.[222] The effects of cold on the phosphorus metabolism of animals can be explained as an effect on the production of ACTH by the adrenals.[223] The activation energy of the exchange of phosphate between the red blood cells and plasma is 19·8 kcal./mole over the range 15·5–37·5°C. The transfer is an active transport process dependent on glycolysis.[224] Most of the organic phosphorus of red blood cells appears to be present as adenosine triphosphate (ATP).[225-6] Uptake of phosphorus by the lens of the eye and the incorporation into phosphorylated intermediates appear to follow a different pathway under the influence of inhibitors such as fluoride or cyanide.[227-8] After injection of $^{32}PO_4'''$ into laying hens the radioactive phosphorus can be detected in the yolks of the 2nd to the 7th eggs laid over a period of 10 days.[229] Yolk is the principal source of phosphorus compounds for the developing embryo.[230] Phosphorolytic enzymes of the glycolytic pathway are detectable in the chick embryo at the 23rd hr. of development.[231] The determination of phosphorus combined as deoxyribonucleic acid (DNA) has proved useful for the rapid estimation of the numbers of cells in a sample of tissue.[232] Through the use of $^{32}PO_4'''$ it has been found that the time cycle for cell division in human bone-marrow is 40–80 hr. while the period of DNA synthesis is 12–15 hr.[233] The phosphorus required for the synthesis of both cytoplasmic and nuclear ribonucleic acid and of deoxyribonucleic acid comes from the cytoplasm alone and not from the nucleus.[234]

One of the earliest applications of radioactive phosphorus was in the study of the metabolism of phospholipids in mammals. After feeding $^{32}PO_4'''$ with or without olive oil to rats, labelled phospholipids rapidly appear in many organs, such as liver, intestine, kidney, etc.[235-7] but more slowly in brain.[238] The lungs are particularly active in phospholipid synthesis and a single injection of phosphate and oil doubles the phosphatide content of the tissue while the specific activity of the lungs rises to 5 times that of controls not receiving oil.[239] The amount of phosphorus synthesized into phosphatides is larger than the amount of phosphate administered.[240] The phosphorus of phospholipids circulating in the blood does not appear to be drawn from the same source as the phosphate of urine.[241] The synthesis of phospholipids is accelerated by choline, the effect being proportional to the amount administered.[242-3] Acetylcholine is even more potent, stimulating the incorporation of $^{32}$P into choline-containing lipids by 400–600% and into non-choline-containing lipids by 1000–2500%.[244] Betaine is also active but less effective than choline.[245] The dietary protein level may also play an important rôle in the synthesis of phospholipids.[246] Coenzyme *A* increases the rate of incorporation of $^{32}$P into phospholipids if present below a certain concentration; otherwise the rate is decreased.[247] The adrenocorticotropic hormone (ACTH) increases the synthesis of brain phospholipids which are used up during periods of intensive brain activity, other phosphorus-containing fractions remaining constant.[248] There is some evidence that increased phosphorylation of lecithin is associated with mitosis of cells.[249] Studies of the rate of incorporation of $^{32}PO_4'''$ into ATP of muscle indicates that the terminal phosphorus atom is replaced 6–8 times faster than the middle phosphorus atom and 100–200 times faster than the innermost phosphorus atom.[250] The inorganic phosphate of muscle is used up in glycolytic processes during shock and application of high pressures.[251-2] The rate of incorporation of $^{32}PO_4'''$ into ATP has also been determined in brain tissue.[253] During excitation by drugs the rate of exchange of the phosphorus atom of ATP and phospholipids is increased.[254] Oxygen deficiency[255] and narcotic sleep[256] reduce the rate of exchange.

Recent work on the metabolism of phosphorus in bone has been reviewed.[257] Radioactive phosphorus has been used in such studies and although it appears to have no detectable interference with bone-healing processes[258] administration to pregnant mice has resulted in disturbances to osteogenesis and odontogenesis.[259] Calcium and phosphorus are laid down in the long bones in the ratio 2:1.[260] Calcium and phosphorus salts have the apatite lattice but their composition is variable and ranges from α-tricalcium phosphate to hydroxyapatite.[261] The ion-exchange properties of bone have been investigated and the rate-determining step in the exchange of phosphate appears to be the escape of phosphate ions from the crystal surface to the hydration shell.[262] Both beryllium ions and histidine inhibit calcification, but the exact mechanism is not clear[263] since phosphorus is utilized for ossification equally well from inorganic phosphate, phosphate esters, and ATP.[264] Fractionation of the phosphorus compounds present in ossifying cartilage indicates the major constituents to be orthophosphate and ATP.[265] The epiphyses acquire labelled phosphate from the blood stream at twice the rate for the diaphyses, but this difference is later reduced.[266] The actual mode of action of the anti-rachitic vitamins of the *D* group remains obscure. Part of their influence on ossification may be by regulating the absorption of calcium and phosphorus from the intestines,[267] and partly by facilitating the conversion of organic to inorganic phosphate.[268] They also appear to have some influence on the mobilization of skeletal phosphate.[269] Irradiation of guinea pigs with ultra-violet light results in increased calcium and phosphorus in the bones as well as in the whole organism.[270] Cortisone appears to be the only hormone concerned with bone repair.[271] An excess of phosphate does not influence the rate of normal bone healing,[272] During the healing of fractures in rats fixation of phosphate is small during the first 20 days but rapid in the following 10 days.[273] In bone transplants in rabbits depositions of phosphorus reached a maximum at 7–12 days and then declined.[274] The pathology of tetany has been explained as a disturbance of the equilibrium between the various phases of calcium phosphate resulting in an increase in the concentration of phosphate ions.[275] Increased feeding of phosphate had very little effect on the dentine of teeth.[276] The incorporation of $^{32}$P into nucleic acid increases greatly in vitamin *E* deficiency in rabbits.[277] The isotope is synthesized more rapidly into ribonucleic acid than into deoxyribonucleic acid.[278]

USE OF RADIOACTIVE PHOSPHORUS FOR DIAGNOSTIC AND THERAPEUTIC PURPOSES

The isotope $^{32}P$ has found considerable application in biology not only for the study of normal physiological and metabolic processes but also for the diagnosis and therapy of pathological conditions. There are available a number of general reviews.[279-82] Techniques range from the quantitative determination of the radioactivity taken up by tissues and organs using counting methods[283] to localization of the radioactivity inside tissues and cells by autoradiography.[284]

Red blood cells and lymphocytes labelled with $^{32}P$ have been used to study the biological life of the cells inside the animal body[285-9] and also to measure the total blood volume.[290-1] The phosphorus of the red blood cells in sickle-cell anæmia has a turnover time 2·5 times greater than that of normal cells.[292] Radiation effects of the $^{32}PO_4'''$ taken up by the cells may interfere with the experiment. Thus $^{32}PO_4'''$ produces changes in chicken blood that are not produced by *X*-irradiation, namely a great decrease in the eosinophils.[293] Lethal changes may be produced in cell nuclei[294] and gross histological changes in many tissues.[295] In a number of leukæmia patients the logarithm of the white cell count plotted against integral radiation dose from ingested $^{32}P$ was a straight line.[296] Considerable variations in response to small doses of $^{32}P$ may be found among different species. Thus rats have a much higher rate of elimination of $^{32}P$ than have guinea pigs.[297] The hen appears to be very resistant to radiation damage from ingested $^{32}P$,[298] but the developing chick embryo is very sensitive.[299] Administration of antibiotics reduced mortality in rats given lethal doses of $^{32}P$, by preventing invasion of the tissues by pathogenic microorganisms.[300]

The most useful application of radioactive phosphorus has been in the diagnosis and treatment of cancer. Recent work on these aspects has been reviewed.[301-7] Many forms of malignant tumour exhibit reduced respiration and an increased glycolytic activity which results in the increased metabolism of phosphorus.[308-9] The rate of turnover of phosphorus in deoxyribonucleic acid may be increased threefold in certain carcinomas.[310] This increased metabolic activity usually implies an increased uptake and concentration of radioactive phosphorus compounds in the tissue following administration of $^{32}PO_4'''$.[311] Care must be taken in assessing quantitative turnover rates since the virulent cells may take up phosphorus from dead cells.[312] Autoradiography shows that $^{32}P$ accumulates largely in the sarcoma cells of ascitic fluid withdrawn from mice inoculated with Yoshida sarcoma.[313] There is also increased uptake in meningiomas, metastic cancer, neuromas and especially in gliomas.[314] Diagnosis is considered significant if the activity of pathological sites is 25% greater than corresponding normal sites.[315] The relative concentration over normal in 13 histologically proved tumours varied from 0·9:1 to 34:1.[316] In malignant tumours of mammary glands the excess over normal varied from 21–600%, whereas in benign tumours the range was 0·1–11%.[317] Increased uptake of $^{32}P$ by eye tumours may or may not be observed[318-9] and a test is regarded as positive if the uptake in 1 hr. is 30% above normal and if the uptake continues to increase over 24 hr.[320] Uptake of $^{32}P$ by mammary tumours in female mice is significantly increased by œstrogens and decreased by testosterone.[321] Accumulation of $^{32}P$ in tumours is reduced by *X*-irradiation,[322] the reduction being largely in the DNA-phosphorus.[323] Since injected $^{32}PO_4'''$ is preferentially taken up by tumour tissues, it should act as an internally distributed source of radiation with the highest intensity at the required site.[324] The highest concentration of $^{32}P$ usually occurs in the bone marrow and in sites of leukæmic infiltration and the highest therapeutic success has accordingly been achieved in blood diseases such as leukæmia and particularly polycythæmia[325-6] although remissions usually occur in 2–5 years.[327-8] Other therapeutic applications of varying success include metastatic, peritoneal and pleural carcinoma, carcinoma of the breast, prostate, cervix etc.[329] The number of dead tumour cells present in ascitic fluid may increase by 100% after the ingestion of $^{32}PO_4'''$.[330] A small percentage of osteogenic tumours has been reported in mice treated with $^{32}P$ possibly attributable to the radiation effects.[331]

## PHOSPHORUS AND PROTEINS AND ENZYMES

Proteins have been labelled with $^{32}$P by treatment with phosphoryl chloride, but the reagent considerably modifies the properties of the protein.[332] Analysis of the ash of proteins shows that phosphorus is present in most if not all[333] of them. The heat coagulation of caseinogen appears to be related to dephosphorylation of the protein.[334] Careful enzymic hydrolysis of $\alpha$-casein shows that 40% of the phosphorus is present as the monoester, 20% as pyrophosphate and 40% as the diester.[335] An enzyme has been found in rat liver mitochondria which catalyzes the transfer of phosphate from adenosine triphosphate to proteins.[336] Other enzymes catalyze the exchange of phosphate from ATP to ribonucleic acid,[337] to glycerol,[338] and in many other phosphorylations for the study of which radioactive phosphate has been found a valuable tool.[339–40]

### SECTION XL

# THE TOXICITY OF PHOSPHORUS COMPOUNDS

BY A. F. CHILDS AND H. COATES

## Introduction

PHOSPHORUS and its compounds show a very wide range of toxicity. On the one hand orthophosphates are a major component of the skeletal tissue of many animals, and play an essential part in the biochemistry of both plants and animals (see Section XXXVIII). On the other hand white phosphorus and certain of its inorganic compounds (phosphine, and phosphides yielding phosphine on hydrolysis) have a high toxicity. The organic compounds of phosphorus exhibit a similar variation, some being without apparent physiological effect at very high doses, while others are among the most toxic synthetic materials known to man.

## INORGANIC PHOSPHORUS COMPOUNDS

### Phosphorus

Toxic phenomena due to the ingestion or inhalation of elemental phosphorus are virtually confined to white (yellow) phosphorus. The amorphous polymeric allotropes (red phosphorus) are generally considered as almost non-toxic, although there have been suggestions of a toxicity not due to residual untransformed white phosphorus.[1] No detailed reports of the toxicity of the other phosphorus allotropes have appeared.

#### CHRONIC PHOSPHORUS POISONING

The most common symptom of chronic poisoning by the ingestion or inhalation of white phosphorus is a form of bone necrosis or osteomyelitis, which since it appears mainly in the upper and lower jaw has been known for many years as 'phossy jaw'.

The first cases of phossy jaw arose in Vienna in 1839 following the use of white phosphorus in the match industry. Commercial manufacture of red phosphorus started in 1851, and with its application in the match industry (1855), followed by the alternative use of phosphorus sesquisulphide (1898), and the prohibition of the use of yellow phosphorus in matches by the Berne Convention of 1906, the incidence of phossy jaw has declined to negligible proportions. The disease is now indeed largely confined to factories manufacturing elemental phosphorus, though there was a minor recrudescence of the condition associated with the use of white phosphorus in the manufacture of fireworks during the first decades of the 20th century.[2] With legislation against the indiscriminate use of white phosphorus, and marked improvements in manufacturing plant ventilation and the oral and dental hygiene of workers, such cases as now occur are usually very mild[3-4] in comparison with earlier observations.[5-6]

The condition usually starts with toothache and local inflammation, or a generalized dull and lifeless appearance of the gum, which is followed by rupture of the surface and a discharge. Even if the tooth is extracted the cavity is slow to heal, and exudes pus. Treatment by antibiotics usually controls this, and the lesion becomes sterile. In either case a small sequestrum of bone may separate, as a spongy mass similar in appearance to pumice stone.[3] Under the influence of antibiotics the lesion is almost dry, and the healing, though still somewhat slow, is uneventful with little or no permanent disability, except the loss of natural teeth in the areas involved. The sequestra differ from those in staphylococcal osteomyelitis in being light in weight, spongy, and yellow or brown in colour, rather than hard and well calcified.

The cause of phosphorus necrosis is almost as obscure as when the disease was first described[3]; indeed, it is not even certain whether the causative agent is white phosphorus itself or one of its lower oxidation products. Arsenic, a common minor constituent of phosphorus, caused a similar necrosis when used in dentistry to kill the roots of teeth, but since the disease is unknown in arsenic smelters, arsenic is not likely to be involved in phosphorus necrosis. It was, and is still, believed that the jaws are affected because of direct exposure to the fumes, which encourages subsequent attack by pathogenic organisms present in the mouth. However, there is considerable evidence that the disease is systemic in nature. Thus the condition usually requires a long induction period for its onset, e.g., 10 months to 18 years,[3] 7 weeks being the minimum reported,[8] and it may appear long after exposure to phosphorus has ceased.[8–9] Further evidence for the systemic nature of the malady is given by delayed healing after an iliac crest biopsy, done in order to investigate the relation of phosphorus necrosis to general bone metabolism.[3] There are also frequent early references to the fragility of the bones of some phosphorus workers,[6,10–1] though these were not borne out by a later study.[3] One case of extensive necrosis and malformation of the bones of the foot, following a deep and untreated phosphorus burn, has been described.[7]

Study of the disease is made more difficult by its low incidence. A recent author states that less than 5% of those exposed were affected,[5] while other estimates were even lower.[6,12] No systematic difference of any kind was found in the incidence of general infections, bone fractures, hæmatological findings or biochemical studies of blood and urine, between two groups of healthy workmen, one exposed to phosphorus and the other not. There were, however, significant differences between the two groups in the appearance of the dental tartar and the interior surface of the mouth.[3] Unlike acute phosphorus poisoning the chronic condition causes no apparent liver disease.[13]

Acute phosphorus poisoning in growing animals causes zones of increased density in the epiphyses of the long bones, and a reduction in the process of tubulation in the shaft, said to be due to diminished resorption of cartilage matrix and bone.[14] Significant bone changes are caused by administration of 0·05 mg./kg./day of white phosphorus, a dose well below the lethal one,[15–6] though these can be reversible in mild cases.[18] This has suggested that chronic phosphorus poisoning acts in a similar way by interfering with the blood supply to the bone, thereby rendering it more liable to infection, but no sound experimental evidence exists for this widely held theory. Some parallels can be drawn between phossy jaw and the radiation-induced necrosis suffered by luminous dial painters, and this and other evidence has been adduced in favour of a free radical mechanism for the bone and tooth damage caused by chronic white phosphorus poisoning.[16]

The present maximum allowable concentration of phosphorus vapour in air accepted in Britain is 0·1 mg./m.$^3$ This is based on animal experiments,[19–20] but the finding that fatty infiltration of the livers of rats exposed for a total of 30 hr. to phosphorus vapour could be caused by as little as 2·8 mg./m.$^3$ suggests that the figure might be reduced[16] perhaps to the level of 0·04 mg./m.$^3$ recommended in the U.S.S.R.[21] In any case a maximum allowable concentration cannot be meaningfully defined except in terms of an analytical method capable of determining white phosphorus vapour in air separately from its oxidation products.[16–7]

Prophylactic measures against chronic phosphorus poisoning include improved ventilation of working areas, medical (especially dental) examination of employees exposed to phosphorus, and removal from exposure of all those showing symptoms of the disease.[4,13]

### ACUTE PHOSPHORUS POISONING

Because of the use of white phosphorus in rat poisons, and in pharmacological preparations of various kinds,[12,22] fireworks,[2] attempted suicide[23] and deliberate administration in other ways,[25-6] much is known of the pathology of phosphorus poisoning. The clinical picture of acute phosphorus poisoning is well described by Mellor (VIII, 794). As little as 8 mg. of phosphorus has been reported to cause acute toxicity and death in man, but the fatal oral dose is normally considered to be of the order of 100 mg. ($1\frac{1}{2}$ grains),[13] and one case has been reported of recovery from a dose of 130 mg.[27] In 56 cases of attempted suicide the mortality was 48%, and the toxicity appeared to be increased by alcohol.[23] One fatal case of acute phosphorus poisoning showed a progressive fall in total urinary nitrogen excretion and high values for $\alpha$-amino nitrogen, probably due to kidney damage.[24]

Phosphorus appears to be equally poisonous to other animals. The effect on rats has been mentioned above and cases of poisoning in cattle,[28] pigs,[29] and waterfowl (ducks)[30] have been described. The median lethal concentration of phosphorus in water for fish (Bluegill, *Lepomis macrochirus*) lies between 0·025 and 0·105 mg./l., but death is due to colloidal phosphorus solutions, and not to the small concentration in true solution.[31] The median lethal oral dose for the American cockroach (0·02 mg./g.) was lower than that for the German variety (0·13 mg./g.).[32]

In mammals, including man, the main pathological lesion is fatty infiltration of various organs, particularly the liver, but also the kidney and the heart. Liver glycogen becomes depleted in the periphery of the lobule, followed by peripheral fatty infiltration and necrosis.[33] In rats this fat deposition appears to be associated with splanchnic stimulation and adrenaline activity, since it can be prevented by cutting the spinal cord above the tenth thoracic vertebra.[34] The liver damage can be detected by an impaired ability to metabolize blood acetone[35] or levulose,[36] and to synthesize glucuronic acid.[37]

Marked histological changes take place in the affected liver,[38] heart[39] and brain, though the last shows no fatty degeneration.[40] In the blood, red and white cell counts fall, sometimes after a fleeting increase, as do platelets, serum protein and hæmoglobin.[41-3] Studies with radioactive white phosphorus show high concentrations in the heart, spleen, and blood, as well as the liver and kidney,[44] the distribution in mice, rats, and rabbits being almost identical with that in humans.[45]

The treatment of acute phosphorus poisoning has received much attention. Where the poison has been taken by mouth early emesis or repeated stomach washing is of great value.[46] The oral administration of 0·1–0·2 g. of copper sulphate in 1% solution, or of 0·1% aqueous potassium permanganate solution, is also indicated. The patient should be given a diet high in protein and carbohydrate and low in fat.[26] The worst consequences of liver failure may be avoided by massive transfusions of blood,[76] vitamins (including vitamin-*K*),[43,52-4,56] glucose, fructose, and methionine.[47,55] Adrenal cortex extracts,[51] Mn(II),[57] methylthiouracil,[48] thyroxine[49] and carbanil,[50] have also been claimed to have therapeutic activity.

Because of its spontaneously inflammable character, white phosphorus is a common cause of skin burns. These are primarily thermal, but are aggravated by the toxic action of phosphorus itself and its oxidation products. The burning phosphorus must be immediately extinguished by water or sand, care being taken not to spread it. The remaining portions of phosphorus are then treated with 1–2% copper sulphate solution, to coat them and prevent their reignition,[59-63] and removed mechanically by scraping with a spatula or blunt knife, residual phosphoric acid being neutralized by treatment with 5% sodium bicarbonate solution.[58] Solvents for phosphorus, such as oils or fats, merely spread it and should be avoided. Other bases which have been employed in the later stages of treatment include magnesium hydroxide[64] and sodium percarbonate.[65]

## Phosphine

Phosphine is a very poisonous substance, and because it may be formed during a number of industrial operations there are many reports of cases of poisoning, including some deaths. Phosphine has been reported as a hazard in acetylene manufacture from calcium carbide containing phosphide[66-7]; in the use of aluminium phosphide as a grain fumigant[66,68]; in the treatment of phosphorus with alkali, especially during the manufacture of hypophosphites[69]; in the machining of metals such as cast iron[70]; and particularly in the handling of phosphorus-containing ferrosilicon.[66,71-2] In the last case grades of ferrosilicon containing 15–30% and 75–80% silicon are considered safe, the greatest hazard arising from a grade containing 30–45% silicon.[73]

Symptoms of acute phosphine poisoning may be of three types; firstly nervous disturbances, including headache, vertigo, tremors, and unsteady gait, leading in severe cases to convulsions, coma and death; secondly gastro-intestinal symptoms, including loss of appetite, thirst, nausea and vomiting, diarrhœa and severe epigastric pain; thirdly respiratory disorders such as oppression and pain in the chest and shortness of breath.[68-9,74-5] A characteristic but seldom-mentioned symptom is a sharp fall in blood pressure.[76] There have been suggestions of chronic effects, including anæmia, bronchitis, and gastro-intestinal, speech, and motor disturbances, from continued exposure to low concentrations,[75] though these are by no means general. Unlike arsine, phosphine does not cause hæmolysis of red blood cells.[69]

The following table showing the effects of phosphine on man has been compiled[67] and appears to be generally accepted.

*The Action of Phosphine on Man*

| Effect | Concentration | |
|---|---|---|
| | mg./l. | Parts per million |
| Rapidly fatal | 2·8 | 2000 |
| Death follows ½–1 hr. exposure | 0·56–0·84 | 400–600 |
| Dangerous to life after ½–1 hr. | 0·4–0·6 | 290–430 |
| Maximum exposure for ½–1 hr. without serious effects | 0·14–0·26 | 100–190 |
| Serious effects after several hours | 0·01 | 7 |
| Limit of perceptibility | 0·002–0·004 | 1·4–2·8 |

Two deaths were reported among the crew of a barge carrying ferrosilicon, a concentration of 5·9–6·1 p.p.m. phosphine being reported in the hold, and 1·0–2·0 p.p.m. in the crew room.[72] Fatal poisoning was also reported to result from daily exposure over several hours to 6·9–9·4 p.p.m.[77] However, several cases showing mild symptoms recovered without any apparent after-effect from transient concentrations as high as 35 p.p.m. The authors concluded from their observations that phosphine may not be as severely toxic as had been previously reported,[68] and this seems to concur with a subsequent relaxation of the maximum allowable concentration from 0·05[74] to 0·3 p.p.m. (ACGIH (recommended)).[75] However, it should be noted that even this higher value is below the limit of perceptibility by smell, and chemical means of detection should always be used where the presence of phosphine is suspected.[74] This is reinforced by the discovery that the odour-producing fraction of phosphine can be preferentially absorbed by various materials, leaving very high concentrations of the gas in the atmosphere without any detectable odour.[78]

The biochemical mechanism of phosphine poisoning is obscure, but it is known that the respiration of isolated liver mitochondria and isolated sarcosomes of the heart muscle in rats is affected. Sarcosomal respiration and phosphorylation are uncoupled. The respiration of *Neurospora crassa* is also affected, and this appears to be a general effect in living cells. Chronic administration of phosphine causes a similar effect in mitochondria at doses well below the toxic level.[79]

## Phosphides

Apart from the specific toxicity of the particular metal concerned, phosphides are normally toxic in so far as they evolve phosphine on hydrolysis by water or acids. In practice this behaviour is restricted to the phosphides of metals in the first three groups of the Periodic Table,[66, 80] and in particular to those of zinc, sodium, calcium, magnesium, and aluminium, which have been extensively used commercially as rodenticides, insecticides, and fumigants, and in marine signals.

Zinc phosphide, $Zn_3P_2$, has been used as a rodenticide since the second world war.[81-2] A review in 1947 pointed out its potential toxicity to man[83] and a number of cases of poisoning, accidental or deliberate, have been reported due to its use.[84-8] A review of 20 cases of this kind showed that the minimum dose to have caused death was 4–5 g., whilst a 50 g. dose had been survived. Dosages in the region of 100 mg. daily appear to be harmless.[89]

Early symptoms after ingestion of zinc phosphide include nausea, abdominal pain, chest tightness, excitement and agitation, and a feeling of chill. Vomiting is usual, and if it can be induced sufficiently early the chances of survival are increased. Death appears to arise from pulmonary œdema or cardiac damage, whilst those alive after three days recover completely.

Animal studies have shed some light on the mechanism of poisoning by zinc phosphide. Rats fed zinc phosphide in excess of the $LD_{50}$ ($40{\cdot}5 \pm 2{\cdot}9$ mg./kg.[82]) rapidly died, and phosphine could be detected in the expired air during life,[90] and in the liver during autopsy.[91] In lower doses there was good evidence, both in rats, and (in one case) in man, that zinc phosphide itself was present in the blood and the liver. It was assumed that some of the particles in commercial zinc phosphide were sufficiently small ($0{\cdot}1\ \mu$) to pass through the intestine wall into the blood stream.[91] This and other evidence was taken to prove that evolved phosphine is responsible for early symptoms, but that absorbed zinc phosphide particles give rise to the more usual delayed illness.[89]

Zinc phosphide has been shown to be toxic by inhalation,[84] percutaneous absorption,[92] and parenteral injection,[93] as well as by oral ingestion. It is also known to be toxic to sheep (LD 60–70 mg./kg.[94]), fowls ($LD_{50}$ 7–17 mg./kg.[95]), and pheasants ($LD_{50}$ 9 mg./kg.[96]), as well as to many game animals.[97]

Much less is known of the toxicity of other phosphides. A fatal case of poisoning by swallowing a proprietary composition containing 75% of $Ca_3(PO_4)_2$ and 25% of $Ca_3P_2$ has been described. It appeared to be due to the phosphine evolved.[88] Aluminium phosphide has been extensively used for the fumigation of bulk wheat supplies without apparently causing any cases of direct poisoning, though there is no reason to assume that it is intrinsically any less toxic than calcium phosphide.[68] Iron phosphide (ferrophosphorus), a major by-product of the manufacture of phosphorus and used extensively in the steel industry, is unreactive with water or acids, and no cases of poisoning by it have been reported.

## Phosphorus Oxides

Phosphorus pentoxide does not appear to have any specific toxic action towards mammals except that which would be expected from its highly exothermic hydrolysis to form the strong mineral acid, phosphoric acid. Dusts and smokes containing phosphorus pentoxide are formed during the commercial manufacture of phosphorus and phosphoric acid, and these irritate mucous surfaces, the eyes, and skin.[69, 75] However, the incidence of pulmonary disorders is not increased by chronic exposure to phosphorus pentoxide smokes arising from phosphorus furnaces, a behaviour in sharp contrast to that of the common oxides of nitrogen and sulphur.[76] The maximum allowable concentration in air (AIHA Guide) is 1 mg./m.$^3$ air,[69] while in the U.S.S.R. a lower desirable level is set (0·15 mg./m.$^3$ (instantaneous max.) and 0·05 mg./m.$^3$ (average/day))[98] (see also ref. 99).

The solid oxide can cause serious burns on the skin, because of its heat of hydration, and coagulation of skin protein by the phosphoric acid formed. For this reason it should always be washed off by copious quantities of water, followed by 5% aqueous sodium bicarbonate solution. One case of death has been reported from swallowing the solid oxide.[100]

No toxicological data have been reported for the other oxides of phosphorus, though they are assumed to behave similarly to the pentoxide.[75]

## Phosphorus Sulphides

Phosphorus sesquisulphide (tetraphosphorus trisulphide) was used to replace white phosphorus in the manufacture of matches in the belief that it was non-toxic. This appeared to be confirmed by experiments on dogs and man.[101] However the commercial sulphide can contain free phosphorus,[67] and more recently oral administration of the sesquisulphide in rabbits has produced histological changes similar to those produced by white phosphorus, but not entirely explicable by the amount of that substance present as impurity.[102] Nevertheless the acute oral toxicity of the substance must be relatively low.[69]

The most characteristic physiological action of the sulphide is the irritation caused by the dust on the lungs, eyes, and skin.[69] Affected eyes show symptoms of conjunctivitis of varying severity ('sesqui sore-eye'), but this normally disappears without apparent after-effect a day or so after removal from exposure.[76] The skin may show eczema, often referred to as 'match-box dermatitis', since it is commonly found on the skin of the thigh near to trouser pockets in which boxes of 'strike-anywhere' matches are carried. It may also occur on the hands, arms and face of workers handling the sulphide, those with oily skins being more susceptible. The affected skin becomes irritated, inflamed and rough, and in severe cases blisters may form.[104] Sensitivity of this type is by no means universal, and in many cases an allergic reaction having a delayed onset appears to be involved.[104-7] Indeed some authorities have associated the condition with the presence of chromium compounds in the match heads, rather than the sulphide itself,[103] but on the whole there seems little doubt that the sulphide is the allergenic agent in most cases.[108] No maximum allowable concentration has been set for the sesquisulphide.[69]

Phosphorus pentasulphide (tetraphosphorus decasulphide) hydrolyzes to hydrogen sulphide and various thiophosphoric acids. It is therefore strongly irritant to the upper respiratory and pulmonary tissue, as well as having a high systemic toxicity. The maximum allowable concentration (ACGIH threshold limit value) is 1 mg./m.$^3$ of air.[75,109-10]

## Phosphorus Halides

Phosphorus halides as a general class show the corrosive action one would expect from acids produced by hydrolysis. The skin, eyes, mucous membranes and lungs are all attacked, the severity depending on the concentration, time and facility for hydrolysis. Direct contact with the neat liquid can cause severe and often deep-seated burns.

### PHOSPHORUS TRICHLORIDE

Even though it is initially less soluble in water phosphorus trichloride appears to give more immediate symptoms than does phosphorus oxychloride, which tends to warn the affected person to leave the contaminated area before the lungs have been seriously affected.

Phosphorus trichloride has a pungent irritating odour resembling hydrogen chloride. It causes a feeling of suffocation, difficulty in breathing, lachrymation, bronchitis, œdema and inflammation of the lungs, and in severe cases a frothy bloodstained sputum. A concentration of 600 p.p.m. is lethal in a few minutes, while 50–80 p.p.m. can be harmful after 30–60 min.; 2–4 p.p.m. can be borne for up to 60 min. without serious symptoms, while 0·7 p.p.m. is the maximum tolerable for exposures of several hours.[74, 111–2] The maximum allowable concentration (TLV, ACGIH (recommended)) is 0·5 p.p.m.[75] Several cases of industrial poisoning by phosphorus trichloride,[113] including one fatal occurrence,[114] have been described.

Phosphorus trichloride is very aggressive to the skin and must be removed by washing with copious quantities of water.[115–6]

### PHOSPHORYL CHLORIDE

Because its immediately irritant effect is smaller, phosphoryl chloride vapour has a more insidious and dangerous effect than phosphorus trichloride. Inhalation causes pain in the throat and coughing, with burning and redness of the eyes. After a delay of 2–12 hr. secondary symptoms of lung damage may appear, including shortness of breath, coughing with bloodstained sputum, bronchitis, asthma, and emphysema.[67] Heart damage may occur. The condition resembles, but is normally milder than, phosgene poisoning.[117]

Various cases of poisoning by phosphoryl chloride have been described, both acute and chronic.[118–21] In general the patient should be treated as for phosgene poisoning, being removed to the fresh air, given artificial respiration if necessary, and kept warm. Inhalation of an aerosol of sodium bicarbonate solution with procaine, calcium to strengthen cell membranes, and penicillin against infection, has been recommended,[122] but nowadays penicillin or broad spectrum antibiotics, to combat secondary infection and treatment for pulmonary œdema, possibly including intermittent alcohol inhalations, together with treatment for the bronchial spasm, would be the treatment of choice.[76] Inhalation of ammonia, on the other hand, although it may allay irritation may worsen the clinical effects, and is not advised.[123]

### PHOSPHORUS PENTACHLORIDE

Phosphorus pentachloride has a pungent, unpleasant odour and its vapour or fume is irritant to mucous tissue, including the lungs. Hydrolysis of the pentachloride yields phosphoryl chloride, and massive exposure can give symptoms of poisoning by the latter.[67] However, because of its lower volatility it is less toxic, so long as it is not present as a particulate cloud, and the maximum allowable concentration recommended by the ACGIH is 1 mg./m.$^3$ air.[75]

### OTHER HALIDES

The other halides and oxyhalides of phosphorus, including the lower alkylphosphonic chlorides,[123] have a similar physiological action to the chlorides. Those containing fluorine hydrolyze to hydrogen fluoride as well as the appropriate phosphorus oxyacid, and therefore may cause the lesions of the skin and upper respiratory tract characteristic of poisoning by hydrogen fluoride.[75, 112] The bromides similarly yield hydrogen bromide on hydrolysis and are also very poisonous.

Thiophosphoryl chloride is a particularly insidious substance. The vapour, which has an odour somewhat resembling camphor, is not immediately aggressive, and it is possible to inhale a dangerous or even lethal dose without initial discomfort. Symptoms resembling those of phosphoryl chloride poisoning, particularly conjunctivitis and photophobia, may appear after a latent period of 2 hr. or more.[76, 114] The toxicity of thiophosphoryl chloride to rats by inhalation is somewhat higher than that of phosphoryl chloride.[124] Alkylthiophosphonic halides and the lower phosphonitrilic chlorides also have pleasant characteristic smells, but cause similar delayed effects to thiophosphoryl chloride.

## Phosphoric Acid and Phosphates

### PHOSPHORIC ACID

Phosphoric acid is less toxic than many other mineral acids, but being a strong acid, it can cause skin burns in some individuals if applied in concentrated solution.

No systemic effects have been reported, and although disturbances of breathing can be caused by inhalation of a phosphoric acid aerosol, the chance of œdema or other severe injury to the lungs is remote. Contact with the eyes may produce irritation or burns, but no permanent damage is to be expected. Flushing with copious amounts of water is the best treatment for both skin and eye contact. The threshold limit value (MAC), recommended by the ACGIH, is 1 mg./cu. m., although the vapour pressure is so low that this is not likely to be reached at room temperature except in an aerosol or spray.[75,125]

The phosphorus essential to the metabolism of all living things is ingested and transported mainly in the form of inorganic orthophosphate. This, and derived organic phosphates, are concerned with the structure of bone, the cyclic metabolism of carbohydrate, and the regulation of calcium level and acid/base equilibrium in body fluids. It is not surprising, therefore, that phosphate at reasonable concentrations has little pharmacological effect,[126] the normal plasma level being regulated at 3–4 mg./100 ml. in adults by the action of the parathyroid hormone.[12,127] Phosphate ion is not readily absorbed by the gastro-intestinal tract, and if large amounts are administered the quantity remaining unabsorbed gives rise to a mild cathartic action.[12] However, massive oral doses of mono- or disodium phosphate have been shown to cause kidney damage in young rats, including calcification and necrosis of the cells of the convoluted tubules,[128–30] as well as calcification of other tissues, such as the stomach and aorta.[127] While some workers have fed rats with food containing up to 1·30% of phosphorus without causing apparent ill effects,[131] others have observed signs of calcification in the kidneys of rats on a diet containing as little as 0·71% of phosphorus.[132] The effect is obviously dependent on other dietary components.

Sodium phosphate in moderate doses acts mainly as an indifferent saline when injected intravenously, but large doses (0·7 g./kg.) injected into dogs cause tetany, due to a major fall in blood calcium level. Phosphoric acid produces a similar fall of calcium without tetany.[126,12]

The absorption of calcium and phosphate by the intestine is linked, large amounts of either interfering with the absorption of the other by formation of insoluble calcium phosphate,[126] though moderate amounts are without effect.[127] For communities with a low calcium intake 30 mg/kg of phosphate is acceptable as a total dietary intake of phosphate. Where calcium is high this can be raised to 70 mg./kg.[133] The long-continued daily intake of 5–7 g. $NaH_2PO_4$ is without adverse effects in man.[134] The calcium and phosphorus intake of domestic animals can be increased by feeding dicalcium phosphate ($CaHPO_4$) often in the form of defluorinated apatite. The F/P ratio in such cases should be less than 0·025.[135] Calcium phosphate (2–3%) has also been suggested as a means of killing pests of stored grain.[136] Chromic phosphate (2·0 mg./g.) was lethal to rats on intravenous injection, possibly because of the chromium content.[137]

Slight pathological changes which have been observed in the skeleton and upper respiratory passages of workers engaged in superphosphate manufacture have been generally ascribed to the hydrogen fluoride evolved in this process.[138–40]

### DIPHOSPHATES (PYROPHOSPHATES)

Diphosphate is formed from adenosine triphosphate by enzymatic reactions, and itself takes part in phosphorylation reactions or is hydrolyzed to orthophosphate. Ingested diphosphate is excreted as orthophosphate.[127]

High concentrations (>1%) of diphosphate administered orally cause kidney calcification similar to that from orthophosphate, the effect of a given dose being slightly more severe. Larger doses cause hypertrophy and hæmorrhage of the stomach,[141] probably due to hydrolysis and resulting acidification. These effects are not likely to occur in the concentrations at present used in food products, and the acceptable daily intake of pyrophosphate for man can be calculated simply on the basis of its contribution to the total orthophosphate intake.[127]

### POLYPHOSPHATES

Because of their application in the detergent and food processing industries, pentasodium triphosphate and higher polyphosphates have been the subject of extensive toxicological studies, reviewed by a number of authors.[127, 142–6] If taken orally the polyphosphates are not absorbed as such to any significant effect, but only in the form of orthophosphate to which they are hydrolyzed, possibly in part by the intestinal flora. In spite of its powerful sequestering action, 'sodium hexametaphosphate' (Graham's salt) has no effect on the absorption or utilization of calcium[148] or iron[149] by rats. The acceptable oral intake of polyphosphates can be related to the total dietary phosphate as if they were all hydrolyzed to orthophosphate. The calcification and necrosis which they cause to kidney tissue are similar to those from orthophosphate.

The intravenous toxicity of condensed phosphates is higher than their oral toxicity. Thus a commercial preparation consisting of $\frac{1}{3}$ Kurrol's salt and $\frac{2}{3}$ mixture of disodium and tetrasodium pyrophosphate had a median lethal dose in rats of 4000 mg./kg. body weight. Intravenously the $LD_{50}$ was 18 mg./kg. Calcium phosphate incrustation of the kidney tissue was evident even at 1% level in diet, and damage increased above this dose level.[142]

The following toxicological data have been recorded for the mouse[147]:

*Median Lethal Dose* ($LD_{50}$) *g./kg.*

| Compound | By route | | |
|---|---|---|---|
| | Oral | Subcutaneous | Intravenous |
| $Na_2H_2P_2O_7$ | 2·65 | 0·48 | 0·059 |
| $Na_4P_2O_7$ | 2·90 | 0·40 | 0·069 |
| $Na_5P_3O_{10}$ | 3·21 | 0·90 | 0·071 |
| $Na_6P_4O_{13}$ | 3·92 | 0·875 | — |
| Graham's salt | 7·25 | 1·30 | 0·062 |
| (cyclic) $Na_3P_3O_9$ | 10·30 | 5·94 | 1·165 |
| (cf. NaCl) | 5·89 | 3·00 | 0·645 |

### OTHER PHOSPHORUS OXYACIDS

Sodium hypophosphite has been taken orally for many years as a component of various 'tonics' without apparent ill effect, except possibly headache, vertigo and colic, resulting from overdose.[150] Hypophosphites are excreted rapidly, and almost completely unchanged.[12] Hypophosphorous acid also has a low toxicity, although as a strong acid its concentrated solution must be handled with care.[100]

Very little is recorded of the toxicity of phosphites, but it appears to be of the same order as that of hypophosphites, since phosphites show a negligible or low-order toxicity in rats, and cause little interference with enzyme activity.[151]

Nothing is known of the toxicity of hypophosphates. Aqueous solutions of the free acid cause blistering of the skin, which may take several days to appear, and is slow to heal. They also cause severe eye damage.[152]

Both monofluorophosphoric acid and hexafluorophosphoric acid are highly corrosive liquids, with an effect on the skin or eyes reminiscent of that of hydrogen fluoride.[75]

Rats fed diets containing up to 0·34% of $Na_2PO_3F$ showed no changes in the liver, spleen or adrenals, but histological changes in the kidney indistinguishable from those caused by the administration of similar quantities of sodium fluoride. The data indicated that the toxicities of sodium monofluorophosphate and sodium fluoride are of the same order.[153] Experiments with $^{18}F$ and $^{32}P$ labelled sodium monofluorophosphate revealed high concentrations of $^{18}F$ absorbed in the intestinal lumen and the liver and of $^{32}P$ in the intestinal wall, as compared with the same isotopes in the form of fluoride and orthophosphate ions, respectively.[154]

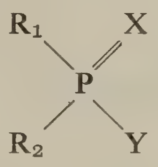
The monofluorophosphate ion is rapidly taken up by dental enamel, possibly by exchange of $PO_3F^{2-}$ and $PO_4^{3-}$ ions in the crystal structure, and for this reason monofluorophosphates have been suggested for the prophylaxis of dental caries.[156-7]

A study of the biochemistry and pharmacology of sodium monothiophosphate revealed that it was metabolized to hydrogen sulphide and finally to thiosulphate in the liver. Monothiophosphate can replace phosphate in the triosephosphate dehydrogenase system, but an unstable intermediate is formed. The $LD_{50}$ of sodium monothiophosphate injected intraperitoneally in mice is 950 mg./kg. body weight. In the unanæsthetized cat, intravenous injection of the substance causes depression of respiration and blood pressure. Its pharmacological effects are different from those of hydrogen sulphide.[155]

## ORGANOPHOSPHORUS COMPOUNDS

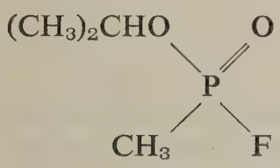
### Anticholinesterase Activity

No account of the toxicity of phosphorus compounds would be complete without some reference, however brief, to the organic derivatives of phosphorus. By far the most general and well-established type of activity is the cholinergic action shown by phosphorus esters of the structure

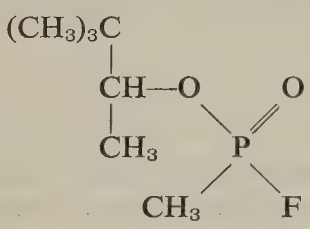


where $R_1$ and $R_2$ are alkyl, alkoxy or alkylamino groups, X is O or S, and Y is the anion of a weak acid such as cyanide, fluoride, alkyl mercaptide, p-nitrophenoxy or dialkyl phosphate.

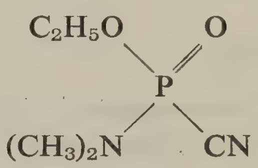
This biological activity was first observed in 1932 in diethyl phosphorofluoridates.[158] Similar compounds were subsequently developed in Germany[159] and England[160] as insecticides and chemical warfare agents. Besides a number of substances still in use as insecticides (see Table I), the German group had by 1940 developed three compounds of high mammalian toxicity, which were considered to be potential chemical warfare agents:



Sarin



Soman



Tabun

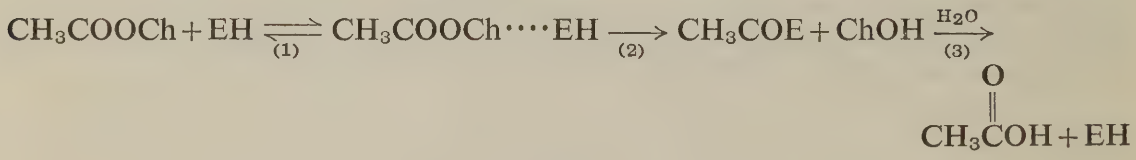
A plant capable of producing 100 tons/month of Tabun had been erected by 1945.[160] This work was reported after the war,[161-2] and led to the synthesis of a very wide variety of new compounds of similar activity.

Although the toxicity of such compounds to mammals varies widely, the symptoms of poisoning are similar. They resemble those produced by the alkaloids, eserine, muscarine and nicotine. Muscarinic effects include nausea, pallor, sweating, salivation, abdominal cramps, vomiting, involuntary defæcation and urination, miosis (constriction of the pupils of the eyes), excessive bronchial secretion and bronchoconstriction. Nicotinic effects include muscular fasciculations and weakness, leading in severe cases to muscular paralysis. There are also effects on the central nervous system, including giddiness, headache, unconsciousness and finally paralysis of the respiratory centre.[163] Death in mammals is usually caused by respiratory failure, resulting from paralysis of the respiratory muscles or the respiratory centre, or broncho-constriction.[164]

The similarity between these symptoms and those of poisoning by eserine led to the hypothesis that such organophosphorus compounds were, like eserine, potent inhibitors of the enzyme acetylcholinesterase.[165] This was later confirmed, but the inhibition was shown, unlike that by eserine, to be effectively irreversible by dilution or dialysis.[166] The cause of the inhibition was shown to be phosphorylation of the active (esteratic) centre of the enzyme.[167-8] The phosphorylated enzyme could no longer carry out its normal function of hydrolyzing the acetylcholine, which is essential for the proper action of the nervous system in the insects and higher animals. Accumulating acetylcholine then caused the symptoms described above.[169]

*In vitro* studies have shown that the reaction between the enzyme and the phosphorus compound is bimolecular ($S_N2$). It involves the attack of a nucleophilic group in the enzyme (probably an amino-acid) on the electrophilic phosphorus atom, in a manner entirely analogous to the normal enzyme-substrate reaction:

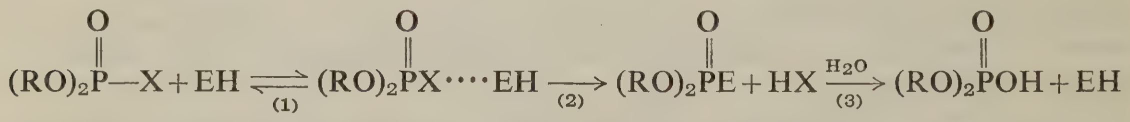
Normal reaction:



$$CH_3COOCh + EH \underset{(1)}{\rightleftharpoons} CH_3COOCh\cdots EH \xrightarrow[(2)]{} CH_3COE + ChOH \xrightarrow[(3)]{H_2O} CH_3\overset{O}{\overset{\|}{C}}OH + EH$$

$(ChOH = Me_3\overset{+}{N}CH_2CH_2OH. \qquad EH = enzyme)$

Inhibition reaction:



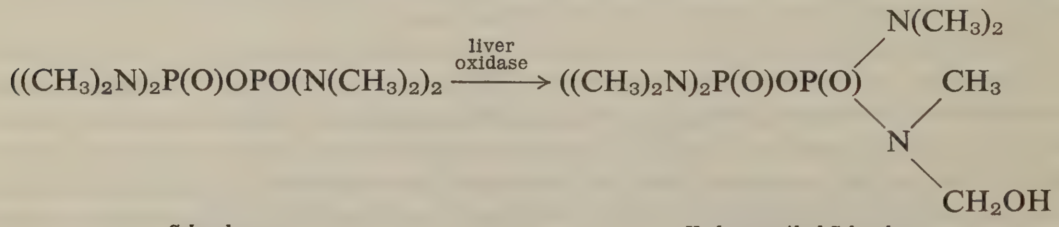
$$(RO)_2\overset{O}{\overset{\|}{P}}-X + EH \underset{(1)}{\rightleftharpoons} (RO)_2\overset{O}{\overset{\|}{P}}X\cdots EH \xrightarrow[(2)]{} (RO)_2\overset{O}{\overset{\|}{P}}E + HX \xrightarrow[(3)]{H_2O} (RO)_2\overset{O}{\overset{\|}{P}}OH + EH$$

However, in the normal reaction the hydrolysis (3) is fast and reaction (1) is rate-determining, whereas in the inhibition reaction the hydrolysis is very slow and therefore becomes the rate-determining step.[169]

The amino-acid involved in the reaction at the active site is not known for certain; histidine[170] and serine[171-2] have been suggested. There is evidence that the initial phosphorylated enzyme rearranges to another form which is more difficult to reactivate.[173]

ACTIVATION

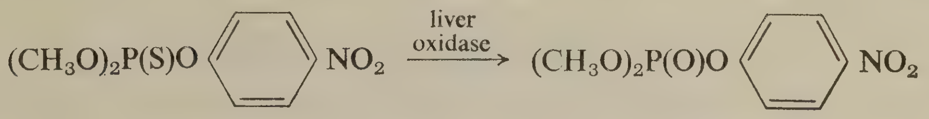
Phosphorothionates, $(RO)_2P(S)OX$, and N-methyl phosphoramidates, e.g. $Me_2NP(O)X_2$, have usually poor anticholinesterase activity *in vitro*. *In vivo* they are converted to more potent anticholinesterases by enzymes present in insects, and in the liver of mammals.[174-6] In the case of phosphoramidates such as schradan the active body is probably a hydroxymethyl compound[169]:



*Schradan*
Poor *in vitro* inhibitor

*Hydroxymethyl Schradan*
Active *in vitro*

Phosphorothionates on the other hand are metabolized to phosphates, a typical case being the formation of the potent inhibitor paraoxon from parathion:

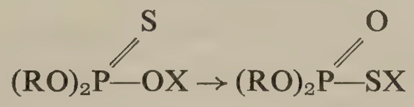


Parathion
poor inhibitor

Paraoxon
powerful inhibitor

Other reactions which can lead to an increase in anticholinesterase activity include thionate-thiolate isomerization (i) as in Systox[177];

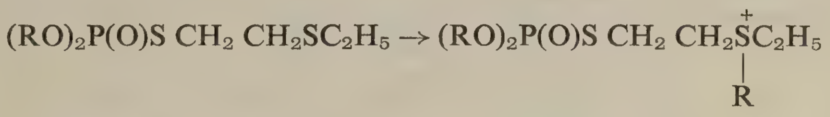
(i)



$$(RO)_2\overset{\overset{S}{/\!/}}{P}\text{—}OX \rightarrow (RO)_2\overset{\overset{O}{/\!/}}{P}\text{—}SX$$

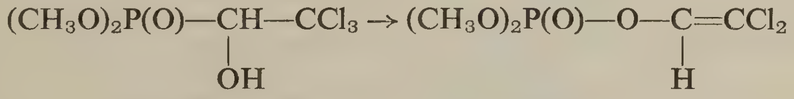
cis-trans isomerism as in Phosdrin[178]; methylation as in thiolosystox[179] (ii):

(ii)



$$(RO)_2P(O)S\,CH_2\,CH_2SC_2H_5 \rightarrow (RO)_2P(O)S\,CH_2\,CH_2\underset{\underset{R}{|}}{\overset{+}{S}}C_2H_5$$

and the unexpected dehydrohalogenation rearrangement by which Vapona (DDVP) is formed from Dipterex[180]:



$$(CH_3O)_2P(O)\text{—}\underset{\underset{OH}{|}}{CH}\text{—}CCl_3 \rightarrow (CH_3O)_2P(O)\text{—}O\text{—}\underset{\underset{H}{|}}{C}{=}CCl_2$$

Dipterex Vapona

Finally transesterification of methyl by methoxyethyl groups in methyl cellosolve solution has been shown to increase the toxicity of Dimethoate, Malathion, Ronnel, and Dow ET-15 (O-methyl O-(2,4,5-trichlorophenyl) phosphoramidothionate) several-fold.[196]

### SYNERGISM (POTENTIATION)

In certain cases mixtures of organophosphorus compounds show a higher toxicity than would be expected from a simple addition of their effects. This was first demonstrated in malathion/EPN mixtures.[181] The effect was particularly marked in dogs, where all were killed by a combination of less than 1/40 $LD_{50}$ of malathion with less than 1/50 $LD_{50}$ of EPN.[182] Tri(o-tolyl) phosphate[183] and many other substances[184] were found to have a similar effect on malathion toxicity. This was shown to be due to the inhibition of an enzyme, 'malathionase', present in the mammalian liver, which normally rapidly degrades malathion to a more harmless substance. A similar phenomenon has been observed in dipterex[195] and dimethoate.[196]

### ORGANOPHOSPHORUS INSECTICIDES

A representative selection of the commoner commercially used organophosphorus insecticides is given in Table I. The table gives the trivial name or names by which they are commonly referred to (even in the scientific literature), their systematic name, the main field of application, and the toxicity to rats by the oral route.[185-6] From what has been said above, it will be appreciated that there may be considerable variations in toxicity between batches of compound with different histories, added to the variation normally observed between animals of different sex and age, and even between different solvents used as vehicles for administration.[187] The figures given are therefore usually only an indication of the comparative order of toxicity. Other toxicity figures are given in the notes following the table. The first five compounds were the earliest to be applied commercially and have been extensively described. The remainder were developed as improvements in one way or another, and are arranged in alphabetical order of their trivial names.

*Table I.—Organophosphorus Insecticides*

| Trivial name | Systematic name | Main application* | Oral toxicity[186] to rats (LD$_{50}$) |
|---|---|---|---|
| TEPP | tetraethyl pyrophosphate | | 2(a) |
| Demeton (=Systox) | O,O-diethyl O(S)-2-ethylthioethyl phosphorothioate | SP | 2·5–12(b) |
| Dimefox (=Hanane) | N,N′-tetramethyl phosphorodiamidic fluoride | SP | 5(c) |
| Parathion | O,O-diethyl O-p-nitrophenyl phosphorothioate | BS | 6–15(d) |
| Schradan (=OMPA) | N,N′,N″,N‴-octamethyl pyrophosphoramide | SP | 14(e) |
| Co-Ral (=Coumaphos) | O,O-diethyl O-(3-chloro-4-methyl-2-oxo-2H-1-benzopyran-7-yl) phosphorothioate | SA | 90–110(f) |
| Diazinon | O,O-diethyl O(-2-isopropyl-4-methyl-pyrimidyl-6) phosphorothionate | BS | 76–108(g) |
| Dimethoate | O,O-dimethyl S(-N-methylcarbamoyl-methyl) phosphorodithioate | SP | 185–245(h) |

* SP=Systemic in plants; SA=Systemic in animals; BS=Broad spectrum (general application).

(a) Other values (LD$_{50}$ mg./kg.): Mouse, or. 7·0, s.c. 0·9–1·0, i.p. 0·85; rat, or. 1·2–2·0, s.c. 0·7, inh. 0·8–1·0; guinea-pig, or. 2·3; rabbit, ct. 2·0–5. Estimated lethal dose in man 100 mg. oral.[198]

(b) Other values (LD$_{50}$ mg./kg.): Rat, or. 1·5 (thiol), 7·5 (thiono), 9·4, ~9, 10, 4, i.p. 3; rabbit, ct. 24; man estimated acute dose 10–20 mg.[198]; rat, or. 6·4–7·9, i.p. 4·6.[194]

(c) Other values ($LD_{50}$ mg./kg.): Rat, or. 7·5, i.p. 5·0; mouse 1·0 s.c., 1·4–5·0 i.p.; guinea-pig, i.p. 2·5[198]; for a review see ref. 201.

(d) Other values ($LD_{50}$ mg./kg.): Rat, or. 6·4–16·9, i.p. 4·6–14·4, i.v. 1·05–5·4, s.c. 7·8–13·6[187]: Rat, or. 3·0–30·0 (10 determinations), i.p. 4–7, i.v. 3; guinea-pig, or. 32; rabbit, ct. 40–50, 420, 870; cat, i.p. 3–5; dog, i.p. 12–20. Man, estimated lethal dose 20–100 mg. The chronic toxicity of parathion is fairly low, though repeated exposure increases the susceptibility to larger doses. Several deaths reported due to careless use including one from 120 mg. taken orally.[198]

(e) Other values ($LD_{50}$ mg./kg.): Mouse, or. 30, s.c. 1·5–7, i.p. 8–17; rat, or. 10–35·5 (4 determinations), i.p. 8–8·5; guinea-pig, or. 15·0, i.p. 10·0; rabbit, or. 25, ct. < 780; dog, i.v. 5–10. The upper safe therapeutic dose for man, in the treatment of myasthenia gravis is 30 mg./day.[198]

(f) Other values ($LD_{50}$ mg./kg.): Rat, or. 56–230.[185] For an account of Co-Ral poisoning in cattle see ref. 202.

(g) Other values ($LD_{50}$ mg./kg.): Mouse, or. 82, 100, 122·5; rat, or. 100–150, 264·5, 220–270, 712·5, 900; guinea-pig, or. 320 mm.$^3$/kg.; rabbit, ct. > 4,000[198]; rat, or. 293–408, ct. > 1,000.[188]

(h) Other values ($LD_{50}$ mg./kg.): Rat, or. 247, ct. 1120.[188] For synergism with other substances see ref. 196.

(i) Other values ($LD_{50}$ mg./kg.): Rat, or. 450–500, i.p. 225; mouse, or. 500; guinea-pig, or. 300[198]: rat, or. 649, ct. > 2,800[188]; calves, or. > 220[189]; sheep, or. > 165[190] (see also ref. 191 and (for synergism with other insecticides)).[195]

(j) Other values ($LD_{50}$ mg./kg.): Rat, or. 2–12·5.[185] For a review of toxicity and mechanism of action, see ref. 204.

(k) Other values ($LD_{50}$ mg./kg.): Mouse, or. 45·5, i.p. 48; rat, or. (24 hr.) 12–76: or. 7–91, i.p. 24, 64; guinea-pig, or. 79·4. The variability of toxicity, between sexes and between species, is high. Many further data are given in the reference 198.

(l) Other values ($LD_{50}$ mg./kg.): Rat, or. 96; rabbit, ct. 915[185].

(m) Rat, or. 325 mg./kg.[185] (see also ref. 192).

(n) Rat, or. 35 mg./kg.[193]

(o) Other values ($LD_{50}$ mg./kg.): Rat, or. 12, ct. 220.[185]

(p) Other values ($LD_{50}$ mg./kg.): Mouse, or. 720–3300 (6 values); rat, or. 300–4700 (10 values), ct. > 4,000, i.p. 750, i.v. ~ 50; guinea-pig, or. 570[198]: rat, ct. > 5,000, or. 1,375[185]: rat, or. 233–1400, i.p. 132–695, i.v. 184–453[187]: mouse, or. 815.[194]

(q) Other values ($LD_{50}$ mg./kg.): Rat, or. 80[185]: rat, or. 129, ct. 443[188]: rat, or. 63, i.v. 65.[179] For the toxicity of the sulphoxide (Metasystox R) see ref. 205.

(r) Other values ($LD_{50}$ mg./kg.): Rat, or. 9–25, 15·2, 14–42, i.p. 3·5; mouse, or. 100–200, s.c. 50–100; rabbit, or. 420–1270[198]; rat, or. 17·1–58, i.v. 2·3–14·2, i.p. 8·6–18·5, s.c. 18·0.[187]

(s) $LD_{50}$ or. rat 3·7 mg./kg.[185]

(t) $LD_{50}$ or. rat 6·8 mg./kg.[185]

(u) Effective dose 100 mg./kg.[185] (see also ref. 197).

(v) $LD_{50}$ or. rat 1,000 mg./kg.[185]

(w) Other values ($LD_{50}$ mg./kg.): Mouse ct. > 3,000[185]: rat, or. 673, ct. > 3,000; mouse, or. 870, ct. > 3,000; guinea-pig, or. 1,833.[199]

(x) Other values ($LD_{50}$ mg./kg.): Rat, or. 80[185]: rat, or. 56–80, ct. 75–107.[198, 200]

It will be seen from Table I that there is a wide variation in the mammalian toxicity of the organophosphorus anticholinesterase insecticides. While the first to be discovered were quite toxic to mammals, some more recent examples have oral toxicities one or two orders lower. However, the toxicity to insects does not always parallel that to mammals: indeed it has been pointed out that these compounds can be divided into three classes, according to whether their mammalian toxicity is much greater than, roughly equal to, or much less than, their toxicity to insects.[169, 203]

It is obvious that while members of the first class are highly hazardous in use, the third class of ‘selective insecticides’ can be used with relative safety. Thus such compounds as Ronnel, Ruelene or Co-Ral can be safely given to animals in doses high enough to make their tissues toxic to parasites such as cattle flies, lice, mites, ticks, screw-worm larvæ or helminths.[189] This parallels the action of systemic plant insecticides such as Demeton or Schradan which have been known much longer.[185]

Members of the first class of ‘selective mammalicides’, on the other hand, have been proposed as war gases. They are toxic both by inhalation and by absorption through the skin.[213] The most toxic of those commonly reported is Sarin (*iso*propyl methylphosphonofluoridate ($LD_{50}$ (mg./kg.) 0·127 s.c. (rats),[215] 0·036 inhalation (dogs)[216]). Symptoms of poisoning in man are typically muscarinic and nicotinic, as described above.[217] Tabun (ethyl N-dimethyl phosphoramidocyanidate) is somewhat less toxic ($LD_{50}$ ~ 0·8 mg./kg. s.c. (rats)).[213–4] Other compounds proposed for the same purpose include di-*iso*propyl phosphorofluoridate (DFP), $LD_{50}$ (mg./kg.) 36·8 oral, 3·71 s.c. (mice): 1·82 i.v. (rats): 9·78 oral, 0·34 i.v. (rabbits):

*Table II.—Selective Toxicity of Some Organophosphates*[(a)]

| Compound | Mammal used | Housefly treatment: injected (i) or topical (t) | $LD_{50}$ mammal/ $LD_{50}$ housefly |
|---|---|---|---|
| Selective insecticides | | | |
| Malathion | Mouse | t | 68 |
| Dimethoate | Mouse | t | 325 |
| Co-Ral | Mouse | t | 16 |
| Diazinon | Mouse | t | 27 |
| Dipterex | Rat | t | 31 |
| Selective mammalicides | | | |
| Schradan | Rat | t | 0·009 |
| Iso-Systox methosulphate | Mouse | i | 0·03 |
| Tetram | Mouse | i | 0·00042 |
| Ro 30412 | Mouse | i | 0·004 |
| Nonselective compounds | | | |
| Phosdrin isomers | Rat | t | 0·8 |
| Parathion | Mouse | t | 6 |
| DFP | Rat | t | 9 |
| Thimet | Rat | t | 6 |
| TEPP | Mouse | t | 0·17 |

(a) $LD_{50}$'s at 24 hr. Mouse: intraperitoneal application. Rat: subcutaneous application.

3·43 i.v. (dogs): 1·63 i.v. (cats)[218] and N,N′-tetramethylphosphorodiamidic fluoride, $LD_{50}$ 1 mg./kg. s.c. (mice). An estimate of the toxicity to man of these substances, compared with that of better known war gases, has been published,[219] see Table III.

*Table III.—Comparison of Toxicity of Nerve Gases and Other Agents*

| Agent | Median lethal breathing[(a)] dose (mg. min. $m^3$) | Lethal dose percutaneous[(b)] (mg.) |
|---|---|---|
| Tabun | 100–200 | 200–400 |
| Sarin | 50–100 | 100–200 |
| DFP | 1500–2000 | — |
| Phosgene | 3300 | — |
| Mustard gas | 1500 | 4000–5000 |

(a) Median lethal dose is the dose which would be expected to kill 50 per cent of the population subjected to it.
(b) Estimated for man, published Swedish figures.

Further details of the toxicology and pharmacology of these substances are given in a number of reviews.[159–60, 169, 198, 220–2, 230] Of particular interest is the review by Schrader[223] of the relation between structure and activity.

### THERAPY OF ORGANOPHOSPHATE POISONING

Poisoning by phosphorus anticholinesterases was first treated by injection of atropine, which counters their muscarinic action[12] but has undesirable effects of its own. More recently it has been found that nucleophilic agents such as hydroxylamine,[206] hydroxamic acids,[207] *iso*nitroso compounds,[208] and oximes, especially pyridine-2-aldoxime methiodide (2.PAM),[209–10] will reactivate freshly inhibited cholinesterase. The latter compound, and the corresponding methanesulphonate, have been used with success in treating a number of cases of human poisoning, particularly by parathion.[211] Instructions for the treatment of patients suffering from poisoning by organophosphorus anticholinesterases have been issued.[212]

### Demyelinating Action

A number of organophosphorus compounds can produce in man a characteristic multiple neuritis, which in severe cases can lead to a flaccid paralysis. The condition was first observed clinically in 1930 in the United States, when about 20,000 people were affected after drinking a contaminated alcoholic extract of ginger ('ginger jake'). The effects were soon shown to be due to tri-ortho-cresyl phosphate (TOCP) which was present in the extract to the extent of 2%.[224] Aryl phosphates made from phenolic mixtures containing *o*-cresol have been extensively used since then, as plasticizers, functional fluids, and petrol and lubricating-oil additives, and many more cases of poisoning have been reported, some leading to death or permanent paralysis.[12, 225] The major disasters have always been associated with the adulteration of food or drink. Thus in an outbreak of poisoning in Morocco in 1959, 10,000 persons were affected by cooking oil adulterated with jet-engine lubricating-oil containing 3% mixed cresyl phosphates.[227] The clinical picture presented in such cases is always similar. After transient gastro-intestinal disturbances there is a latent period of 1–4 weeks, after which the characteristic symptoms of flaccid paralysis of the feet and wrists appear, preceded by soreness or pains in the affected muscles. The feet and legs are always more affected than the hands and fore-arms and the upper arms and the large muscles of the thigh are seldom affected. There is no sensory disturbance[225] and no involvement of the cranial nerves. Mildly affected patients can recover completely,[169] but in severe cases paralysis may be permanent.[226]

The lesions which cause paralysis consist in the degeneration of the myelin sheath of the peripheral nerves, the white matter of the spinal cord, and of the pyramidal cells.[169, 12] Experimental studies have shown that humans, calves and chickens over 4 months old are paralysed by TOCP given by any route. Dogs and monkeys are unaffected by large doses given orally, but develop the characteristic symptoms after subcutaneous or intramuscular dosage.[224] Rats seem to be little affected by TOCP, however administered.[228] Young chicks are also insensitive to TOCP poisoning.[229] The minimum paralytic dose in man has been estimated to be between 10 and 30 mg./kg.[230]

Intravenous injection of TOCP in cats caused typical symptoms. The effects were cumulative, the minimum lethal dose for cats being about 0·1 ml./kg. whether given at one time or over a period. Larger doses tended to cause more rapid and severe paralysis.[231]

Although tri-*o*-cresyl phosphate was the first compound implicated in this way it was soon found that other aryl phosphates behaved similarly, although only the tri-esters were toxic. Thus mono-*o*-cresyl dihydrogen phosphate gave only transient symptoms of cresol poisoning and di-*o*-cresyl monohydrogen phosphate produced no effects on the nervous system.[232]

Of triaryl phosphates, triphenyl phosphate produced an atypical generalized delayed paralysis in cats and monkeys, but appeared to be without effect in man, chickens or rabbits.[233] Aryl phosphates made from mixed alkyl phenols caused paralysis, however, those containing only one *o*-cresyl group being the most highly toxic. The toxicity of *o*-cresyl diphenyl phosphate was found to be twice that of *o*-cresyl *m*-cresyl *p*-cresyl phosphate, 20 times that of tri-*o*-cresyl phosphate, and 80 times that of *o*-cresyl di-(3,5-xylyl) phosphate.[234–5] This work was later confirmed and extended.[236–7] No universal rule connecting toxicity with structure could be established, though certain regularities appeared. Thus from Table IV it will be seen that compounds containing one, two or three 2-Me phenyl groups are toxic, other groups exerting a modifying effect on the toxicity (e.g., 2Me 4Me 4Me > 2Me 3,5diMe 3,5diMe). The 2-Me group must be the sole substituent in the ring, since tris-2,3, tris-2,5 and tris-2,6 diMe-phenyl phosphates are not toxic.[237]

No similar generalizations are possible for ethyl or propyl substitution: e.g., tris-2-Et- and tris-2-Pr-phenyl phosphates are non-toxic, 2-Pr-phenyl bis-4-Et-phenyl phosphate is very toxic, 2-Pr-phenyl bis-3,5-diMe phenyl phosphate is again non-toxic. Finally tris-4-ethylphenyl phosphate is unexpectedly toxic,[239] whereas all other 4-alkyl substituted derivatives (including tris-2-Me-4-Et-phenyl phosphate) are not.[237]

Many of the compounds inhibited plasma or brain pseudo-cholinesterase and liver or intestinal phenylbutyrate esterase, but again there was no correlation between these activities and neurotoxicity.[237]

*Table IV.—Neurotoxic Activity of Tris-(alkylphenyl) Phosphates*[236–7]

(The position of substitution in the three phenyl radicals is indicated by arabic numerals, followed by an abbreviation showing the nature of the substituent alkyl groups.)

| Very toxic(a) | Toxic(b) | Slightly toxic(c) | Non-toxic(d) |
|---|---|---|---|
| 2Me 4Me 4Me | 2Me 2Me 2Me | 2Me 2Me 4Me | 3Me 3Me 3Me |
| | 2Me 2Me 3Me | 2Me 3,5diMe 3,5diMe | 4Me 4Me 4Me |
| 2Et 4Me 4Me | 2Et 2Et 4Me | 2Et 3,5diMe 3,5diMe | 2Et 2Et 2Et |
| | 4Et 4Et 4Et | | 3Et 3Et 3Et |
| | | | 3Et 3Et 4Et |
| | | | 3Et 3Et 4Me |
| | | | 4Et 4Et 4Me |
| | | | 4Et 4Me 4Me |
| | | | 4Et 3,5diMe 3,5diMe |
| 2Pr 4Et 4Et | | 2Pr 2Pr 4Me | 2Pr 2Pr 2Pr |
| | | | 2Pr 3,5diMe 3,5diMe |
| | | | 2Cl 2Cl 2Cl |
| | | | tri-(2Me 4Et) |

(a) Caused ataxia in a single dose of < 100 mg./kg.
(b) Caused ataxia in a single dose of 200–500 mg./kg.
(c) Caused ataxia in single or successive doses totalling > 1000 mg./kg.
(d) Caused no ataxia at doses up to 5 × 500 mg./kg.

Further search has revealed similar neurotoxic activity in other organophosphorus compounds.[229, 238, 241] Severe paralysis in two workers exposed to the insecticide Mipafox (N,N′ di-*iso*-propyl phosphorodiamidic fluoride)[240] led to the discovery that this substance was capable of causing nerve demyelination in hens.[229] Other workers showed that phosphorofluoridates (e.g., DFP) and phosphonofluoridates (e.g., Sarin) has a similar effect. Dialkylphosphinic fluorides, dialkyl pyrophosphonates, and other alkyl phosphate esters not containing fluorine, were not toxic. In general compounds of the formula (RA)R′P(:B)F were found to be neurotoxic if R was an alkyl group, R′ alkyl alkoxyl or alkylamino group, A was O or a secondary amine group, and B was O or S.[241] Trimethyl phosphate[242] and aryl phosphites[243] have also been reported to cause paralysis in certain mammals, though no cases in man are known.

### MISCELLANEOUS ACTIVITY

In general alkyl phosphates are not very toxic, though tris-2-chloroethyl phosphate produces epileptiform convulsions in the rat at a level of 0·28 g./kg. (i.p.). Toxicological data have been recorded for a range of phosphates,[230] median lethal doses being in general around 1 g./kg. Alkyl phosphites are of a similar order of toxicity.[230] A single study of trimethyl and triethyl trithiophosphites, however, showed these to be highly toxic to rats ($LD_{50}$ (i.p.) 44 mg./kg. or 105 mg./kg. for the trimethyl compound). Death was due to circulatory collapse.[244]

# INDEX

*Introductory note.* The diversity of constitution of phosphorus compounds and their complex nomenclature have made indexing difficult in some instances. The following points may help the user of the index:

1. If a specific compound is not found in the Index, refer to the parent *group*; in covering organophosphorus compounds, particularly, it has not been feasible to list every individual compound treated under a group heading. Salts of acids or bases are usually treated under the parent acid or base. (Note that in Mellor, phosphates are treated in volumes covering the metallic components; phosphides, however, are considered in detail in this volume and indexed under their metal constituents.)

2. 'Phosphoric oxide' is indexed under 'Phosphorus pentoxide', and the suffixes '-ic' and '-ous' are avoided in indexing binary compounds. Halides are listed as 'trichloride', 'pentachloride', etc. Mixed halides are distinguished by formula under headings such as 'Phosphorus trihalides'. For clarity, certain compounds not quickly recognizable by name are also quoted by formula under appropriate general headings.

3. The prefixes 'ortho-', 'meta-', and 'pyro-', used particularly in regard to the phosphoric acids, are regarded as separable, and 'orthophosphoric acid' is indexed under 'Phosphoric acid, ortho-'; similarly in other cases. Variety of modes of use prohibits any general rule for the use of 'mono-', 'di-', 'tri-', 'tetra-', 'poly-', 'iso-', 'hypo-', etc., and in any case of difficulty the appropriate alternatives should be tried in referring to the index; for example, 'Hypophosphites' might have been indexed as 'Phosphites, hypo-', and 'Chlorophosphoric acid, di-' might have been referred to as 'Dichlorophosphoric acid'. In instances of this kind, the alternative chosen has often been determined by a need to put analogous compounds in close proximity in the index.
